So accurately are the root and the socket adapted to each other over their whole extent, and so firmly does the periosteum bind them together, that under normal conditions the tooth is quite firmly fixed in the bone, and no movement of the root within the socket can take place; the vessels and nerves entering at the apex are thus secured against pressure or strain.

When, however, the alveolar periosteum is inflamed it becomes swollen and exquisitely sensitive; the tooth, as a result of the swelling, is pushed partly out of its socket, its crown projects above those of its neighbours and strikes against the opposing teeth when the mouth is closed, giving rise to much pain and discomfort.

The **neck** corresponds to the line along which the gum and alveolar periosteum meet, or along which the gum is united to the tooth; but, as already pointed out, the gum does not stop at the neck, but forms a free fold which surrounds the base of the crown collar-wise for a short distance. The outline of the margin of the gum opposite the labial and lingual surfaces of the crown is usually concave, but opposite the contact surfaces of the tooth it is convex, and reaches much nearer to the edge of the crown than on the other surfaces.

Tartar is a hard, calcareous deposit from the saliva, often found on the teeth near their necks. It is composed of lime-salts, and its deposit is largely determined by the presence of organisms (leptothrix, etc.) in the mouth.

Structure of Teeth

Each tooth consists of two chief portions—namely, the **dentine** (ivory) derived from mesoderm and the **enamel** derived from ectoderm. The dentine constitutes the chief mass of the tooth, and the enamel forms a cap for the crown. A third special tissue—the **cement**—is connected with the wall of the socket by the alveolar periosteum.

The dentine and enamel, but particularly the enamel, are the hardest and most resistant structures in the body.

The **enamel** is the dense, white, glistening layer which forms a cap for the crown of each tooth and is thickest over the tubercles. At the neck it ceases gradually, being there slightly overlapped by the cement.

The enamel consists of minute, solid, calcified hexagonal prisms, called the *enamel prisms*, which radiate from the surface of the dentine to the surface of the crown; they terminate there by free ends, and most of them reach from the dentine to the surface of the crown without interruption. The prisms are held together by a very small amount of *interprismatic substance*, but opinions still differ on its nature and the extent of its calcification (Tims & Henry, 1923; Churchill, 1935; Orban, 1944). In old teeth the cap of enamel is often worn away over the tubercles; the dentine is then exposed, and can be recognized by its yellowish colour, which contrasts strongly with the whiteness of the enamel.

Whilst adjacent enamel prisms are in general parallel to one another, they do not usually take a straight course but are rather wavy, and in alternate layers they are often inclined in opposite directions, thus giving rise to certain radial striations seen by reflected light (Schreger's lines). Certain other dark lines, more or less parallel to the surface, are also seen in the enamel (striæ of Retzius). They are due to periodic intermissions in the deposition of calcium during growth.

The *cuticle of the tooth* is an extremely thin (1·5 μ) layer which covers the enamel of recently cut teeth, and is very indestructible—resisting almost all reagents. It is produced by the outer layer of cells of the enamel-organ.

Dentine or **ivory** is the hard and elastic, yellowish-white substance which forms the greater part of every tooth (Fig. 484). Like the enamel it is highly calcified, but it

differs from it in containing a very considerable amount (28 per cent) of organic matter and water incorporated with its salts, which are chiefly phosphate and carbonate of lime (72 per cent).

Dentine consists of a homogeneous, highly calcified, organic matrix, everywhere traversed by tubes—the **dental canaliculi**—which give to that tissue a finely striated appearance, the striæ usually running in wavy lines. The canaliculi begin by open mouths on the wall of the tooth-cavity, whence they run an undulating and spiral course towards the periphery of the dentine. They give off fine anastomosing branches, and in the peripheral zone of the dentine they end in an arborization, a few of the terminal canaliculi penetrating the innermost part of the enamel.

The dental canaliculi are generally described as being lined with special sheaths (*dentinal sheaths* of Neumann) which are composed of a most resistant material, and possibly are calcified. They are occupied by processes prolonged from the outermost cells of the pulp—called after their discoverer, *Tomes' fibrils*. The question whether they contain also neurofibrils (Mummery) cannot be said to be settled, though nerve-fibres have been traced from the pulp through the odontoblast layer (see below) and some of them appear to end in fine branches which enter the mouths of the canaliculi (Lewinsky & Stewart, 1936).

In addition to the radial striation which results from the canaliculi, the dentine shows contour striations or *lines of Owen*. These correspond to the intervals between the concentric laminæ in which the fibrillar branches are arranged at right angles to the canaliculi, and they are associated also with variations in the density with which the dentine is deposited during growth. Certain **interglobular spaces** are left in the dentine as a result of imperfect calcification, and are bounded by the fully calcified surrounding tissue. These spaces form a zone in the outer or "granular layer" of the dentine. The concentric *lines of Schreger*, frequently seen in the dentine, are optical effects due to bends in successive canaliculi along regular lines which run parallel to the periphery of the dentine.

The **cement** is a layer of modified bone which encases the whole of the tooth except its crown. It begins at the neck as a very thin stratum which slightly overlaps the enamel. From there it is continued, increasing in amount, towards the apex, which is formed entirely of this substance. It is relatively small in amount in the child, but it increases during life. In places the dentine seems to pass imperceptibly into the cement, the "granular layer" marking the junction of the two, and some of the dental canaliculi are continuous with the lacunæ of the cement. Like true bone, it is laminated, possesses lacunæ and canaliculi, and, when in large masses, may even contain a few Haversian canals.

The **pulp of the tooth** is composed of a number of branched fibrous tissue cells, whose anastomosing processes form a fine network which contains in its meshes a jelly-like material, in addition to numerous blood-vessels, nerves, and slender lymph-vessels. The most superficial of these cells are arranged in the young tooth as a continuous layer of columnar, epithelium-like cells that lie on the surface of the tooth-pulp against the dentine; they are known as **odontoblasts**, for they are the active agents in the formation of the dentine. The vessels of the tooth-pulp are numerous, and form a capillary plexus immediately internal to the odontoblasts. Fine nerve-bundles run through the pulp from the root-canals towards the crown of the tooth, and some of their fibres enter the odontoblast layer and may possibly supply the dentine.

The **alveolar periosteum** is a layer of fibrous tissue free from elastic fibres but well supplied both with blood-vessels and nerves; it fixes the root of the tooth in the socket, being firmly united by perforating fibres of Sharpey to the cement on the one hand and to the wall of the socket on the other. It establishes a communication between the bone of the jaw and the cement, and it is continuous with the tissue of the gum. Its blood comes chiefly from the arteries which subsequently enter the root-foramina for the supply of the tooth-pulp, but in part also from the vessels of the surrounding bone and of the gum (hence the relief obtained in dental periostitis by lancing the gum).

Permanent Teeth

The **permanent teeth** are thirty-two in number, eight above and eight below on each side. In each set of eight there are:—two incisor teeth, a medial and a lateral; a single canine; two premolars, first and second; and three molars, first, second, and third, arranged in that order from the median plane. When the dentition is perfect each set is bilaterally symmetrical. The human "dental

formula" showing the number of teeth of each class above and below on one side is therefore :—I $\frac{2}{2}$, C $\frac{1}{1}$, PM $\frac{2}{2}$, M $\frac{3}{3}$.

Incisor Teeth.—The **crown** is chisel-shaped, its labial surface convex, the lingual surface concave, the edge chisel-like and, when first cut, surmounted by three small tubercles. These tubercles, however, are soon worn down, and the edge becomes straight or nearly so. The upper incisors usually overlap the lower and hence the cutting edge is bevelled on the lingual aspect of the upper incisors and on the labial aspect of the lower. The upper, and particularly the central upper incisors, are of large size, and slope slightly forwards; the lower incisors, all of nearly equal size, are smaller—being the smallest of all the teeth—and are vertical. The roots of the incisors are single, though a groove is occasionally seen on each side, suggesting a division.

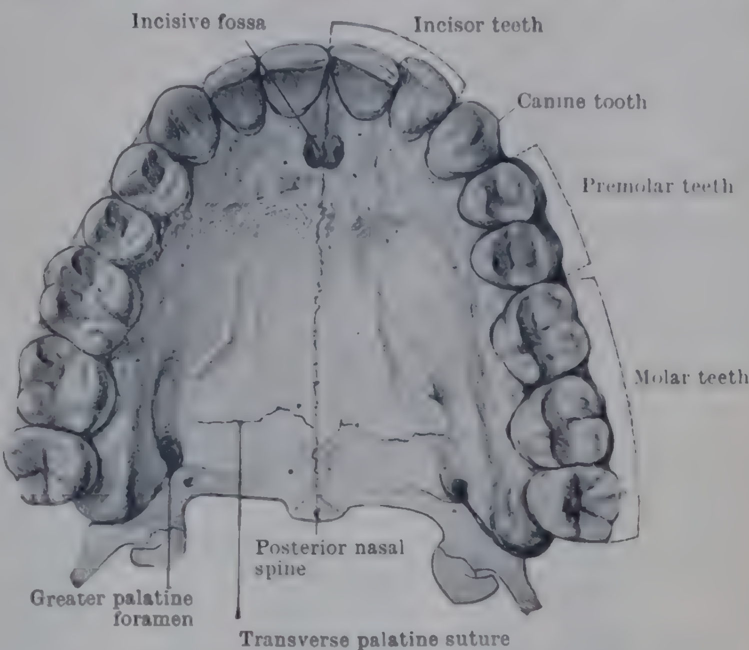

Fig. 485.—Bony Palate and Upper Permanent Teeth.

The central upper incisors are very much larger than the lateral upper incisors (Fig. 486), but in the mandible the lateral incisors are slightly the larger. In all incisors the lateral angle of the crown is more rounded than the medial. The concave lingual surface of the crown in the upper incisors is usually limited towards the gum by a Λ-shaped ridge known as the **cingulum** (Fig. 487). The two limbs of the Λ are continued along the sides of the lingual surface, and the apex points towards

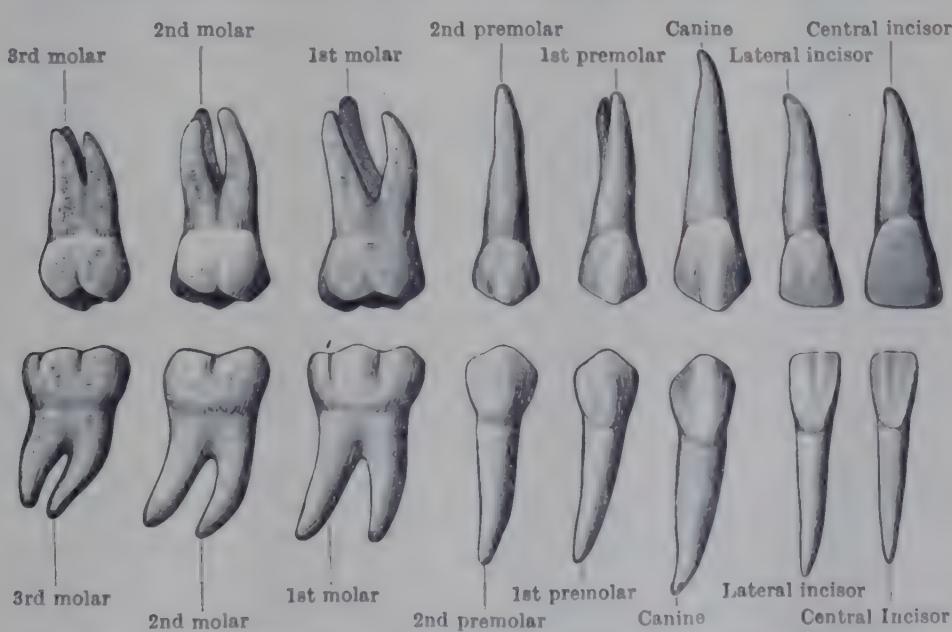

Fig. 486.—Permanent Teeth of Right Side, Labial or Buccal Surfaces.
The wide vertical "labial ridge" is distinct on the upper canine and premolar teeth.

the gum; and here, particularly in the lateral incisor, there is often developed a small **lingual tubercle**. The cingulum is rarely found on the lower incisors.

The roots of the upper incisors and canines are conical and rounded (the lateral incisors and canines not so distinctly as the central incisors), whilst those of the mandible are flattened from side to side.

Canine Teeth.—The **crown** is large and conical, and resembles in general form a very large central incisor with its angles cut away. The labial surface is convex, the lingual is usually slightly concave; and both surfaces show a slight

ridge which extends from the base of the crown to the apex. The root is single and long; that of the upper canine is longer than that of any other tooth, and produces the canine eminence on the anterior surface of the maxilla. The upper canines are larger than the lower ones, and are known as the "eye-teeth".

The upper canine presents on its lingual surface a well-marked cingulum, and often a distinct lingual tubercle; in addition, there is usually a ridge (separated from the lateral part of the cingulum on each side by a slight depression) which runs over the middle of the surface from the apex of the crown to the cingulum. These features are neither so well marked nor so constant in the lower as in the upper canine (Fig. 487). Of the two margins of the crown, the lateral is the longer in both teeth. After it has been a little worn the lower canine is less distinctly pointed than the upper; its root also is more flattened.

Premolar Teeth.—The **crown**, flattened antero-posteriorly, shows a flat chewing surface with two tubercles—the larger one on the buccal side, the other on the lingual side (Fig. 487). The buccal and lingual surfaces are both convex. The **root** is single, but is usually flattened antero-posteriorly and grooved, and it

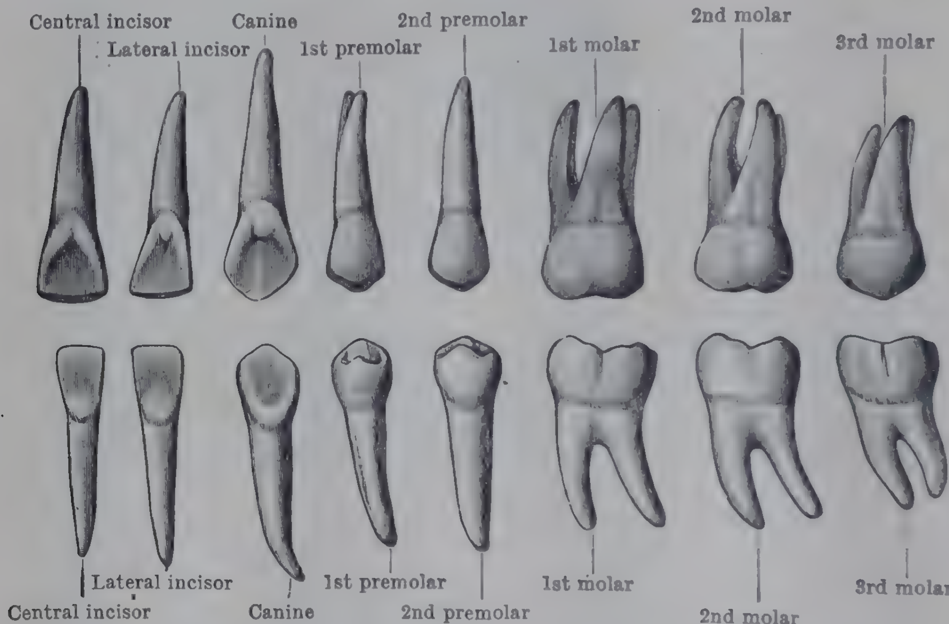

FIG. 487.—PERMANENT TEETH OF RIGHT SIDE, LINGUAL SURFACES.
The cingulum is distinct on the upper incisors and both canines, the lingual tubercle on the upper lateral incisor and the upper canine.

shows a tendency to division which is often actually present in the first upper premolar. In the upper premolars the two tubercles are large and are separated from each other by a distinct antero-posterior fissure (Fig. 485); in the lower premolars they are united by a central ridge between two dimple-like depressions (Fig. 488).

The first premolar is occasionally slightly larger than the second in the upper set but not in the lower. The labial surface of the crown is usually slightly larger than the lingual in all premolars. As a general rule, in the lower premolars the labial surface of the crown is sloped medially near the masticating surface. The first can usually be distinguished from the second by the fact that the lingual tubercle and surface are smaller than the labial in the first, but are of nearly the same size as the labial in the second. In addition, the root of the first upper premolar is bifid or nearly so, and it has a fairly distinct labial ridge, which is indistinct in the second. In the first lower premolar the lingual tubercle and surface are very small; in fact the tubercle is quite rudimentary. It should, however, be added that it is often extremely difficult to identify the various premolars.

Molar Teeth.—The molar teeth are distinguished as first, second, and third molars. Each third molar is known also as a "wisdom tooth" or **dens serotinus** (*serotinus* = late in appearing). All the molars are characterized by the large crown, with three or more trihedral tubercles on its masticating surface (Figs. 485 and 488). They are the largest of all the teeth and diminish in size, as a rule, from the first to the third. In shape the crown is more or less quadrangular, with convex labial

and lingual surfaces. The roots are either two or three in number, but frequently in the last molars they are united to a varying degree.

The molars of the maxilla and mandible differ considerably in detail. Normally the upper molars possess three roots (Figs. 486 and 487); the lower molars have two at most. The number of tubercles, though not so reliable a guide as the form of the root, is also generally sufficient to distinguish them; in the upper molars there are either three or four tubercles, whilst in the lower there are most commonly five.

In the **upper molars**, the **crown** (Fig. 485) is rhomboidal in shape (*i.e.*, quadrangular with the angles not right angles). The number of *tubercles* is either four or three. On the *first* there are invariably four—two on the labial and two on the lingual side—the anterior lingual of these being connected with the posterior labial by an oblique ridge. The *second* has either four or three tubercles in about an

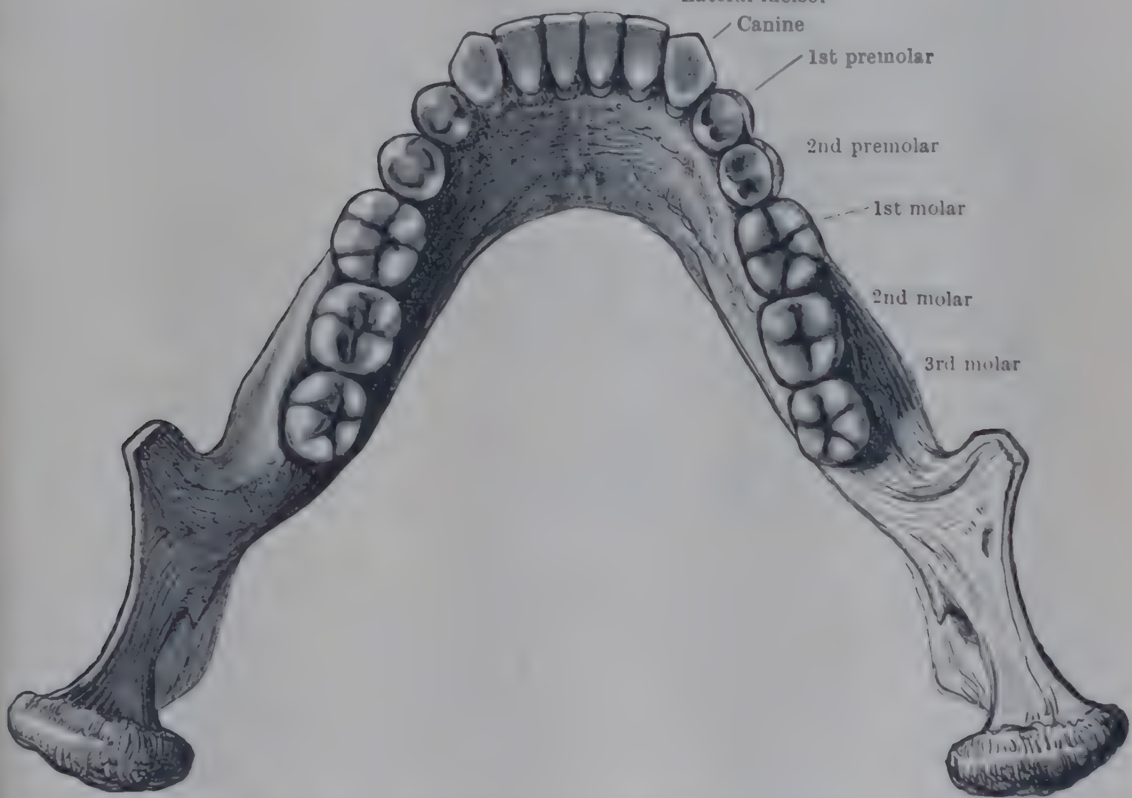

FIG. 488.—MANDIBLE AND LOWER PERMANENT TEETH.

equal proportion; in the *third* the number is much more frequently three. The upper molars have three **roots**—two buccal, and the third lingual—but they are occasionally confluent in the third molar.

In the **lower molars**, the **crown** is nearly cubical and more massive than in the upper. The *first*, as a rule, bears five *tubercles*, two labial, two lingual, and the fifth behind and buccal. The *second* has usually only four tubercles; a fifth, however, is sometimes present. The *third* has either four or five—usually four. Each has two **roots**—one anterior with two root-canals, the other posterior. They are wide roots, flattened antero-posteriorly and grooved; and both are usually recurved in their lower portions (Fig. 486). As in the upper set, the roots of the third are often more or less united into a single mass.

The upper molars slope downwards and laterally; the lower molars slope upwards and medially, and the buccal tubercles of the lower molars lie in the groove between the lingual and buccal tubercles of the upper teeth. As a result, the buccal edge of the crown is sharp and the lingual edge rounded in the upper molars; and the lingual edge is sharp and the buccal edge rounded in the lower set.

The fissures which separate the cusps on the grinding surfaces of the molar teeth are generally continued as faint grooves on the labial and lingual surfaces. A cruciform groove separates the four chief tubercles from one another; it bifurcates behind to enclose the fifth, which lies slightly to the buccal side of the middle of the tooth.

The anterior and posterior surfaces of the upper molars are in oblique planes which converge strongly postero-medially.

The backward curvature of the roots of the lower molars may make their extraction difficult.

Deciduous Teeth

The **deciduous teeth** are twenty in number—namely, two incisors, one canine, and two molars, on each side above and below; and the formula for them is therefore :—$i\,\frac{2}{2}$, $c\,\frac{1}{1}$, $m\,\frac{2}{2}$. They are distinguished from the permanent teeth by their smaller size, their constricted necks, and, in the case of the molars, by the wide divergence of their roots (Fig. 489). Otherwise they correspond closely to the same-named teeth of the permanent set. The first upper molar has, however, but three tubercles—two buccal and one lingual; the first lower molar has four—two buccal and two lingual—and the crowns of both are flattened from side to side. The second upper molar has four tubercles; the second lower has five. In each jaw, the second molar is much larger than the first.

The tubercles are sharper and are separated by deeper fissures than those of the permanent teeth; but the roots, except for their greater divergence, agree with those of the permanent set.

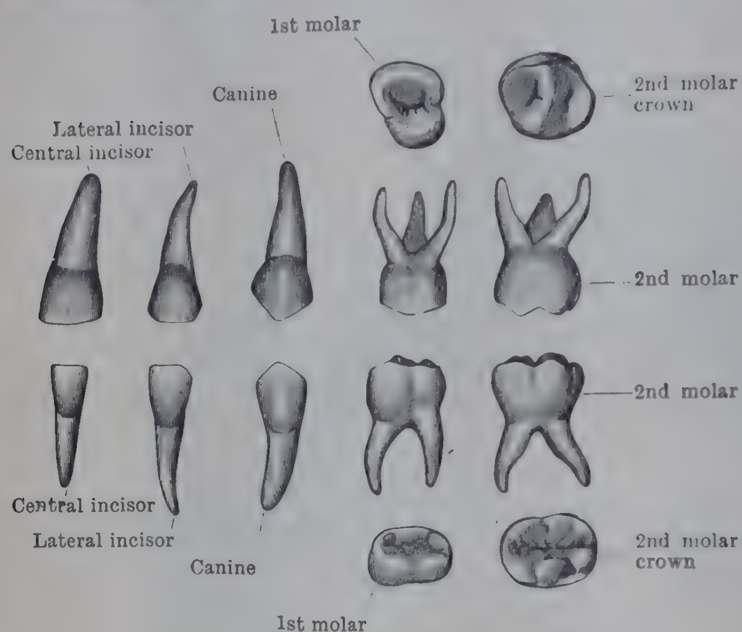

Fig. 489.—Deciduous Teeth of Left Side.

The masticating surfaces of the two upper molars are shown above. In the second row the upper teeth are viewed from the outer or labial side. In the third row the lower teeth are shown from the same side; and below are the masticating surfaces of the two lower molars. In the specimen from which the first upper molar was drawn the two labial tubercles were not distinctly separated, as is often the case.

The marked constriction at the neck of the deciduous teeth (Fig. 489) is due to a great thickening of the cap of enamel on the crown, and its abrupt termination as the neck is reached. The enamel, too, is much whiter as a rule than in the permanent teeth. The buccal surfaces of the lower molars slope strongly inwards from the neck to the crown; and the masticating surfaces of the crowns are, as a result, relatively much reduced in width.

The divergence of the roots of the deciduous molars allows the crowns of their permanent successors (premolars) to fit in between them before they are shed.

Eruption of Teeth.—The mouth of the infant at birth contains no teeth, although a number, partly developed, lie embedded in the jaws beneath the gum. Some six months later, teeth begin to appear; and, by the end of the second year, a set known as the **deciduous** or **milk-teeth**, twenty in number, has been "cut" (Pl. XLVII, p. 558, Fig. 2). The individual teeth of that set usually appear at the following ages: the lower central incisors between six and nine months, the upper incisors between eight and ten months, lower lateral incisors and first molars between fifteen and twenty-one months, the canines between sixteen and twenty months, the second molars between twenty and twenty-four months.

Then follows a pause of about four years, during which no visible change takes place in the mouth, although active preparation for further development is going on beneath the gum.

About the sixth year the next stage in the production of the adult condition begins. It consists in the eruption of four new teeth—the first permanent molars—one on each side above and below, behind those of the deciduous set. That eruption is followed by the gradual falling out of the twenty deciduous teeth, and the substitution for them of twenty new teeth, which take up, one by one, the

vacancies created by the dropping out of each of the deciduous set in the following order :—

First, about the age of seven, the central deciduous incisors are replaced; then the other deciduous teeth are replaced by the permanent teeth in the following order: lateral incisors, 1st premolars, 2nd premolars, canines. It will be observed that the eruption of the permanent canine is delayed until the two premolars, which succeed it in the row, are cut, so that it breaks the otherwise regular order of eruption. Finally, the adult condition is attained by the eruption of eight additional teeth—the 2nd and 3rd molars—two on each side above and below, behind those which have already appeared. All the **permanent teeth** have appeared by the end of the twelfth or thirteenth year, except the four "wisdom-teeth", which are usually cut between the seventeenth and twenty-fifth year, but are often delayed until a very much later period, and occasionally never appear. The 1st molar is sometimes popularly known, owing to the date of its eruption, as the "six-year-old tooth", and the 2nd molar as "the twelve-year-old tooth".

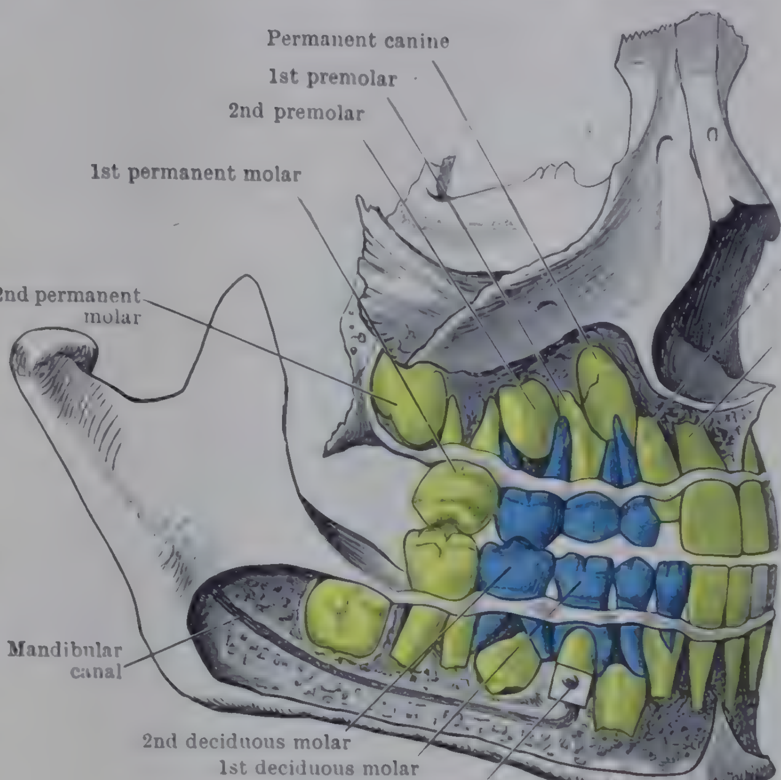

FIG. 490.—TEETH OF CHILD OVER SEVEN YEARS OLD. (Modified from Testut.) Compare with Figs. 2 and 3, Pl. XLVII, p. 558.

By the removal of the bony outer wall of the alveoli, the roots of the teeth which have been erupted, and the permanent teeth which are still embedded in the mandible and maxilla, have been exposed. The deciduous teeth are coloured blue, the permanent teeth yellow. It will be seen that the first permanent molars have appeared, the central and lateral deciduous incisors have been replaced by the corresponding permanent teeth in the maxilla, but the deciduous canine and molars have not yet been shed. In the mandible the central deciduous incisor has been replaced by the permanent central; the lateral has not yet been shed, but its permanent successor is making its way up to the surface on its lingual side. In addition, the canine and two molars of the deciduous set persist. The position of the crowns of the permanent teeth between the roots of the deciduous molars, and the deep situation occupied by the permanent canines, should be noted. Observe also the absorption of the root of the lower lateral incisor.

The usual dates of eruption of the lower permanent teeth may be stated as follows ; those of the upper jaw appear a little later :—

1st molars appear about the 6th year.					
Central incisors appear about the 7th year.					
Lateral	,,	,,	8th	,,	
1st premolars	,,	,,	9th	,,	
2nd ,,	,,	,,	10th	,,	
Canines	,,	,,	11th	,,	
2nd molars	,,	,,	12th	,,	
3rd ,,	,,	from the	17th	,,	to 21st year, or even later.

Stages in the eruption of the permanent teeth are shown in Fig. 490 and, radiographically, in Figs. 2 and 3, Pl. XLVII, p. 558.

Arrangement of Teeth in the Jaws.—The teeth in each jaw are arranged in a curved row—the **dental arch**, upper and lower—of approximately a semi-oval

form (Figs. 485 and 488). The curve formed by the upper teeth, however, is wider than that formed by the lower set, so that when the two are brought in contact the upper incisors and canines overlap the lower ones in front, and the labial tubercles of the upper premolars and molars overlap those of the lower teeth (Fig. 155, p. 162). It will be seen also that, as a rule, the teeth in one jaw are not placed exactly opposite their fellows but opposite the interval between two teeth in the other jaw (Fig. 155). That arrangement is brought about largely by the great width of the upper central incisor as compared with the lower, which throws the upper lateral incisor and the succeeding teeth into a position behind that of the corresponding teeth of the lower set. But as the lower molars are larger in their antero-posterior diameter than those of the upper row—and this remark applies particularly to the third molars—the two dental arches end behind in approximately the same plane.

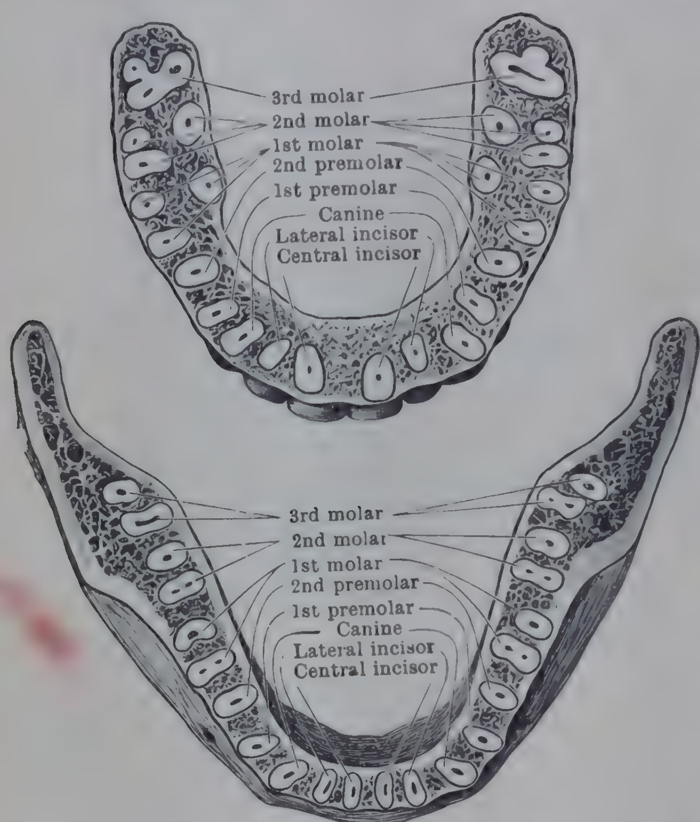

Fig. 491.—Horizontal Sections through Maxilla and Mandible to show the Roots of the Teeth.

The sections were carried through the bones a short distance from the edge of their alveolar borders. Note the flattened roots of the lower incisors, the two root-canals in the anterior root of each lower molar, and the confluence of the three roots of the upper third molars.

The upper dental arch is said to form an **elliptical curve**, the lower a **parabolic** one (Fig. 491). The line formed by the masticating surfaces of the upper teeth, as seen on profile view (Figs. 155 and 500), is usually slightly convex, owing largely to the failure of the third molar to descend into line with the others. Similarly the line of the lower teeth is as a rule concave.

In both jaws the crowns of the front teeth are higher (longer) than those of the molars.

Among civilized peoples it is rare to find a perfect arrangement of the teeth. Irregularities of individual teeth and abnormal relations of the opposed dental arches are of common occurrence and give rise to "malocclusion" (Brash, 1929).

Radiographic Examination of Teeth.—Owing to the density of their structure and to the fact that they are embedded in spongy bone, which is relatively radio-translucent, the general form and arrangement of the teeth are strikingly displayed by means of X-rays (Fig. 1, Pl. XLVII, p. 558). The enamel cannot be distinguished from the dentine or the cement; but the tooth-cavities and the root-canals are clearly visible, and their form and extent may be observed.

The *periodontal membrane* (alveolar periosteum) is seen as a black line surrounding the roots of the teeth; and the layer of compact bone in the wall of the alveolus—known in dentistry as the *lamina dura*—produces a white line on the film external to the periodontal membrane. The periodontal membrane and the lamina dura are often altered in appearance when disease is present.

The position of unerupted teeth can be exactly shown radiographically (Figs. 2 and 3, Pl. XLVII).

TONGUE

The **tongue** is a mass of interlacing bundles of striated muscle mingled with fat and entirely enclosed in mucous membrane except the posterior half of its lower part, which is called its **root** and through which the extrinsic muscles, the vessels, and the nerves gain entrance into the tongue. It lies in the floor of the mouth and also forms part of the anterior wall of the pharynx; the portion in the mouth forms a mobile elevation separated from the teeth and gums by a deep groove which ends posteriorly at the palato-glossal arches.

The movements of the tongue are important and complex, for it participates in the mastication of food, it plays an important part in swallowing, and it is essential for articulate speech. Its sensory activities are twofold, for not only does its mucous membrane possess ordinary sensation, but in addition, most, if not all, of the receptor-organs for the sense of taste are placed upon its surface.

Besides its root, the tongue has an inferior surface, a dorsum, right and left margins and a tip. The **tip** and the **margins** are in relation with the teeth; the margins are blunt; the tip is pointed when the tongue is protruded, but is blunt and rounded when the tongue is at rest. The **inferior surface** belongs to the anterior half of the tongue—the part in front of the root—and is the surface seen when the living tongue is turned upwards. The **dorsum** is a highly arched surface, reaching its maximum antero-posterior curvature at the level of the palato-glossal

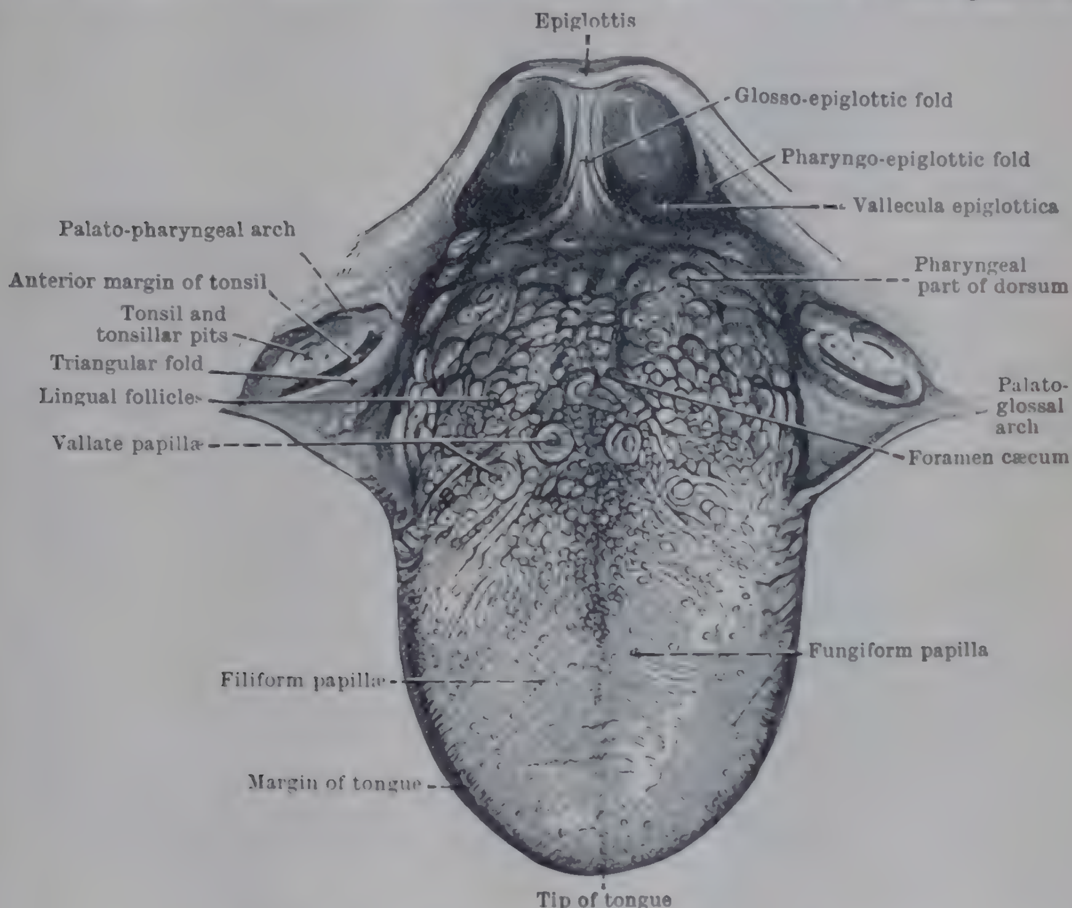

Fig. 492.—Dorsum of Tongue and *the* Tonsils.

arches. It may be conveniently divided into (1) a *palatine part* which looks upwards and is the surface seen in the open mouth, and (2) a *pharyngeal part* which looks backwards into the cavity of the pharynx and forms part of its anterior wall. These two parts are separated by a distinct V-shaped groove called the *sulcus terminalis*; the limbs of the groove diverge widely to reach the margins of the tongue; the apex of the V points backwards and is marked by a pit called the *foramen cæcum*, which indicates the position of the outgrowth of the thyroid diverticulum in the embryo.

Mucous Membrane of Tongue.—The mucous membrane of the *palatine part of the dorsum* of the tongue is inspected in the routine examination of patients. In health, it is moist and is pink in colour; and it shows a velvety or shaggy surface, as it is thickly studded with filiform papillæ, among which may be seen occasional larger, rounded projections called the fungiform papillæ. At other times it is yellowish in colour from the accumulation of shed epithelial cells, remains of the food, and organisms. At its posterior part, immediately in front of the sulcus terminalis, there is a V-shaped row of large papillæ named the vallate papillæ. The mucous membrane of the palatine part of the dorsum is firmly adherent to the underlying corium, and so affords for the filiform papillæ a firm basis, resting upon which they may rub the food against the palate.

The mucous membrane of the *pharyngeal part of the dorsum* has a smooth nodular glistening surface, and contains numerous serous glands; it is separated from the muscular substance by a submucous layer which contains mucous glands and nodules of lymphoid tissue called *lingual follicles* (Figs. 495, 502). Its surface is free from evident papillæ, but it is thickly studded with rounded projections, each presenting, as a rule, a little pit, visible to the naked eye, at its centre. These nodules are produced by the follicles, which are similar to the lymph-follicles found in the tonsils and collectively are called the **lingual tonsil**. At each side the mucous membrane is continuous with the mucous covering of *the* tonsil and of the side-wall of the pharynx. Posteriorly, it is reflected on to the front of the epiglottis, being raised up in the median plane to form a sharp ridge called the **glosso-epiglottic fold**, at each side of which there is a wide depression called the **vallecula epiglottica** (Fig. 492 and Pl. LXI., p. 696). The vallecula is bounded laterally by a less

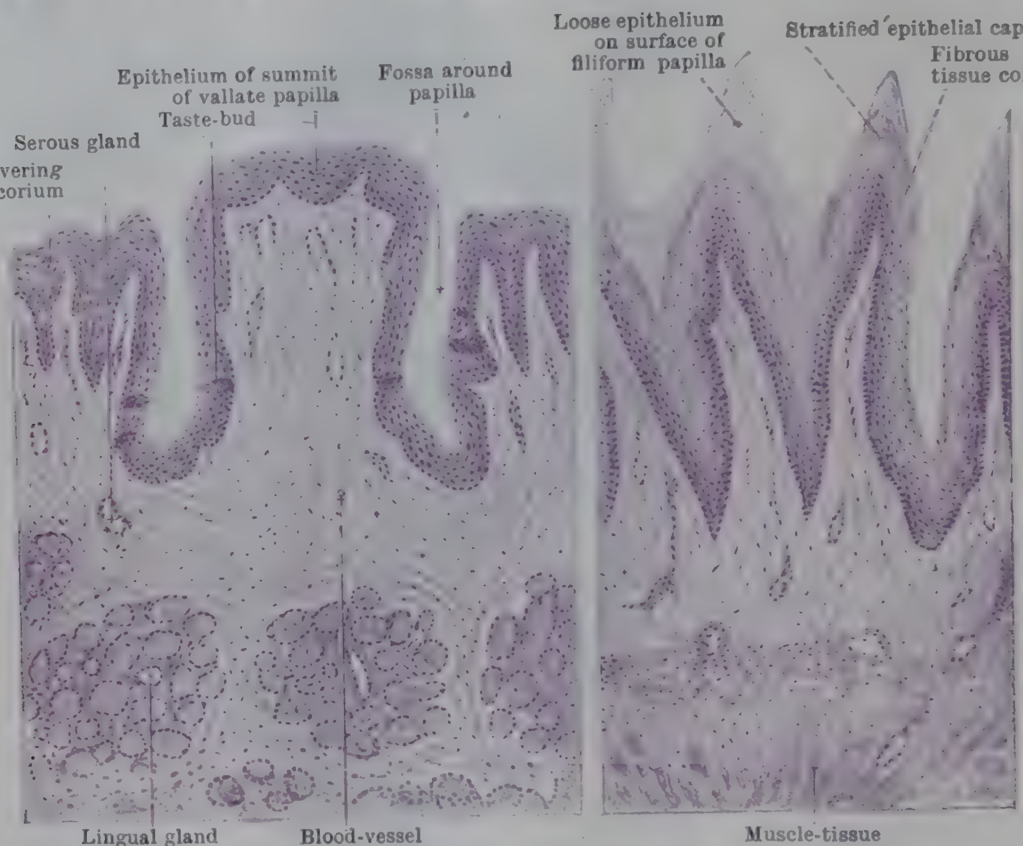

Fig. 493. A. Section of Vallate Papilla of Tongue. B. Section of Filiform Papillæ of Tongue.

distinct ridge of mucous membrane, called the **pharyngo-epiglottic fold**, which passes laterally and upwards from the margin of the epiglottis to blend with the mucous lining of the side-wall of the pharynx.

On the pharyngeal part of the tongue there are also small papillary projections of the corium, but the epithelium fills up all the intervals between the papillæ, and levels off the surface, so that none are visible to the eye as projections above the general level. Over the anterior part of the tongue, on the contrary, the projections of the corium are large and prominent, and the intervals between them are not filled up by the epithelium, so that the projections stand out distinctly and independently, and in places attain a height of nearly 2 mm. above the general surface.

On the margins of the tongue the mucous membrane is thin, usually pink in colour, and, immediately in front of the attachments of the palato-glossal arch, there are five or six vertical folds of mucous membrane, termed the **folia of the tongue**, which are studded with taste-buds. They represent the foliate papillæ on the sides of the tongue in rabbits, hares, and other animals.

The *inferior surface* is covered with a smooth, thin mucous membrane devoid of papillæ. On its middle, except near the tip, there is a depression from which a fold of mucous membrane, called the **frenulum of the tongue**, passes down to the floor of the mouth and the posterior aspect of the mandible. At each side of the frenulum, and a short distance from it, the profunda linguæ vein is distinctly

seen through the mucous membrane. Still farther from the frenulum, on each side, there is a fringed fold called the **fimbriated fold**; these two folds converge slightly as they are followed forwards towards the tip, near which they are lost.

Papillæ of Tongue (Fig. 492).—The papillæ are variously-shaped projections of the corium of the mucous membrane covered with thick caps of epithelium, and they are of three main varieties: filiform, fungiform, and vallate.

The **filiform papillæ** (Fig. 493), the smallest and most numerous, form a dense crop of minute projections all over the anterior two-thirds of the dorsum of the tongue, and on the upper surface of its margins and tip. Posteriorly they lie in divergent rows that run laterally and forwards from the raphe parallel to the limbs of the sulcus terminalis. More anteriorly, the rows become nearly transverse, and near the tip irregular. Each papilla is composed of a conical projection of the corium from which secondary papillæ project, covered by a thick, pointed cap of stratified squamous epithelium.

In many of them the cap of epithelium is broken up into several long, slender, pointed processes. The cap of epithelium is being constantly shed and renewed, and an excessive or diminished rate of shedding or renewal, coupled with the presence of various organisms, gives rise to the several varieties of "tongue" found in different diseases.

The filiform papillæ are highly developed and horny in carnivora.

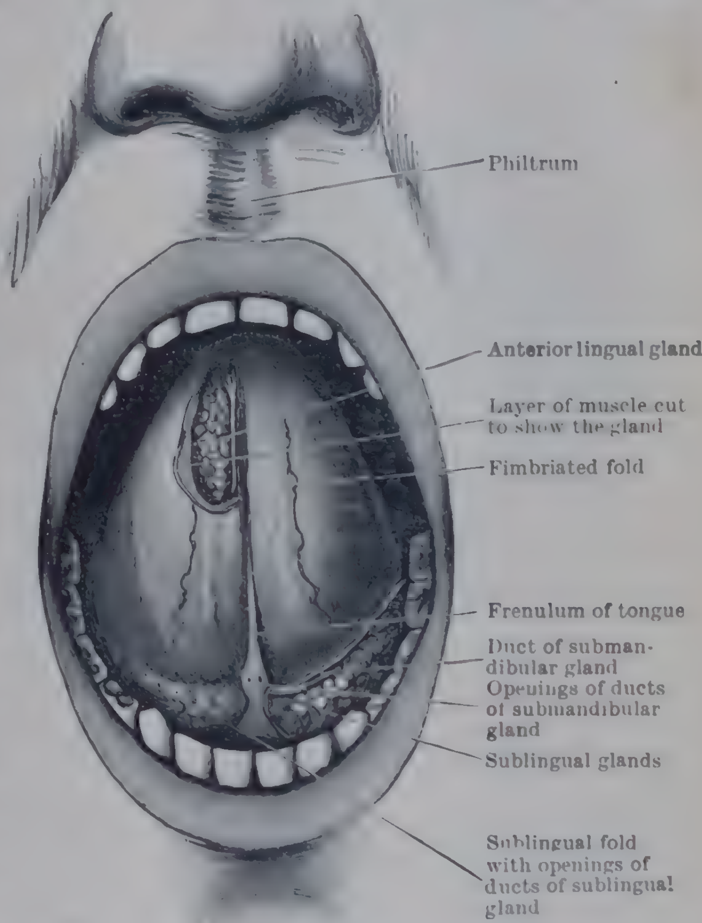

Fig. 494.—Open Mouth with Tongue raised, and the Sublingual and Anterior Lingual Glands exposed.

The sublingual gland of the left side has been laid bare by the removal of the mucous membrane; to expose the anterior lingual gland of the right side a thin layer of muscle, in addition to the mucous membrane, has been removed. A branch of the lingual nerve is seen running on the medial side of the gland. The profunda vein also is faintly indicated on this side.

The **fungiform papillæ** (Fig. 492), larger and redder, but less numerous than the filiform, are found chiefly near the tip and margins of the tongue, comparatively few being present over the dorsum generally. Each is in shape like a "puff-ball" fungus, consisting of an enlarged rounded head attached by a narrower base. As in the filiform papillæ, the corium is studded with microscopic papillæ which are buried in the covering of squamous epithelium. Most of the fungiform papillæ, if not all, appear to be furnished with taste-buds.

The **vallate papillæ** (Fig. 493), are much the largest of all the papillæ of the tongue. They are from nine to fourteen in number and are arranged in the form of the letter V, with the apex behind, immediately in front of and parallel to the sulcus terminalis, one or two of the papillæ being placed at the apex of the V. In appearance a vallate papilla resembles very closely the impression left by the barrel of a small pen pressed on soft wax (Fig. 492). Each is a short cylinder (1 to 2·5 mm. wide) that tapers slightly towards its base and is flattened on its crown, which projects a little above the general surface of the tongue. It is surrounded by a deep, narrow, circular fossa, the outer wall of which is known as the **vallum**. The vallum is an encircling collar very slightly raised above the adjacent surface (Fig. 493). As in the other papillæ, a vallate papilla is made up of a central mass of corium, studded with numerous microscopic papillæ on the crown (but not on the sides), and covered over with stratified squamous epithelium,

as are the walls of the fossa. The ducts of some small serous glands open into the fossa (Fig. 493 A). **Taste-buds**—the special end-organs of the sense of taste—are found in considerable numbers in the sides of a vallate papilla, as well as in the vallum; they are described on p. 1214.

Structure of Tongue.—The tongue is composed chiefly of striated muscular tissue, with a considerable admixture of fine fat. A median septum of fibrous tissue divides its central part into symmetrical halves. In addition, there are vessels, nerves, glands, and lymphoid tissue; and the whole is covered with mucous membrane, except at the root (Fig. 495).

The muscular tissue is derived partly from the extrinsic muscles—namely, the hyo-glossus, stylo-glossus, genio-glossus, palato-glossus, and chondro-glossus; and partly from the intrinsic muscles—superior and inferior longitudinal, transverse, and vertical. The external or **cortical portion** is derived from the superior and inferior longitudinal muscles and the hyo-glossus and stylo-glossus. The central or **medullary portion**—divided into

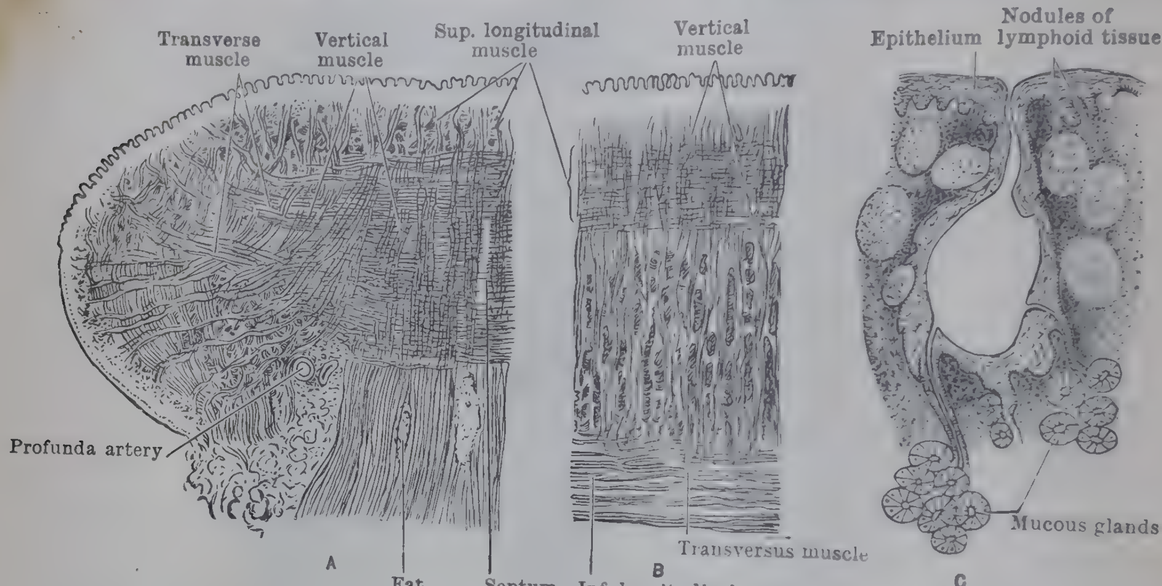

FIG. 495.—A. TRANSVERSE, AND B. LONGITUDINAL VERTICAL SECTION THROUGH TONGUE (Krause); C. LINGUAL FOLLICLE FROM POSTERIOR PART OF TONGUE (Macalister, slightly modified).

two halves by the median **septum**—is composed of the transverse and vertical fibres and of the fibres of the genio-glossi ascending to the dorsum. The muscular fibres end by being inserted into the deep surface of the mucous membrane.

The detailed description of the extrinsic and intrinsic muscles and an account of the movements of the tongue will be found in the Section on Myology (p. 438).

The **septum** is a median fibrous partition found in the medullary portion only. Anteriorly it usually extends to the apex; posteriorly it diminishes in depth and expands transversely into a broad sheet (the hyo-glossal membrane) which is united to the upper border of the hyoid bone and gives attachment to the posterior fibres of the genio-glossus. From the sides of the septum the fibres of the **transverse muscle** of the tongue arise.

Lingual Glands.—Numerous small mucous glands are scattered beneath the mucous membrane of the posterior third of the tongue; and a small collection of similar glands is present at the margin opposite the vallate papillæ. Small serous glands also are embedded in the dorsum near the vallate papillæ, into the fossæ of which their ducts open.

The chief collections of glandular tissue in the tongue, however, are found embedded in the muscle of the under surface, a little way behind the apex, on each side of the middle line (Fig. 494). They are known as the **anterior lingual glands**.

These glands are displayed after the removal, from the under surface of the tongue a little distance behind the apex, of the mucous membrane and a layer of muscle-fibres about 2 mm. thick composed of fibres of the stylo-glossus and inferior longitudinal muscles. The anterior lingual glands are oval in shape, often partly broken up by muscular fibres, and they measure from $\frac{1}{2}$ to $\frac{3}{4}$ in. (12 to 19 mm.) in length. They are mixed serous and mucous glands, and they open by three or four very small ducts on the inferior surface of the tongue.

Vessels and Nerves.—The chief **artery** is the *lingual*. It passes forwards, on each side, medial to the hyo-glossus muscle, and then is continued to the apex—between the genio-glossus on the medial side and the inferior longitudinal muscle laterally—under the name of the *profunda artery*. Anteriorly it is covered by the **inferior longitudinal** muscle, and lies $\frac{1}{8}$ to $\frac{1}{4}$ in.

from the surface. Near the apex the arteries of opposite sides are connected by a branch which pierces the septum; but otherwise, with the exception of capillary anastomosis, they do not communicate. The *dorsales linguae* branches of the lingual artery are distributed to the pharyngeal part of the tongue; and some twigs of the *tonsillar artery* (a branch of the facial) also are distributed in that region.

The **veins** are in three sets. The chief of them is the *profunda vein*, which runs backwards first under cover of the mucous membrane at the side of the frenulum and then over the hyo-glossus with the hypoglossal nerve. The others are the two *venæ comitantes* of the lingual artery and the two or more *dorsales linguæ veins* from the back of the tongue. They end in the internal jugular vein either separately or by a common trunk formed by their union at the posterior border of the hyo-glossus.

The **lymph-vessels** of the tongue end in the *submental* and *submandibular glands*, and in the *deep cervical* group between and including the jugulo-digastric and the jugulo-omo-hyoid glands.

The **nerves** which supply the tongue are the hypoglossal, lingual, and glosso-pharyngeal, and, to a small extent, the internal laryngeal. The *hypoglossal nerve*—the motor nerve of the tongue—enters the genio-glossus and passes up in its substance to the intrinsic muscles, in which it ends. The *lingual nerve* is a branch of the mandibular nerve, and it is joined by the *chorda tympani branch* of the facial nerve. The lingual, after crossing the hyo-glossus, breaks up and enters the inferior longitudinal and genio-glossus muscles, and thus makes its way upwards to the mucous membrane of the anterior two-thirds of the tongue—the lingual itself conferring common sensation on this part, while the chorda tympani carries taste-fibres and parasympathetic fibres to it. The *glosso-pharyngeal nerve* passes forwards beneath the upper part of the hyo-glossus muscle, and sends its terminal branches to the mucous membrane of the posterior third of the tongue, supplying the vallate papillæ and the part of the tongue behind them with both gustatory and common sensory fibres. The *internal laryngeal nerve* distributes a few fibres to the posterior part of the tongue near the epiglottis.

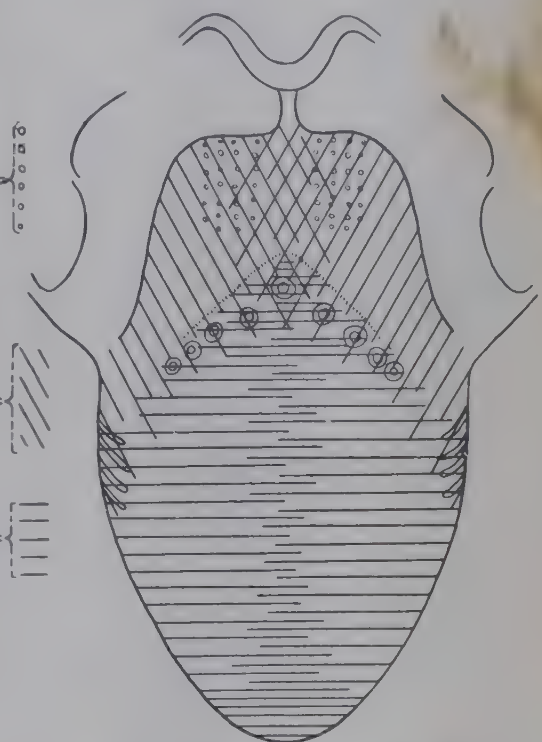

Fig. 496.—Areas of Afferent Nerve-Supply of Tongue.

GLANDS

In the following paragraphs only the true glands of the alimentary system are considered—namely, the glands of epithelial origin characterized by the possession of ducts.

Such glands may be defined as epithelial organs which secrete or excrete some particular substance or substances. Their essential parts are cells; and there may be different kinds of cells in a gland. This type of gland appears as an evagination of an epithelial surface, and it may be of various forms.

The simplest form is a single diverticulum of uniform width forming a simple tubular gland. The intestinal glands are of this kind.

The end of a tubular gland may be widened, forming a sort of pocket, called an alveolus [*alveolus*, small pit or bag]; and this type of gland is known as the simple alveolar gland. It does not exist in the alimentary canal.

In some glands the lower part or fundus of the tube does all the secretion, and the upper part forms a duct that carries the secretion to the surface.

When the outgrowth that forms the gland remains undivided, the gland is known as a **simple gland**. When it breaks up into two or more branches it is

known as a **compound gland**; and a compound gland may be tubular, alveolar, or of a mixed tubular and alveolar form. When the secreting part of a gland becomes differentiated into several enlargements (alveoli) at the end of a single duct, it is called an **acinus** [*acinus* = a unit of a compound berry]. A gland formed of several such structures collected together is often called a **compound acinous** or **racemose gland** [*racemus* = a cluster] from the fancied resemblance to a cluster of compound berries at the end of a stalk.

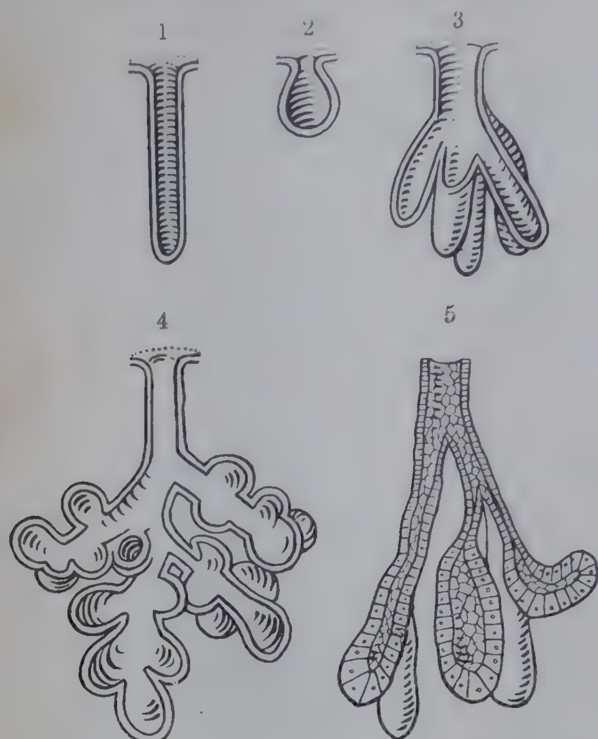

Fig. 497.—Diagram of Structure of Various Types of Glands.

1. Simple tubular gland.
2. Simple alveolar.
3. Compound tubular.
4. Compound acinous or racemose gland.
5. Section of secreting portion of gland and ducts.

General Structure of Glands.—The small glands, such as those of the mouth and pharynx, are placed in the mucous or the submucous coat close to the point at which their ducts open on the surface; but the large glands form distinct masses which often lie at a considerable distance from the points at which their ducts open, and they are generally surrounded by special capsules.

Each of the large glands of the acinous type, such as the parotid or the submandibular, presents the following general arrangement. The gland is made up, as can be seen with the unaided eye, of a number of masses, often as large as peas, which are surrounded and held together by areolar tissue. The masses are known as lobes, and a branch of the duct passes to each. The lobes are in turn made up of a number of smaller masses—lobules—each having a special branch of the lobar duct. Those again are composed of smaller lobules, and finally the smallest are made up of a terminal branch of the duct with a cluster of acini or alveoli leading into it.

The **acini** or **alveoli** are composed of secreting epithelial cells placed on a basement membrane, often fenestrated or basket-like, formed of flattened cells, on the outer side of which the blood-vessels and lymph-vessels lie. The secreting cells, usually polygonal in shape, almost completely fill the alveolus. A small lumen, however, is left, into which the secretion of the cells is shed, and whence it passes into the duct of the lobule, and thus to the main duct.

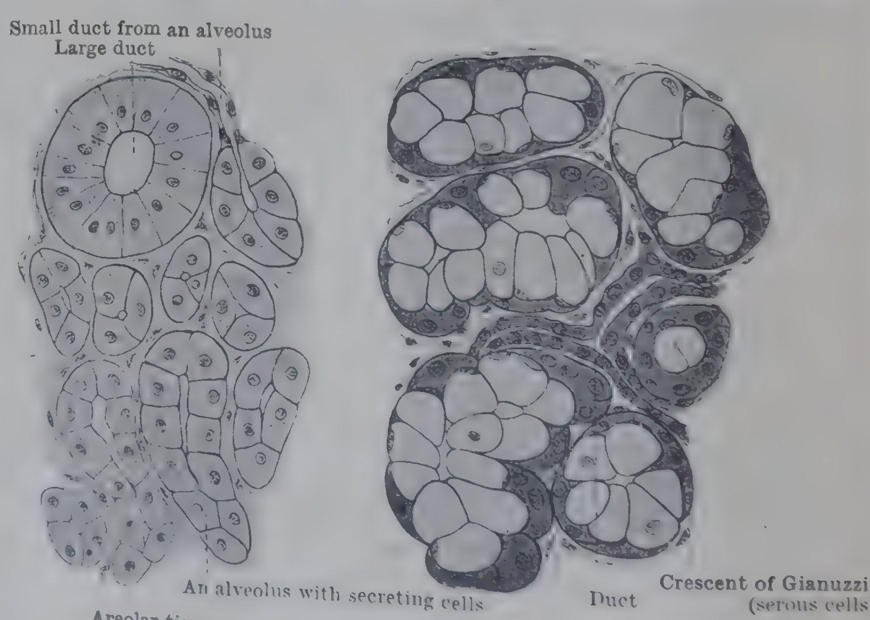

Fig. 498.—Section of a Serous Gland on the left, a Mucous Gland on the right. (Bohm and v. Davidoff.)

In the serous gland the granular secreting cells and the centrally placed nucleus should be noted. The relatively clear (mucus-secreting) cells, with the dark crescents of Gianuzzi, are distinctive in the mucous gland.

Salivary Glands

Saliva is a clear, watery fluid poured by numerous glands into the cavity of the mouth. It moistens the tongue and the walls of the mouth and facilitates the movements of the tongue. Mixed with food by mastication it helps in swallowing. It also contains a ferment which plays an important part in digestion, for it can transform starch into dextrin.

The glands which secrete it are the small glands of the lips, cheeks, and tongue, and also three large paired glands—the parotid, submandibular, and sublingual glands. The three last are the main salivary glands.

Parotid Gland.—The parotid gland, the largest of the salivary glands, is a lobulated mass, of a yellowish or light reddish-brown colour, with a large triangular superficial surface. It lies on the side of the face below and in front of the ear,

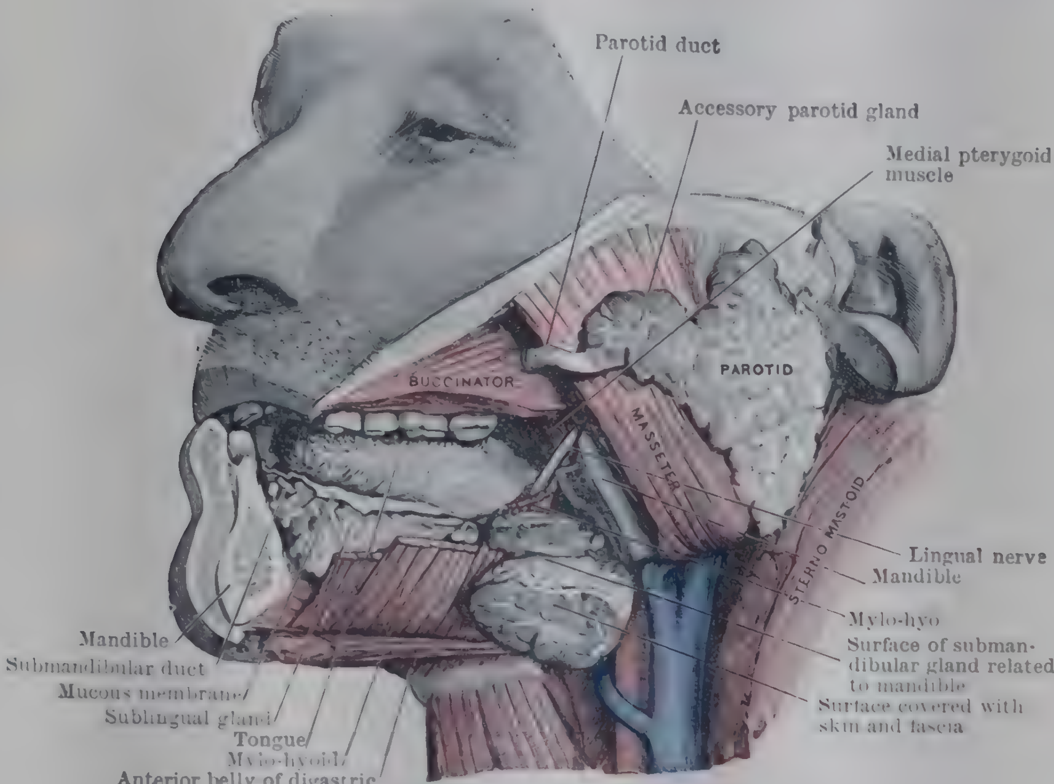

Fig. 499.—Salivary Glands and their Ducts.

mastoid process, and sterno-mastoid muscle, and extends medially behind the medial pterygoid muscle towards the side of the pharynx.

Shape and Relations of Parotid Gland.—In shape the parotid gland with its medial extension is a three-sided wedge (Fig. 507, p. 591), the three surfaces being superficial, anterior, and posterior.

The deeper portion of the gland occupies a space of considerable size, which has two nearly vertical sides, an anterior and posterior, which converge towards each other and meet deeply at an acute angle.

A horizontal section through the head about the middle of the gland (Fig. 507) shows that the posterior wall of the space is formed, medial to the sterno-mastoid muscle, by the posterior belly of the digastric and the stylo-hyoid muscles, and more deeply still, by the root of the styloid process and the carotid sheath and its contents, and especially by the internal jugular vein, which separates the space from the vertebral column. The anterior wall of the space is formed by the ramus of the mandible and the masseter and medial pterygoid muscles. The portion of the gland that lies in the fossa presents a deeply concave anterior surface, and a posterior surface, irregular in outline, directed backwards and medially.

The **superficial surface** is irregularly triangular in outline. Its posterior border lies in front of the external auditory meatus and the sterno-mastoid muscle, and

extends down to the angle of the mandible and the posterior belly of the digastric muscle. Its superior border lies below the zygomatic arch, and the anterior border passes irregularly upwards and forwards to join it. The apex, directed forwards, lies on the masseter muscle, and the duct of the gland issues from it, or immediately below it. A separate portion of parotid tissue, often found lying immediately above the duct, is known as the **accessory parotid gland**. The superficial part of the gland is frequently prolonged downwards over the digastric muscle. It may descend beyond the angle of the mandible, and come into immediate relation with the posterior part of the submandibular gland, from which it is separated merely by a thin layer of the deep cervical fascia. Embedded in the superficial surface there are usually several small, rounded lymph-glands which can be distinguished from the gland-tissue by the difference in their colour.

The **anterior surface** of the gland clasps the posterior border of the ramus of the mandible and the muscles on its surfaces—masseter and medial pterygoid.

The **posterior surface** of the gland is in contact with the sterno-mastoid muscle, the mastoid process, the external auditory meatus, the posterior belly of the digastric muscle, the internal jugular vein, and the root of the styloid process and the styloid muscles. It is often deeply grooved by the posterior belly of the digastric.

The gland is occasionally prolonged medially beyond the lower portion of the styloid process, towards the pharynx. In such cases the lower part of the styloid process lies in a groove on the posterior surface of the gland.

A number of vessels and nerves are found in intimate relation to the parotid gland. The external carotid artery lies at first in a groove in the deep surface of the gland. It then enters the gland substance and lies deeply in it as far as the neck of the mandible, where it divides into its two terminal branches. The superficial temporal artery emerges from the upper border of the gland, and the maxillary artery turns medially and emerges from the deep part of the anterior surface.

The transverse facial artery is given off in the substance of the gland and emerges from it between the zygomatic arch and the duct.

The posterior facial vein descends in the substance of the gland and divides into the two terminal branches which emerge through the lower end of the gland.

The facial nerve enters the posterior surface of the gland slightly below its middle, runs laterally and forwards, and divides into its terminal branches, which radiate through the gland superficial to the external carotid artery and posterior facial vein. Communicating branches to the facial from the auriculo-temporal and great auricular nerves also traverse the gland substance. The suggestion that "the parotid gland is a bilobed structure with the facial nerve running between the lobes" is not borne out by the recent investigation of M'Kenzie (1948).

Parotid Fascia.—The parotid recess is lined by a layer of fascia continuous with the deep cervical fascia. It is connected above to the zygoma, posteriorly to the auditory meatus and anterior border of the sterno-mastoid, and medially to the styloid process; anteriorly it passes over the masseter and blends with the bucco-pharyngeal fascia. Together with the periosteum of the tympanic plate it forms a definite sheath which completely encloses the gland. The lower and anterior part of this sheath is thickened to form a special flat band, called the **stylo-mandibular ligament**, which passes downwards and laterally from the styloid process to the angle of the mandible. It separates the anterior part of the parotid gland from the posterior border of the medial pterygoid muscle and from the upper and posterior part of the submandibular gland.

Parotid Duct.—The parotid duct leaves the anterior border of the gland at its most prominent part (Fig. 499). It first runs forwards across the masseter, below the accessory parotid gland, accompanied by branches of the facial nerve and the transverse facial artery, which is commonly some distance above. The duct turns abruptly round the anterior border of the masseter and runs inwards through the fat of the cheek, almost at right angles to the first part of its course, to reach the buccinator, which it pierces. Then, passing for some distance (5 to 10 mm.) between the buccinator and the mucous membrane, it opens into the vestibule of the mouth by a very small orifice, on a variably developed papilla, opposite the crown of the second upper molar tooth.

The course of the duct can be marked by the middle third of a line from the inferior edge of the auditory meatus to a point midway between the ala of the nose and the red margin of the lip.

The duct measures from $1\frac{1}{2}$ to $2\frac{1}{2}$ inches (40 to 60 mm.) in length, and $\frac{1}{8}$ inch (3 to 4 mm.) in diameter. The calibre of the duct is very much greater than that of its orifice, which admits only a fine bristle, and for that reason the duct may, to some extent, be looked upon as a reservoir for the saliva, as well as a duct for its conveyance. In the child it pierces the buccal pad of fat on its way to the mouth.

Vessels and Nerves.—The **arteries** which supply the gland arise from the *external carotid artery*, and from the branches of that artery in the gland. The **veins** join the *posterior facial vein* and its tributaries. The **lymph-vessels** pass to both the superficial and the deep cervical glands; there are also a few small parotid lymph-glands which lie on the surface of the superior and inferior part of the parotid beneath the sheath. Some are said to be embedded in the substance of the parotid itself.

The **nerves** are derived (*a*) from the *auriculo-temporal*, *great auricular*, and *facial*, and (*b*) from the *external carotid plexus*. The fibres of the sympathetic are mainly vaso-constrictor.

The secretory fibres to the gland arise in the brain-stem, pass through the glosso-pharyngeal

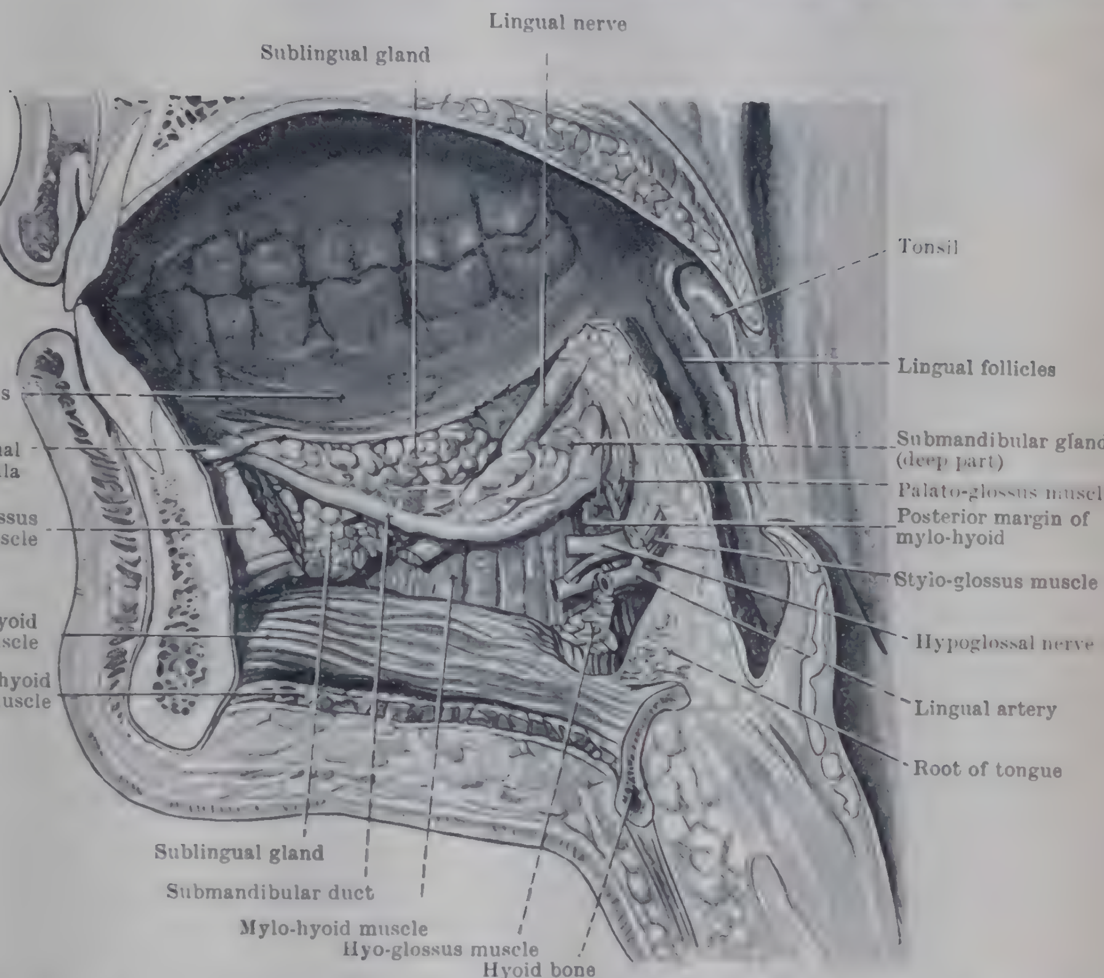

FIG. 500.—SIDE-WALL AND FLOOR OF MOUTH, AFTER REMOVAL OF TONGUE AND MUCOUS MEMBRANE.

nerve and its tympanic branch, and thence through the lesser superficial petrosal nerve to the otic ganglion, and from that ganglion to the gland in the auriculo-temporal nerve (Fig. 906, p. 1036).

Submandibular Gland.—The submandibular gland is smaller than the parotid but resembles it in lobulation and colour. It is placed in the submandibular region, partly under cover of the mandible (Fig. 499), and partly between the mandible and the hyoid bone, overlapping the bellies of the digastric muscle.

In that region there is a three-sided space bounded laterally by the mandible below the mylo-hyoid line, medially and above by the mylo-hyoid muscle, and below and laterally by the skin and fascia passing from the margin of the jaw to the hyoid bone. The gland lies in that space and has therefore three surfaces, which may be named lateral, medial, and inferior.

In each gland two portions may be recognized :—(1) the main part, with three surfaces, which lies in the submandibular triangle, and (2) a thin, deep process which springs from the middle of the medial surface of the gland and passes forwards between the mylo-hyoid and hyo-glossus muscles.

The *lateral surface* of the main part is related to the floor of the submandibular fossa of the mandible and to the medial surface of the medial pterygoid muscle.

The *inferior surface* is covered with skin, superficial fascia, and platysma, and by the investing deep fascia of the neck. It is crossed, under cover of the platysma, by the cervical branch of the facial nerve, and, under cover of the deep fascia, by the anterior facial vein. In the groove between this surface and the lower margin of the mandible there are four to six submandibular lymph-glands.

The *medial surface* is clothed with a thin layer of fascia which extends from the hyoid bone to the mylo-hyoid line of the mandible and separates it from the bellies of the digastric and the stylo-hyoid, from the mylo-hyoid muscle and nerve, and from the hyo-glossus and certain smaller structures that lie on the surface of that muscle.

The posterior part of the gland is the bulkiest. The posterior end is deeply grooved by the facial artery; it reaches as far back as the angle of the mandible,

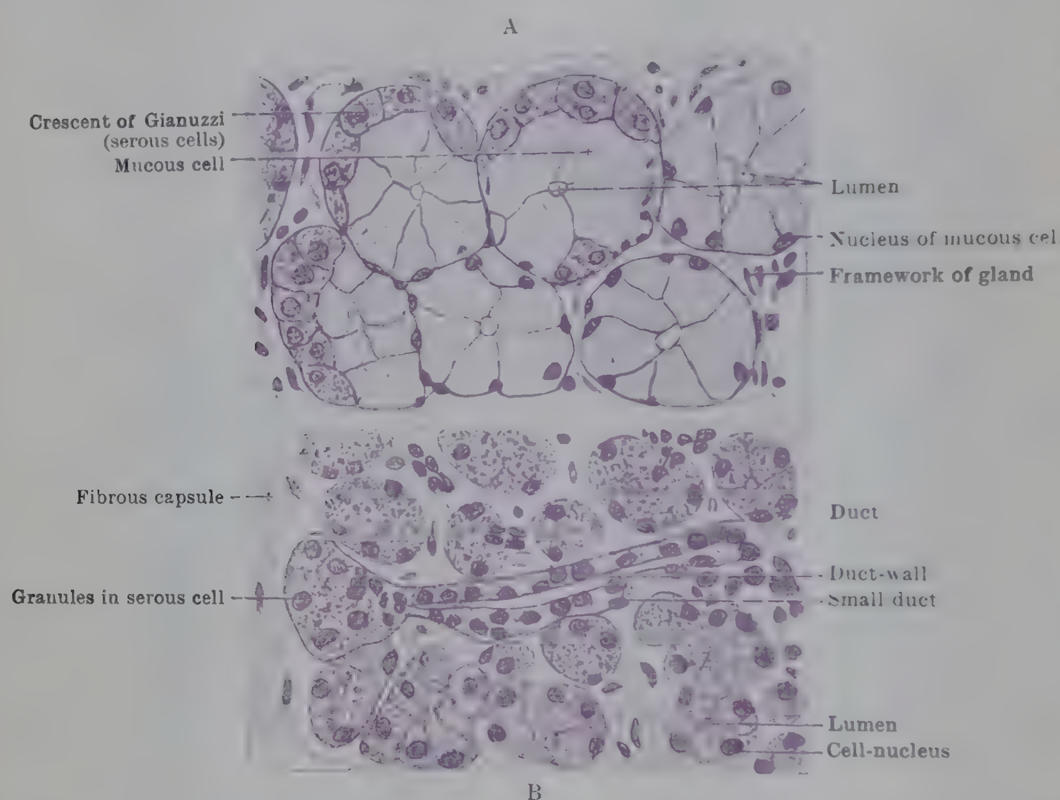

FIG. 501.—SECTIONS OF (A) SUBMANDIBULAR GLAND ($\times$ 400); (B) PAROTID GLAND ($\times$ 400).

where it comes into relation with the lower part of the parotid gland near the anterior border of the sterno-mastoid muscle.

Submandibular Duct.—The submandibular duct is about two inches in length. It leaves the deep surface of the gland about its middle and runs forwards deep to the mylo-hyoid muscle along the medial surface of the deep process of the gland near its upper border (Fig. 500). Pursuing its course forwards beneath the floor of the mouth, on the medial side of the sublingual gland, the duct crosses the hyo-glossus and genio-glossus muscles, and finally opens on the floor of the mouth at the side of the frenulum of the tongue on the summit of the sublingual papilla.

While running forwards beneath the floor of the mouth, the duct is crossed twice by the lingual nerve. In its course to the tongue, the nerve crosses the duct superficially from above downwards at the anterior border of the hyo-glossus opposite the second molar tooth; farther forwards, under cover of the sublingual gland, the nerve curves upwards deep to the duct to reach the tongue.

Like the parotid duct, the submandibular duct is narrowest at its orifice, and may be to some extent a reservoir for the saliva.

Vessels and Nerves.—The arteries come chiefly from the *facial artery* and its *submental branch*: the **veins** accompany the arteries. The **lymph-vessels** pass to the *submandibular lymph-glands*. The **nerves** are derived, through the *submandibular ganglion*, from the *chorda tympani*, *lingual*, and the *sympathetic plexus around the facial artery* (Fig. 903, p. 1033).

Sublingual Gland.—The sublingual gland, the smallest of the principal salivary glands, is situated more deeply than the others. It lies immediately below the mucous membrane of the floor of the mouth in the sublingual fossa between the inner surface of the mandible above the mylo-hyoid line and the genio-glossus muscle. Below, it rests on the mylo-hyoid muscle.

In shape it is almond-like, flattened from side to side, but is much wider (from above downwards) anteriorly than posteriorly. It is usually from $1\frac{1}{2}$ to $1\frac{3}{4}$ inches (37 to 45 mm.) in length, whilst its bulk is about equal to that of two or three almonds.

Its detailed relations are as follows :—Its *lateral surface* rests against the inner aspect of the body of the mandible above the mylo-hyoid line. Its *medial surface* is in contact with the genio-glossus, stylo-glossus, and hyo-glossus muscles, as well as with the submandibular duct, which runs forwards between the gland and the muscles. *Below* it rests on the mylo-hyoid, and at its posterior part on the deep process of the submandibular gland ; its *upper border* is prominent and is covered only by the sublingual fold of the mucous membrane of the mouth (Fig. 494). The anterior half of the gland is much deeper and more bulky than the posterior half, and it meets its fellow in the median plane beneath the frenulum of the tongue. The posterior part grows gradually more slender, but may extend to the posterior part of the mylo-hyoid ridge.

The **sublingual ducts** are about twelve in number and of small size ; they leave the superior part of the gland, and, after a short course, open on a series of papillæ, visible to the naked eye, which are placed along the summit of the sublingual fold.

The gland is not enclosed in a distinct sheath, thus differing from the parotid and submandibular glands ; but its numerous lobules, which are smaller than those of the glands just mentioned, are held together by areolar tissue, loosely, but still in such a manner as to make one more or less consolidated mass out of what was, in the embryo, a number of separate glands.

As a rule all the ducts open separately on the summit of the sublingual fold, and apparently none of them join the submandibular duct. Frequently some of those from the anterior and more bulky part of the gland are larger than the others, but the presence of a large duct running alongside the submandibular duct, and opening with or beside it, is very rare in Man, although normal in the ox, sheep, and goat.

Vessels and Nerves.—The **arteries** are derived from the *sublingual artery*, a branch of the lingual, and from the *submental* branch of the facial. The **nerves** come from the *lingual*, the *chorda tympani*, and the *sympathetic plexus on the facial artery* through a branch of the submandibular ganglion which joins the lingual and is conveyed by it to the gland. The secretory fibres run in the *chorda tympani nerve* and thence through the submandibular ganglion to the gland (Fig. 903, p. 1033).

The **anterior lingual gland** has been described with the tongue.

Structure of Salivary Glands (Fig. 501).—Each of the principal salivary glands is divided into a number of lobules loosely united together by areolar tissue. From each of them one or more ducts emerge. Each duct divides into branches which terminate in a group of saccular or tubular alveoli. The epithelium which lines the ducts is columnar in character, but becomes flattened at the junction with the alveoli. The epithelium of the alveoli shows different characters in different glands. In the parotid and in the small salivary glands of the vallate papillæ, in which the secretion is watery or albuminous, the cells are uniform in character and of small size. When the gland is at rest the cells are filled with small granules which, when the secretion is poured out, are transformed into the gland-ferment—*ptyalin*. After secretion, only the deeper parts of the cells show the presence of granules. The nuclei are rounded and lie near the margin of the cells. In the sublingual, labial, buccal, and other glands of the mouth and palate the secretion is of a mucous character and the cells are larger : and the nuclei are placed deeply. The cells appear clear and swollen unless special methods of preparation are employed, such as examination in serum ; the cells are then seen to contain large and distinct granules of mucigen which in secretion are transformed into mucus.

In the submandibular gland and the anterior lingual gland both varieties of cells are present. In these glands, the larger clear mucous cells line the cavity of the alveolus, and the smaller granular serous cells are arranged upon the basement membrane, deep to the mucous cells, in crescentic masses, termed the *crescents or demilunes of Gianuzzi*. They communicate with the cavity of the alveolus by small channels between adjacent mucous cells.

After secretion, the mucous cells become smaller and stain more deeply than when loaded with mucigen before secretion.

PHARYNX

The **pharynx** lies behind the nasal cavities, the mouth, and the larynx; it communicates with them, and it is continuous inferiorly with the œsophagus or gullet (Fig. 502).

It extends from the base of the skull to the level of the lower border of the

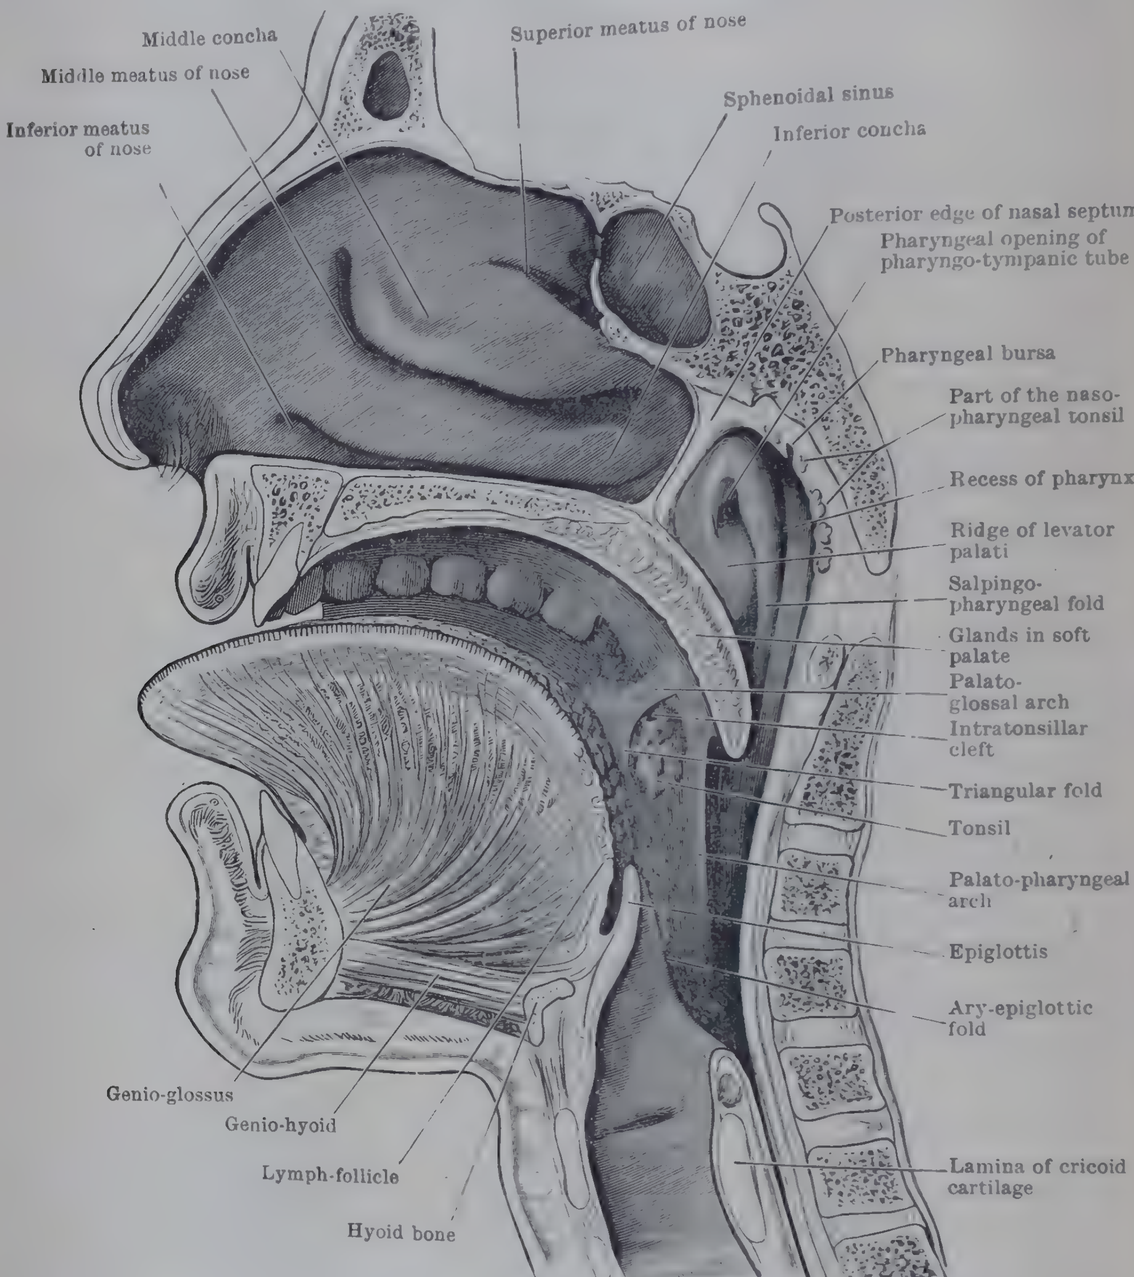

FIG. 502.—SAGITTAL SECTION THROUGH MOUTH, TONGUE, LARYNX, PHARYNX, AND NASAL CAVITY.

The section was slightly oblique, and the posterior edge of the nasal septum has been preserved. The specimen is viewed slightly from below; hence the apparently low position of the inferior concha. For the usual inferior convexity of the crowns of the maxillary molar teeth, see p. 574 and Fig. 500.

cricoid cartilage and of the sixth cervical vertebra (Fig. 502); and in length it varies from 5 to 5½ inches (12·5 to 14·0 cm.).

In the middle part of the pharynx the pathway for respired air, between the nose and the larynx, crosses that of food and drink from the mouth to the œsophagus. The inferior portion alone, below the opening of the larynx, is exclusively a part of the alimentary tract, and the portion above the level of the soft palate is used for respiration only. It is, however, convenient to study the structure and relations of the pharynx as a whole.

Structurally the pharynx is a fibro-muscular bag lined with mucous membrane,

and is of conical form—wide above and narrow below. The fibrous wall of the upper part of the pharynx is firmly attached to the base of the skull, especially around the posterior apertures of the nasal cavities, and hence in that part there is a permanent cavity which contains air. The lower portion gradually assumes a more tubular form, and the anterior and posterior walls approach each other, till, below the level of the opening of the larynx, they are in contact with each other and the cavity is reduced to a slit except during the passage of food.

Dimensions of Pharynx.—From the highest part of the roof to the upper surface of the soft palate at its junction with the hard palate, it measures about $1\frac{1}{4}$ inches, or 3 cm. The

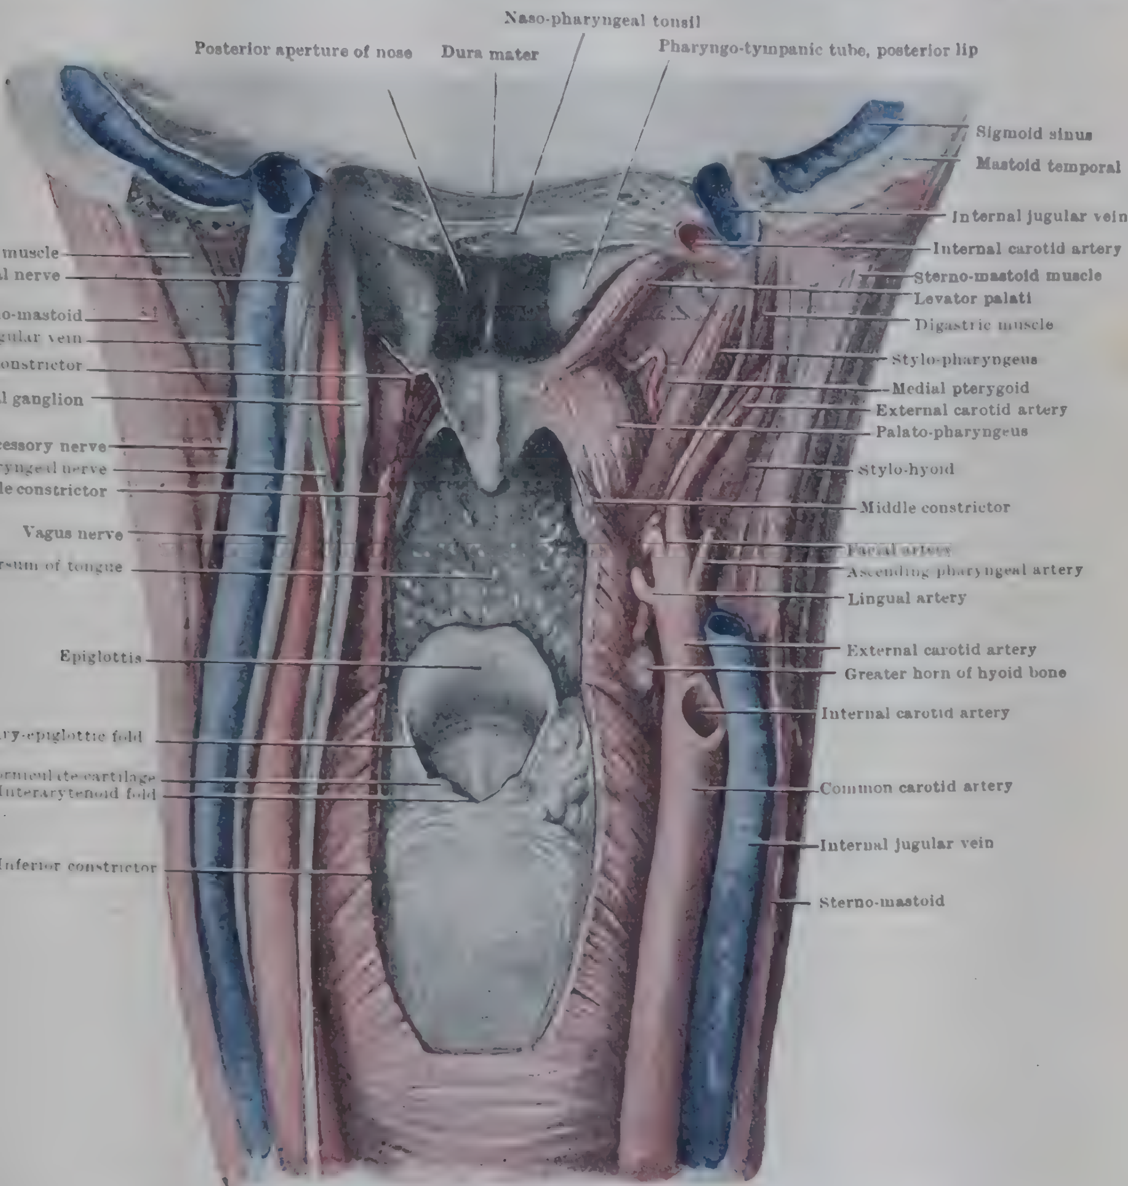

FIG. 503.—INTERIOR OF PHARYNX AND THE STRUCTURES IN RELATION TO ITS SIDE-WALLS, VIEWED FROM BEHIND.

vertical extent of the oral part of the pharynx is about $2\frac{1}{4}$ inches, or 6 cm., and that of the laryngeal part is about $2\frac{3}{4}$ inches, or 7 cm.

The lower end of the pharynx is usually about $5\frac{1}{2}$ to $6\frac{1}{2}$ inches (14 to 16·5 cm.) from the margins of the incisor teeth, in a curved line passing through the cavities of the mouth and oral and laryngeal parts of the pharynx.

The other diameters are as follows:—The antero-posterior diameter of the nasal part, from the lower part of the septum of the nose is 15 to 18 mm., and that of the oral part, from the palato-glossal arches to the posterior wall, is about 10 mm. (two-fifths of an inch).

The **cavity of the pharynx** is incompletely divided into an upper **nasal part** and a lower part (Fig. 502). The lower part is further divided into the **oral part** behind the mouth and tongue, and the **laryngeal part** behind the larynx.

The aperture between the margin of the soft palate and the posterior wall of the pharynx, by which the nasal part of the pharynx communicates with the lower portion of the cavity, is called the **pharyngeal isthmus**.

The pharynx presents *seven openings* by which it communicates with neighbouring cavities (Fig. 502). They are the two **posterior apertures of the nose** on the anterior wall of the nasal part, and the **pharyngeal opening of the pharyngo-tympanic tube** on each of its side-walls; the **oro-pharyngeal isthmus**, which leads into the mouth from the oral part; the **inlet of the larynx** on the anterior wall of the laryngeal part of the cavity; and the **opening of the œsophagus** at its lower end.

Nasal Part (Figs. 502 and 504).—The nasal part is a portion of the true pharynx, but it is functionally part of the respiratory tract. It differs from the rest of the pharynx in that its cavity is, under all conditions, an open

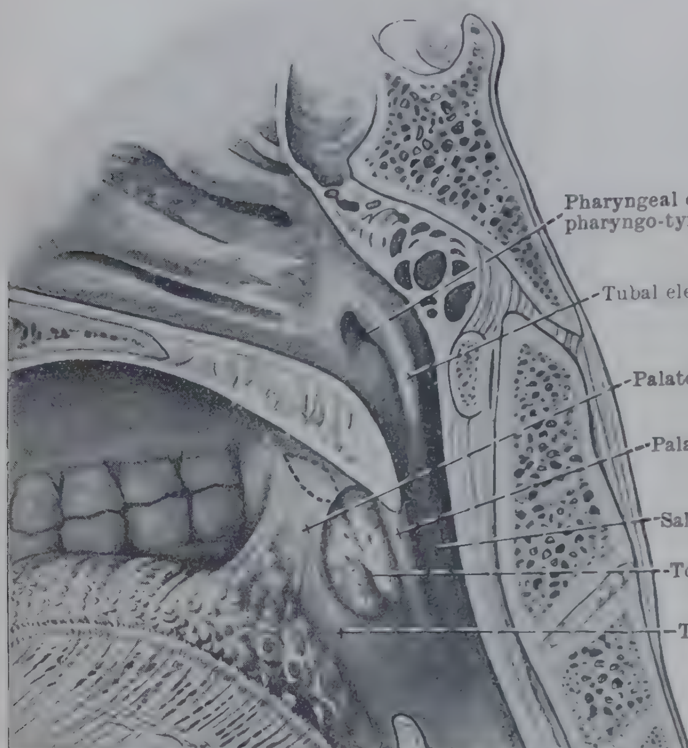

Fig. 504.—Median Section of Pharynx to show the Right Tonsil.
The tonsil is large and divided below by an oblique cleft. The orifice of the intratonsillar cleft is near its upper pole, and the extent of the cleft in this specimen is indicated by a dotted line.

chamber incapable of obliteration, since all its walls, with the single exception of the floor, are immovable.

The cavity of the nasal part is irregular in shape and is enclosed by *six walls*—namely, anterior and posterior, right and left, a floor and a roof or vault.

The *anterior wall* slopes upwards and backwards, and it is a "wall" only in name, for it is represented almost entirely by a pair of large openings—the **posterior apertures of the nose**—separated from each other by the nasal septum.

The *posterior wall* is nearly vertical; it corresponds in extent to the basilar part of the occipital bone, the anterior arch of the atlas, and the body of the axis vertebra.

The *roof* lies under the posterior part of the body of the sphenoid and the basilar part of the occipital bone, and it slopes downwards and backwards to join the posterior wall.

Each *lateral wall* is occupied by the pharyngeal opening of the pharyngo-tympanic tube and the tubal elevation, and, posterior to them, by a vertical depression that leads into a slit-like space called the **pharyngeal recess**. The *floor* is the soft palate.

In the posterior part of the roof and upper part of the posterior wall there is a considerable accumulation of lymphoid tissue, known as the **naso-pharyngeal tonsil**, which is distinct in the child but becomes indistinct, or entirely disappears, in adult life. It is related to that part of the roof which is formed by the body of the sphenoid and the basilar part of the occipital bone (Fig. 502). The mucous membrane which covers it is thickened and thrown into transverse folds.

A similar collection of lymphoid tissue—a lateral prolongation of the naso-pharyngeal tonsil—behind the mouth of the pharyngo-tympanic tube is known as the "*tubal tonsil*".

In the inferior part of the naso-pharyngeal tonsil, there is, constantly in the child and occasionally in the adult, a small median recess, termed the **pharyngeal bursa**, which runs upwards and backwards in the wall of the pharynx for some distance (Fig. 502).

Enlargement of the lymphoid tissue in the nasal part of the pharynx occurs frequently in children, and the swollen lymph-nodules are known as *adenoids*. The enlargement may be so considerable that it extends downwards in front of the upper two cervical vertebræ and bulges

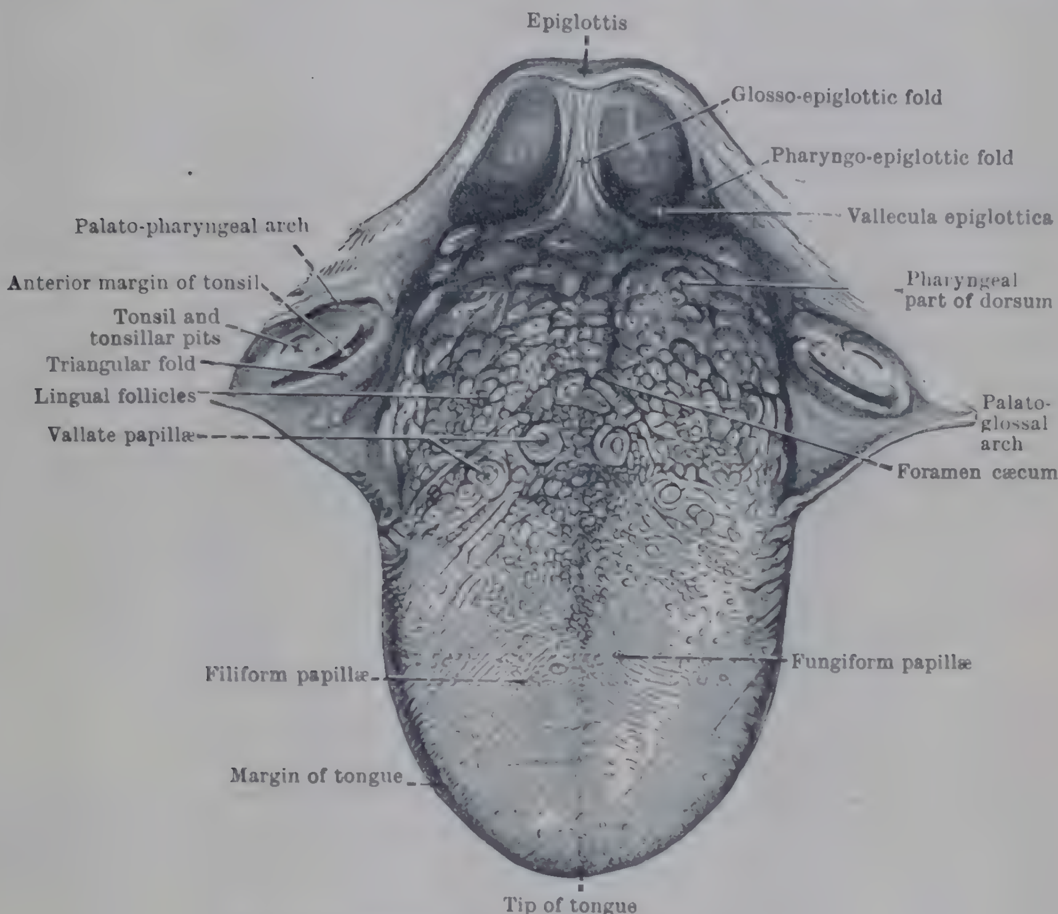

FIG. 505.—DORSUM OF TONGUE AND THE TONSILS.

forwards till it fills up a great part of the cavity of the nasal part of the pharynx. In the operation for adenoids, a prominent anterior tubercle of the atlas sometimes interferes with the manipulation of the curette.

The **pharyngeal opening of the pharyngo-tympanic tube**, oval or triangular, and funnel-like in appearance (Fig. 502), is situated on the side-wall of the nasal part a short distance (about $\frac{1}{3}$ to $\frac{1}{2}$ inch) behind the posterior end of the inferior concha, and immediately above the level of the hard palate (Figs. 502 and 504). It is bounded superiorly and posteriorly by a prominent rounded ridge—the **tubal elevation** (torus tubarius)—formed by the cartilage of the tube. The prominence of the posterior margin, as contrasted with the anterior margin of the orifice, and the direction of the tube itself, which runs backwards and laterally (from the pharynx to the tympanum), greatly facilitate the introduction of a Eustachian (tubal) catheter. The **recess of the pharynx**—a narrow and nearly vertical recess of considerable depth (Fig. 502)—lies immediately behind the tubal elevation. It extends laterally over the upper margin of the superior constrictor, below the petrous portion of the temporal bone (Fig. 376, p. 440).

A slight ridge of the mucous membrane, called the **salpingo-pharyngeal fold**, descends from the lower end of the tubal elevation on the side-wall of the pharynx. Another and less obvious ridge passes from the anterior border of the opening downwards and forwards to join the palate. In front of the latter there is an indistinct groove which indicates the division of the nasal cavity from the nasal part of the pharynx.

The levator palati runs parallel to the tube, and along its lower border. As it enters the palate, it produces, particularly when contracted, an elevation, immediately below the pharyngeal orifice of the tube (Fig. 502), which forms the base of that opening when it assumes its usual triangular shape.

Oral Part.—The oral part of the pharynx lies behind the mouth, between the soft palate above and the inlet of the larynx below. Its *posterior* boundary is the posterior wall of the pharynx, and has no distinguishing feature. *Anteriorly* it communicates with the mouth through the oro-pharyngeal isthmus, and, below that, it is bounded by the pharyngeal surface of the tongue. Each *side-wall* is a triangular area named the **tonsillar sinus** because it is occupied by the tonsil. The sinus is bounded anteriorly by the palato-glossal arch (p. 566), and posteriorly by the palato-pharyngeal arch.

The **palato-pharyngeal arch** is a fold of mucous membrane which contains the palato-pharyngeus muscle. It springs from the posterior edge of the soft palate, passes downwards and slightly backwards, and ends inferiorly on the side-wall of the pharynx (Fig. 502).

From the posterior surface of the palato-glossal arch a thin ***triangular fold***

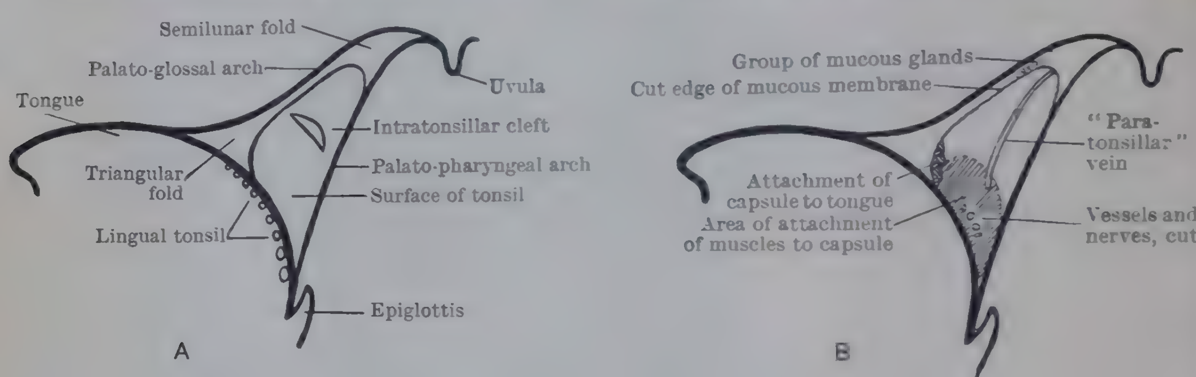

FIG. 506.—DIAGRAMS OF SURROUNDINGS OF TONSIL (Browne, 1929).
A. Tonsil *in situ*; B. After its Removal.

of mucous membrane passes backwards. Its base corresponds to the palato-glossal arch; its superior border passes downwards and backwards, and is free—frequently overlapping the tonsil. Its lower border is attached to the side of the tongue. It covers, medially, the inferior part of the tonsillar sinus.

The **tonsils** are a pair of oval masses of lymphoid tissue which lie one in each tonsillar sinus. The tonsil presents very different forms in different subjects. It may bulge from the sinus into the cavity of the pharynx, or it may be flat and limited to the tonsillar sinus. In some cases the triangular fold is fused with the free surface of the tonsil, and lymphoid tissue may be developed on the medial surface of that fold. It is oval in shape, with the long axis directed vertically; and it has a medial and a lateral surface, a superior and inferior pole, and an anterior and posterior margin. Its size is extremely variable, but as a rule, in early life, it measures a little under 1 inch (20 to 22 mm.) from above downwards, about ¾ inch (18 to 20 mm.) antero-posteriorly, and ½ inch (12 to 15 mm.) medio-laterally.

The medial surface is free, is covered with epithelium and is studded with deep, narrow crypts called the **tonsillar pits** (Fig. 507). On this surface there is a narrow *intratonsillar cleft* which penetrates the substance of the tonsil and extends upwards to the soft palate, into which it may penetrate for as much as a centimetre. The lateral, attached surface is covered by a distinct fibrous sheath which separates the tonsil from the palato-pharyngeus muscle and the superior constrictor muscle of the pharynx. At the lower part of this surface the tonsillar artery enters the tonsil and the veins leave it. The inferior pole projects downwards towards the tongue. The superior pole, rounded and blunt, presents numerous pits.

Structure of Tonsil.—The substance of the tonsil is permeated by the tonsillar pits, each lined with stratified squamous epithelium, external to which there is a layer of lymphoid

tissue 2 to 3 mm. in thickness. In this layer there are rounded germinal centres or nodules, connected together by looser tissue. The lumen of the pits is frequently filled with a cheesy material composed of epithelial cells, of lymphoid cells which have migrated through the epithelial lining, and of organisms. Each tonsillar pit with its wall forms a follicle, and the follicles are connected by loose areolar tissue.

Relations of Tonsil.—The lateral relations of the tonsil are the fibrous sheath, the palato-pharyngeus and the superior constrictor muscle. Lateral to the pharyngeal wall lies the medial pterygoid muscle, and, behind it, a region filled with areolar tissue which contains blood-vessels and nerves. Between the sheath and the muscles one or two veins ("paratonsillar") descend from the soft palate (Browne, 1929).

The sheath of the tonsil is connected by a fibrous band to the base of the tongue, and

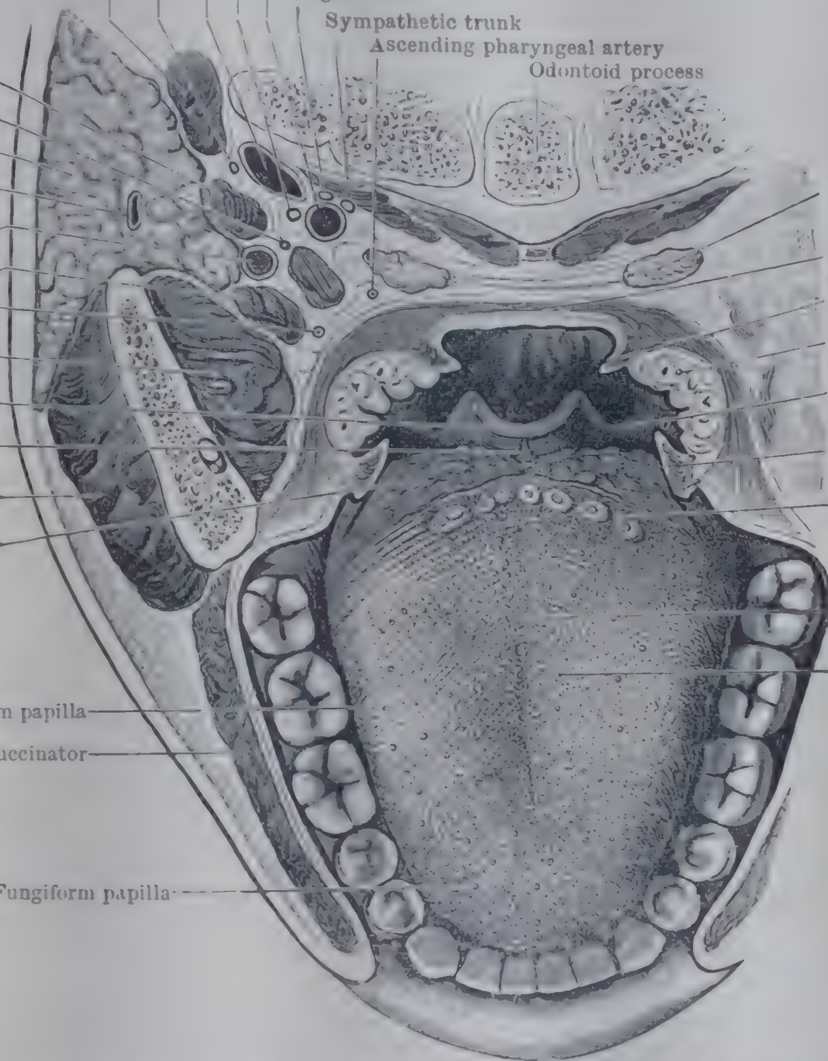

FIG. 507.—HORIZONTAL SECTION THROUGH MOUTH AND PHARYNX AT THE LEVEL OF THE TONSILS.

The prevertebral muscles and the stylo-pharyngeus (which is shown immediately to the medial side of the external carotid artery) are not indicated by reference lines.

decussating fibres of the palato-glossus and palato-pharyngeus muscles run into the lower third of the sheath.

The nearest and most important artery is the facial artery, which, especially if tortuous, has a very close relation to the pharyngeal wall at that level. The ascending palatine and tonsillar branches of the facial artery also are in close relation.

Vessels and Nerves.—The **artery** of the tonsil is the *tonsillar branch of the facial artery*, which enters the lower part of the lateral surface close to the tongue; other arteries from the ascending pharyngeal branch of the external carotid, and the dorsales linguæ of the lingual ramify in the surrounding tissues. The **veins** emerge from the lateral surface as two branches which pierce the superior constrictor muscle and terminate in the *common facial vein*, and connect with the pharyngeal plexus also. The **nerves** are a special branch from the glosso-pharyngeal and branches from the pharyngeal plexus; they unite to form a small *tonsillar plexus* which supplies the organ.

The **lymph-vessels** are numerous. They begin in a plexus which surrounds each follicle, whence vessels pass to the lateral surface of the tonsil; there, they pierce the wall of the

pharynx, and pass to *deep cervical glands* in the neighbourhood of the greater horn of the hyoid bone, behind and below the angle of the mandible.

Laryngeal Part.—The laryngeal part of the pharyngeal cavity is behind the larynx (Fig. 503). It is wide above, but at the level of the cricoid cartilage it narrows rapidly as it passes down to join the œsophagus.

Its *anterior wall* is formed throughout by the larynx, of which the following parts are seen from the pharyngeal cavity:—Above, the epiglottis; below that, the inlet of the larynx bounded at the sides by the ary-epiglottic folds; lateral to each of these folds, there is a deep recess called the **piriform fossa** (Fig. 583, p. 692); lower down still, the mucous membrane which covers the posterior surfaces of the arytenoid and cricoid cartilages.

Relations of Pharynx.—The pharynx as a whole lies anterior to the cervical region of the vertebral column, and is separated from the bodies of the vertebræ and the intervertebral discs by the loose areolar tissue of the retro-pharyngeal space, posterior to which lie the longus capitis and longus cervicis muscles and the anterior longitudinal ligament of the vertebral column.

The lateral relations of the nasal and oral parts on the one hand, and of the laryngeal part on the other hand, are very different.

The laryngeal part, lying in the neck, is in contact on each side with the superior part of the thyroid gland, the carotid sheath, and especially the common and external carotid arteries, and, more posteriorly, the internal carotid artery. The branches that arise from the lower part of the external carotid also are in close lateral relation to it, viz., the superior thyroid and lingual arteries.

The relations of the oral and nasal parts are more complex. Reference to Fig. 507 will help to elucidate them. On each side lies the medial pterygoid muscle. As the medial pterygoid passes backwards and downwards to its insertion, it diverges from the pharynx and a triangular space is left between it and the wall of the pharynx. The styloid process, and the muscles which arise from it, project downwards into that space, and lying beside them are numerous vessels and some nerves. Thus, the stylo-glossus and stylo-pharyngeus come into contact with the side-wall, and the glosso-pharyngeal nerve accompanies the stylo-pharyngeus. The ascending pharyngeal artery runs upwards by the side of the pharyngeal wall. The facial artery, as it passes under the digastric and stylo-hyoid muscles, comes into contact with the superior constrictor muscle; and the ascending palatine and tonsillar branches of the facial artery also ascend in close relation to the pharyngeal wall. The pharyngeal plexus of nerves and also a plexus of veins lie in contact with the side-wall. The internal carotid artery lies a little farther back, with the vagus, accessory, and hypoglossal nerves. In this region the external carotid lies more superficially and is separated by a considerable interval from the pharyngeal wall.

Structure of Pharyngeal Wall.—The fibrous wall of the pharynx is firmly fixed above to the base of the skull, but it is not otherwise attached except to the hyoid bone and the skeleton of the larynx.

The wall is composed of a strong fibrous membrane, called the **pharyngo-basilar fascia**, lined internally with mucous membrane, and covered incompletely on its outer surface by a series of three overlapping muscles—the constrictor muscles of the pharynx. These muscles are covered externally with a thin layer of fascia which passes forwards, at its superior part, on to the surface of the buccinator muscle, and is called the **bucco-pharyngeal fascia**.

With the wall of the pharynx are associated several accessory muscles, viz., the muscles of the soft palate, and also the stylo-pharyngeus muscle, which blends with the wall but is also attached to the larynx (see p. 441).[1]

The pharyngo-basilar fascia is attached to the skull as follows:—

Above, it blends with the periosteum of the basilar part of the occipital bone in front of the pharyngeal tubercle, and on each side it extends to the spine of the sphenoid and the inferior surface of the temporal bone in front of the lower end of the carotid canal, and lateral to the opening of the pharyngo-tympanic tube.

On each side it is attached to the medial pterygoid plate, the pterygo-mandibular ligament, and the mylo-hyoid ridge; and it is eventually lost on the side of the tongue.

[*Facing p.* 592

PLATE L

PLATE L.—OBLIQUE LATERAL RADIOGRAPH OF THORAX OF YOUTH AGED 18, DURING THE PASSAGE OF "BARIUM-PASTE" THROUGH THE ŒSOPHAGUS.

For the relation of the Œsophagus to the Vertebral Column and the back of the Pericardium, see Fig. 509, D and E, p. 594; and note that the "post-cardiac space" is part of the posterior mediastinum occupied mainly by the Œsophagus and the Descending Aorta.

The pharyngo-basilar fascia is particularly strong in the superior part, where there is an area on each side which is not covered by the superior constrictor muscle; and there the tensor and levator palati muscles pass through the wall.

The pharyngo-basilar fascia, which is thick above and thin below, and the bucco-pharyngeal fascia, which is thin above and stouter below, are practically blended into one layer above, near the base of the skull, where the muscular coat is absent. Lower down they are separated by the constrictors, and become two distinct sheets. They are strengthened in the median plane posteriorly by a fibrous band which descends from the pharyngeal tubercle.

The **mucous membrane** of the oral and laryngeal parts of the pharynx is covered with stratified squamous epithelium, and that of the nasal part with ciliated epithelium, the difference in structure being an expression of a difference in function. In the roof of the nasal part of the pharynx there are large masses of lymphoid tissue which constitute the naso-pharyngeal tonsil, and on each side of the oral part lies *the* tonsil. Similar tissue is found in considerable amount in the pharyngeal recess and on the pharyngeal portion of the dorsum of the tongue.

There are also numerous racemose glands, of the mucous type, in the walls of the nasal part, in the soft palate, and in the ary-epiglottic folds.

For the details of the attachments and relations of the **pharyngeal muscles**, see p. 440.

Vessels and Nerves of Pharynx.—The **arteries** of the pharynx are derived from: 1, the *ascending pharyngeal*; 2, the *ascending palatine* branch of the facial; 3, the *greater palatine* from the maxillary, with a few twigs from the dorsales linguæ, tonsillar (of facial), the artery of the pterygoid canal, and the pharyngeal branch of the maxillary. The **veins** go to the *pharyngeal venous plexus*. The plexus communicates with the pterygoid plexus above, and with the internal jugular or common facial vein below.

The **lymph-vessels** of the pharynx pass chiefly to the *upper deep cervical glands*.

The **nerves** of the pharynx, both motor and sensory, are derived chiefly from the *pharyngeal plexus*, which is formed by branches of the vagus, glosso-pharyngeal, and sympathetic. The soft palate and the neighbourhood of the tonsil are supplied by the *palatine branches of the spheno-palatine ganglion*. The tonsil receives a branch from the glosso-pharyngeal direct. The vault of the pharynx, and the region around the opening of the pharyngo-tympanic tube, as well as the opening itself, are supplied by branches from the spheno-palatine ganglion. Finally, the *internal laryngeal nerve* supplies the mucous membrane of the back of the larynx.

Movements of Pharynx.—Three different sets of movements of the pharynx or of its parts may be recognized: (1) closure of the pharyngeal isthmus, or separation of the oral part from the nasal part; (2) closure of the oro-pharyngeal isthmus or separation of the mouth and pharynx; and (3) movements in swallowing.

(1) This is effected by raising the posterior part of the soft palate so that its dorsal surface comes into contact with the mucous membrane on the dorsal wall of the pharynx. At the same time a muscular band—*palato-pharyngeal sphincter* (Whillis, 1930), which passes from the inner aspect of the upper part of the superior constrictor to the palatal aponeurosis, raises a constricting elevation on the pharyngeal wall known to surgeons as Passavant's ridge (p. 445). In the movement of raising the soft palate the levator and tensor palati co-operate with one another.

(2) Closure of the oro-pharyngeal isthmus is effected by elevation of the posterior part of the dorsum of the tongue against the soft palate, slight lowering of the palate, and by movement inwards of the palato-glossal folds. The muscles which bring about these various movements are the palato-glossus, the stylo-glossus, and the intrinsic muscles of the tongue.

(3) The middle and inferior constrictor muscles participate in the final part of swallowing, passing the bolus of food onwards into the œsophagus. (See also pp. 445 and 700.)

Radiographic Examination of Pharynx.—The form of the cavity of the pharynx during life can be shown by X-ray examination. The post-cricoid portion of the laryngeal part of the pharynx appears closed in radiographs taken under ordinary conditions (Pl. LXI, p. 696).

ŒSOPHAGUS

The **œsophagus** or **gullet** is, with the exception of the pylorus, the narrowest, and at the same time one of the most muscular parts of the whole alimentary tube.

It extends from the termination of the pharynx, at the lower border of the cricoid cartilage and opposite the sixth cervical vertebra, to the cardiac orifice of

the stomach opposite the tenth thoracic vertebra. Between those two points it traverses the lower part of the neck, the whole length of the thorax, and, having pierced the diaphragm, it enters the abdomen and immediately afterwards joins the stomach. In its course it does not adhere to the median plane of the body but leaves it twice by curving to the left.

In the lower part of the neck and the

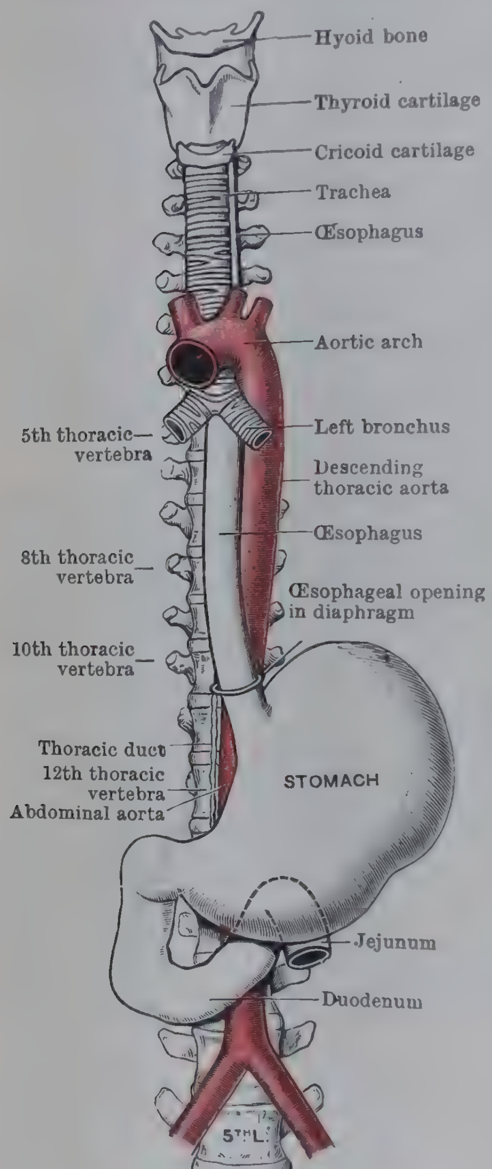

Fig. 508.—Diagram to show Course of Œsophagus in relation to Vertebral Column, Trachea, and Aorta

upper part of the thorax, the œsophagus projects to the left beyond the margin of the trachea to the extent of $\frac{1}{6}$ or $\frac{1}{4}$ inch (4 to 6 mm.). It returns to the median plane at the level of the fourth thoracic vertebra. Lower down, behind the pericardium, at the level of the seventh thoracic vertebra, it again passes to the left, and also forwards, in order to reach the œsophageal opening in the diaphragm, and it

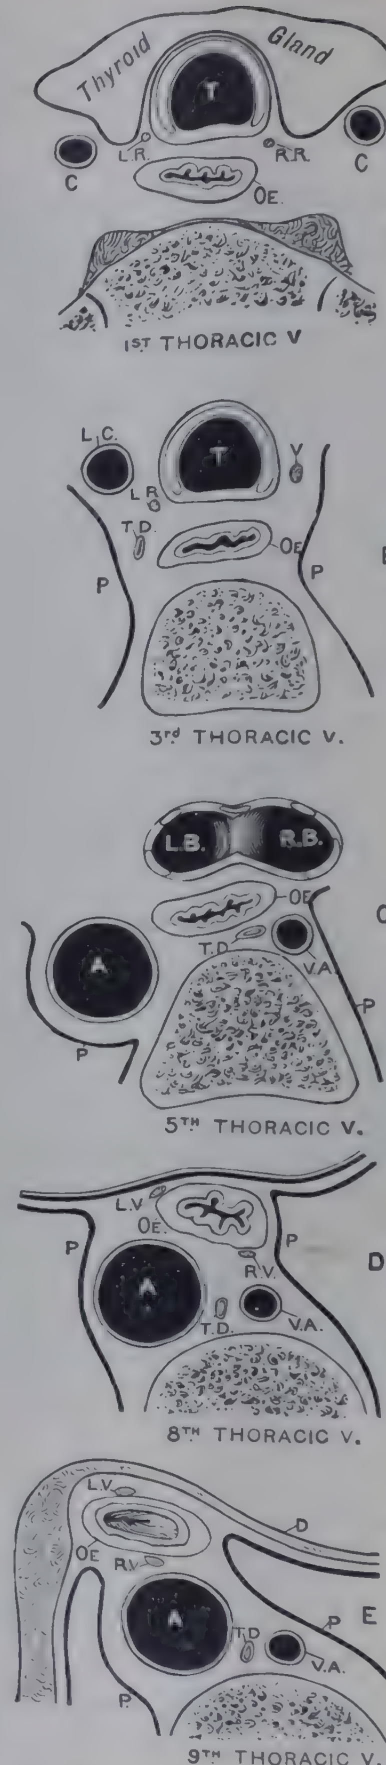

Fig. A is at the level of the superior part of the 1st thoracic vertebra, and shows the chief relations of the œsophagus in the neck and also its divergence to the left.

Fig. B, at the 3rd thoracic vertebra, shows the thoracic duct lying on the left side of the œsophagus. V, Right vagus nerve.

In Fig. C, at the level of the 5th thoracic vertebra, the left bronchus is seen in relation to the anterior surface of the œsophagus.

Fig. D is at the level of the 8th thoracic vertebra, and shows the œsophagus passing behind the pericardium.

Fig. E, at the 9th thoracic vertebra, shows the œsophagus inclining to the left just before piercing the diaphragm.

Fig. 509.—Tracings from Frozen Sections to show Relations of Œsophagus at the levels of the 1st, 3rd, 5th, 8th, and 9th thoracic vertebræ. See also Fig. 593, p. 701.

A., Aorta; C., Common carotid artery; D., Diaphragm; L.B., Left bronchus; L.C., Left subclavian artery; L.R., Left recurrent laryngeal nerve; L.V., Left vagus; OE., Œsophagus; P., Pleura; Pc., Pericardium; R.B., Right bronchus; R.R., Right recurrent laryngeal nerve; R.V., Right vagus; T., Trachea; T.D., Thoracic duct; V.A., Vena azygos.

maintains this direction until the stomach is reached. It passes on to the front of the descending aorta at the level of the eighth thoracic vertebra, and traverses the diaphragm at the level of the tenth.

In addition to the curvatures just described, it is also curved in the antero-posterior direction in correspondence with the form of the vertebral column.

In cross-sections (Fig. 509) the œsophagus appears either as a flattened tube with a transverse, slit-like cavity, or as an oval or rounded canal with a stellate lumen. The former condition is more common in the neck owing to the pressure of the trachea, and the latter in the thorax. When exposed in the ordinary post-mortem examination soon after death, it has rather the appearance of a solid muscular rod or band than of a hollow tube.

The œsophagus presents three distinct *constrictions*—one situated at its beginning, another at the point where it is crossed by the left bronchus, and the third where it passes through the diaphragm. The upper two constrictions are of the same size, and will admit without injury an instrument with a maximum diameter of $\frac{4}{5}$ inch (20 mm.). At each of those points the tube is flattened from before backwards.

In *length* it usually measures from 10 inches to 12 inches (25-30 cm.).

Its *breadth*, where the tube is widest, varies between half an inch (13 mm.) in the empty contracted condition and 1 inch or more (25 to 30 mm.) in the fully distended state.

The distance from the upper incisors to the beginning of the œsophagus averages about 6 inches (15 cm.), to the level of the left bronchus 9 inches, to the opening of the diaphragm 14 to 15 inches, and to the cardiac orifice of the stomach, 16 inches.

Relations of Œsophagus.—The relations (Fig. 509) differ so widely in different regions that they must be described separately for each of them. Three parts may be described—*cervical, thoracic,* and *abdominal.*

Cervical Part.—Anteriorly lies the trachea—to the posterior wall of which the œsophagus is loosely connected by areolar tissue—and in the groove at each side, between the trachea and œsophagus, the recurrent laryngeal nerve ascends to the larynx (Fig. 509, A). Posteriorly lie the vertebral column and the longus cervicis muscles and the prevertebral layer of the cervical fascia. On each side lies the carotid sheath with its contents, a lobe of the thyroid gland and the inferior thyroid artery. Owing to the deviation of the tube to the left in the inferior part of the neck, it lies nearer to the carotid sheath and thyroid gland on the left side than on the right.

Thoracic Part.—The œsophagus passes successively through the superior and posterior mediastina, in the former lying close to the vertebral column, but in the latter advancing into the thoracic cavity and coming into contact with the back of the pericardium. The trachea lies anterior to it as far as the fifth thoracic vertebra, where the trachea bifurcates. Immediately below that level the œsophagus is crossed by the left bronchus (Fig. 509, C), and in the rest of its thoracic course it lies in close relation to the back of the pericardium. Posteriorly, in the upper part of the thorax, it rests on the longus cervicis muscles and the vertebral column; but below the bifurcation of the trachea, it is soon separated from the vertebral column by the vena azygos, the thoracic duct, the upper five posterior intercostal arteries of the right side, and in its lower part by the descending thoracic aorta also.

On its *left side*, in the upper part of the thorax, lie the left pleura and the left subclavian artery, with the thoracic duct posterior to the artery; in the middle region, the aorta, and lower down the left pleura again, for a little way, before the œsophagus pierces the diaphragm. On the *right side* lies the arch of the vena azygos, whilst the right pleura clothes it both below and above that level.

The two vagus nerves, after forming the posterior pulmonary plexuses, descend to the œsophagus, where they form, with each other and with branches of the sympathetic, the **œsophageal plexus.** From this plexus two nerves pass downwards, one on the front and one on the back of the œsophagus, through the opening in the diaphragm. Each of these nerves contains fibres from both vagi, and they are termed the **anterior** and **posterior gastric nerves.**

The terminal part of the thoracic part of the œsophagus, about half an inch in length (1 to 1·5 cm.), passes through the œsophageal opening of the diaphragm and is connected by a considerable amount of strong fibrous tissue to the boundaries of the opening. Above and in front, it is bounded either by the posterior edge of the central tendon or by a few decussating fibres of the muscular portion of the diaphragm. At the sides and behind, decussating bands from the right crus embrace the œsophagus, turn a flat surface (not an edge) towards the opening, and thus, behind and at the sides, the œsophagus is in contact with the diaphragm for a distance of 1 to 1·5 cm.

Immediately above the level at which the œsophagus passes through the diaphragm, there is a fusiform expansion of the tube, of variable length and girth. This dilated portion lies in the lowest part of the posterior mediastinum, where

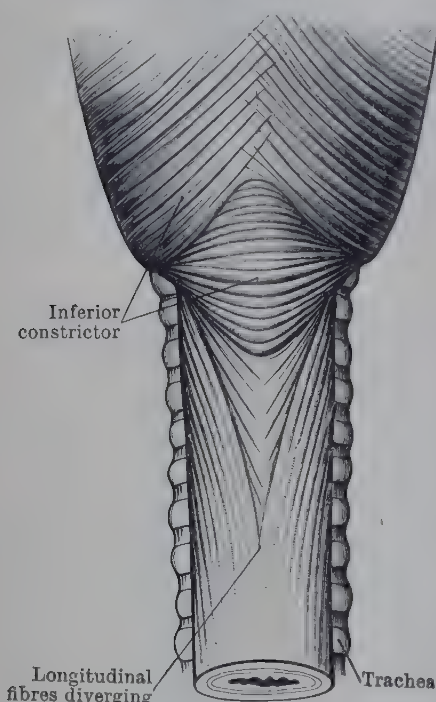

FIG. 510.—ARRANGEMENT OF MUSCULAR FIBRES ON BACK OF ŒSOPHAGUS AND PHARYNX. Traced upwards, the longitudinal muscular fibres of the œsophagus are seen to separate; passing round to the sides, they form two longitudinal bands which meet in front and are united to the cricoid cartilage, as shown in the next figure. Cf. Fig. 376, p. 440.

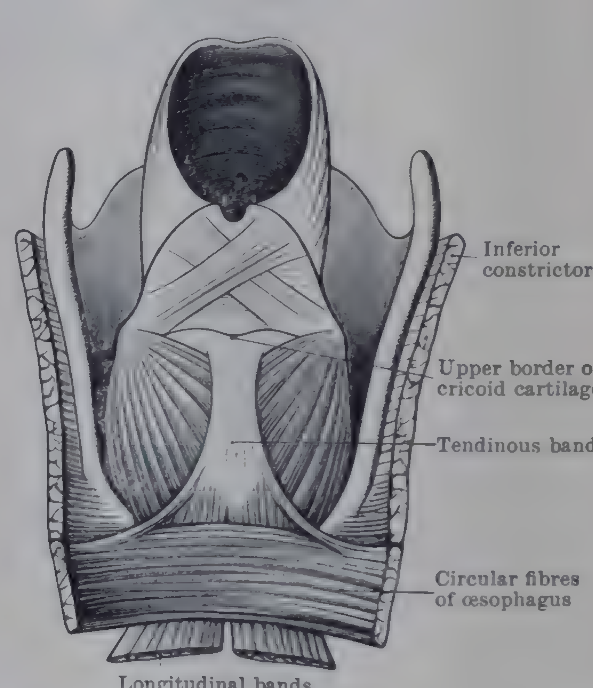

FIG. 511.—RELATION OF MUSCULAR COAT OF ŒSOPHAGUS TO CRICOID CARTILAGE AND PHARYNX. The pharynx and œsophagus have been slit up from behind, and the mucous membrane removed to show the muscular fibres. The two longitudinal bands are seen passing round to the front to be attached by a common tendon to the upper border of the cricoid cartilage. The circular fibres are continuous with the inferior constrictor.

the anterior wall is formed by the sloping posterior part of the diaphragm. Should the œsophagus be obstructed at its passage through the diaphragm, this portion may undergo great distension, and swallowed food may be retained in it and not pass on into the stomach.

Abdominal Part.—This part of the œsophagus is very short and funnel-shaped, widening as it approaches the stomach, and it almost disappears by merging into the stomach wall when the stomach is distended. It lies against the œsophageal groove of the liver in front, with the anterior and posterior gastric nerves on its surfaces.

Relation of Aorta to Œsophagus.—The arch of the aorta, passing back to reach the vertebral column, crosses the left side of the œsophagus; consequently the descending thoracic aorta lies at first to its left; lower down, however, as the aorta passes on to the front of the vertebral column, and the gullet inclines forwards and to the left, the aorta comes to lie posteriorly; and then, as the diaphragm is approached, it lies not only posteriorly, but also slightly to the right of the œsophagus (Figs. 508 and 509).

Relation of Thoracic Duct to Œsophagus.—The thoracic duct, lying to the right of the aorta below, is not directly related to the œsophagus (Fig. 509, E); but higher up (Fig. 509, D and C) it lies posterior to it. About the level of the aortic arch the duct passes to the left, and above that level (Fig. 509, B) it is found on the left side of the œsophagus.

Relation of Pleural Sacs to Œsophagus.—Above the level of the arches of the aorta and of the vena azygos, the pleuræ, though not lying in immediate contact with the œsophagus, are separated from it only by a little areolar tissue, and on the left side also, behind the subclavian artery, by the thoracic duct (Fig. 509, B). There, in thin bodies, the left pleura is very close to the œsophagus, and the thoracic duct may occasionally be seen through the pleural membrane. Below the arch of the azygos vein the right pleura clothes the right side of the œsophagus—and very often even a considerable portion of its posterior surface too, thus forming a deep recess behind it—almost as low down as the opening in the diaphragm. On the left side, below the level of the aortic arch, the left pleura comes in contact with the gullet for a short distance only immediately above the diaphragm (Fig. 509, E).

Variations.—The chief anomalies found in the œsophagus are: (1) Annular or tubular constrictions; (2) diverticula, of which the most interesting are situated on the posterior wall close to its junction with the pharynx; (3) doubling in part of its course; and (4) communication between the trachea and œsophagus.

Structure of Œsophagus (Fig. 512).

—The œsophageal wall is composed of three proper coats—(1) *muscular coat*, (2) *submucous coat*, and (3) *mucous coat*; in addition, it is surrounded by an outer covering of fibro-areolar tissue—(4) *adventitious coat*—by which it is loosely connected to the various structures related to it in its course. That loose covering permits of its free movement and of its increase or diminution in width, during the act of swallowing.

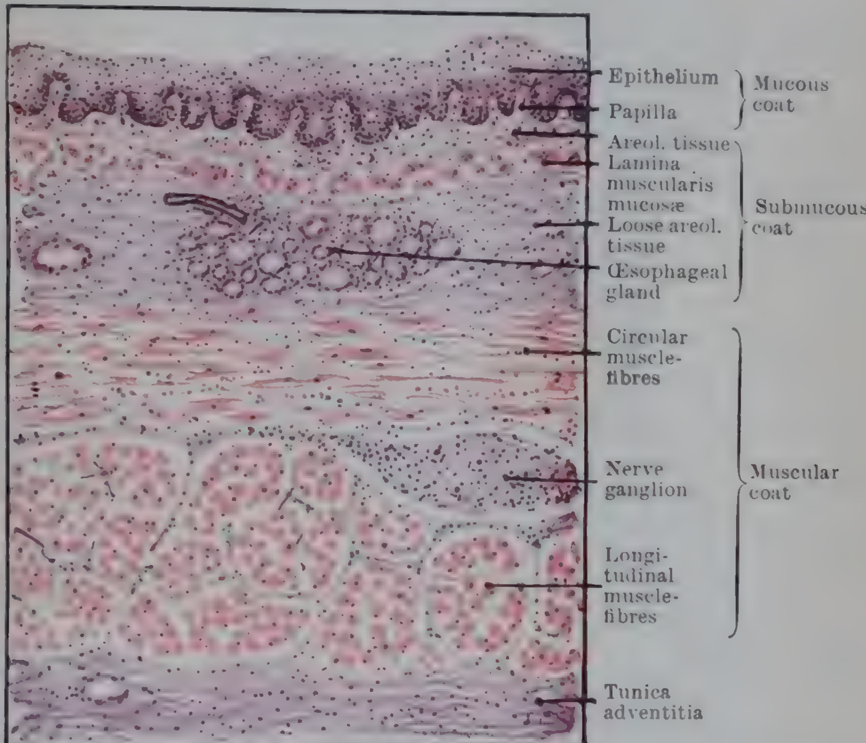

FIG. 512.—TRANSVERSE SECTION OF WALL OF HUMAN ŒSOPHAGUS.

The **muscular coat** is composed of two layers—an outer of longitudinal, and an inner of circular fibres. The *longitudinal layer* is highly developed, and, unlike the condition usually found in the digestive tube, it is as thick as the circular layer and in many places thicker. Along the greater length of the tube its fibres form an even covering and below they are continued into the longitudinal fibres of the stomach. Above, near the upper end of the œsophagus, the longitudinal fibres of each side, separating, at the back, pass round towards the anterior aspect and form two longitudinal bands (Fig. 510); these bands run up on the front of the tube, and are attached by a tendinous band to the ridge on the posterior surface of the cricoid cartilage (Fig. 511). Between these diverging muscular bands there is a thin, poorly supported area on the posterior wall where a protrusion of the mucous coat may occur and form an œsophageal diverticulum.

The *circular muscular fibres*, though not forming such a thick layer as the longitudinal fibres, are nevertheless well developed. Below, they are continued into both the circular and oblique fibres of the stomach. Above, they are continuous with the inferior constrictor of the pharynx. The above account of the fibres of the upper end of the œsophagus is based on Abel (1913).

The longitudinal fibres for about the upper fifth of the tube are entirely striated; in the second fifth striated and plain are mixed; whilst in the lower three-fifths plain fibres only are present as a rule. The circular fibres are entirely striated for the first inch; after that, plain fibres appear; and in the lower two-thirds, only plain muscle-fibres are usually found. For an account of an anomalous case, that of a male negro, with striated muscle in the lower third of the œsophagus, see Arey & Tremaine (1933).

The longitudinal fibres are often joined by slips of plain muscle or of elastic fibres which spring from various sources, including the left pleura (*m. pleuro-œsophageus*), the bronchi (*m. broncho-œsophageus*), back of trachea, pericardium, aorta, etc. (Cunningham,

1876). These slips assist in fixing the œsophagus to the surrounding structures in its passage through the thorax, and they have been aptly compared to the tendrils of a climbing plant.

The **submucous coat**, composed of areolar tissue, is of very considerable thickness in order to allow of the expansion of the tube during swallowing. It connects the mucous membrane loosely to the muscular coat and admits of the former being thrown into folds when empty. In that coat are contained the numerous racemose mucous œsophageal glands which open into the cavity of the œsophagus (Fig. 512).

The **mucous coat** is of a greyish-pink colour, much paler than that of the pharynx, and of a firm and resistant texture. It is covered with a thick, stratified squamous epithelium, on the surface of which the openings of numerous glands are found. Inferiorly, its junction with the gastric mucous membrane is indicated by a distinct, irregularly dentated or crenated line which runs transversely round the tube. In carefully preserved specimens the smooth mucous membrane of the œsophagus above that line contrasts strongly with the mamillated gastric mucous membrane below.

The mucous coat is relatively inelastic, and being but loosely connected to the muscular coat by the submucosa, it is thrown into a series of longitudinal folds when the œsophagus is empty and contracted; hence the stellate lumen often seen in sections of the gullet.

Numerous racemose mucous glands—**œsophageal glands**—large enough to be seen distinctly with the naked eye, are found in the submucous coat and are fairly evenly distributed over the whole tube. In addition to them, other glands, resembling closely those of the cardiac end of the stomach, are found in the mucous membrane of certain portions of the œsophagus. They are entirely confined to the mucous coat and do not extend beyond the lamina muscularis mucosæ. These glands are specially numerous at the ends of the tube.

Vessels and Nerves.—Its **arteries** are numerous small branches derived, in the neck from the *inferior thyroid*, in the thorax from the *bronchial arteries* and *thoracic aorta*, and in the abdomen from the *left gastric artery*, and also from the *left phrenic*.

The **veins** form a plexus on the exterior of the œsophagus from which branches pass, in the lower part of the tube, to the *left gastric vein*, and, higher up, to the *azygos* and *thyroid veins*. There is thus established on the lower part of the œsophagus a free communication between the portal and systemic veins.

The **lymph-vessels** pass to the *lower deep cervical glands* and to the *posterior mediastinal glands*, many of which, of large size, are seen around the tube in the thorax.

The **nerves** are derived from the *recurrent laryngeal* branch of the vagus, from the *cervical sympathetic*, and from the *vagus* and *sympathetic* nerves in the thorax. According to Mitchell (1938) the *sympathetic* nerve-supply of the lower part of the œsophagus and gastro-œsophageal junction comes from (a) the sympathetic trunks between the 6th and the 9th or 10th thoracic ganglia, (b) the greater and occasionally the lesser splanchnic nerves, and (c) the plexuses around the left gastric and phrenic arteries. The *parasympathetic* supply is from the characteristic œsophageal plexus formed by the right and left vagus nerves (Fig. 965, p. 1135).

Radiographic Examination of Œsophagus.—The position and the movements of the œsophagus may be demonstrated by radiographic examinations made during the passage of paste opaque to X-rays (Pl. L, p. 593).

The close relation of the œsophagus to the back of the pericardium, and the interval between the œsophagus and the vertebral column at the same level, as seen in oblique lateral radiographs, are worthy of special note.

ABDOMINAL CAVITY

The abdominal cavity is that portion of the cavity of the trunk which lies below the diaphragm. Its wall is composed in part of bones, muscles, tendons, fascia, etc., and in the cavity lie the greater part of the digestive, urinary, and genital systems of organs, as well as blood-vessels, nerves, and other structures. The greater part of the internal surface of the wall of the cavity and of the external surfaces of the viscera is clothed with a continuous smooth membrane—the peritoneum. The contained organs lie in contact with one another or with the wall, and the so-called cavity is merely a potential space between the peritoneal surfaces of adjacent viscera. When air is admitted, the viscera fall away from one another and an actual space is formed in place of the capillary interval which exists between them under normal conditions.

In the following description the term **abdomen** or **abdominal cavity** is used to indicate the region enclosed by the muscular and bony walls, and the term **peritoneal cavity** the potential space inside the peritoneal membrane.

Shape.—In median section the cavity is of a more or less oval form, with the long axis vertical. The upper end is wider than the lower. In transverse section (Fig. 518) it is almost reniform, flattened from before backwards, and is encroached upon in the median plane posteriorly by the vertebral bodies to such a degree that the front of the vertebral column lies at no great distance from the back of the anterior abdominal wall (usually 2½ to 3 inches), while on each side of the vertebral column there is a deep recess occupied by the kidneys and portions of the intestine.

The abdominal cavity is divisible into the **abdominal cavity proper** and the **pelvis**. Vertical section of the trunk shows that the **pelvis** lies below and behind the abdominal cavity, of which it forms a funnel-shaped termination.

The **inlet of the pelvis** (Figs. 251, 252, pp. 282, 283), which separates these two divisions of the cavity, is bounded behind by the base of the sacrum, on each side by the iliac and pubic parts of the arcuate line, and in front by the pubic crests and the upper border of the symphysis. In the erect position the inlet is inclined backwards at an angle of 55 to 60 degrees with the horizontal. The two portions of the abdominal cavity meet at an angle, the abdomen proper extending almost vertically upwards from it, whilst the pelvic cavity slopes backwards and slightly downwards.

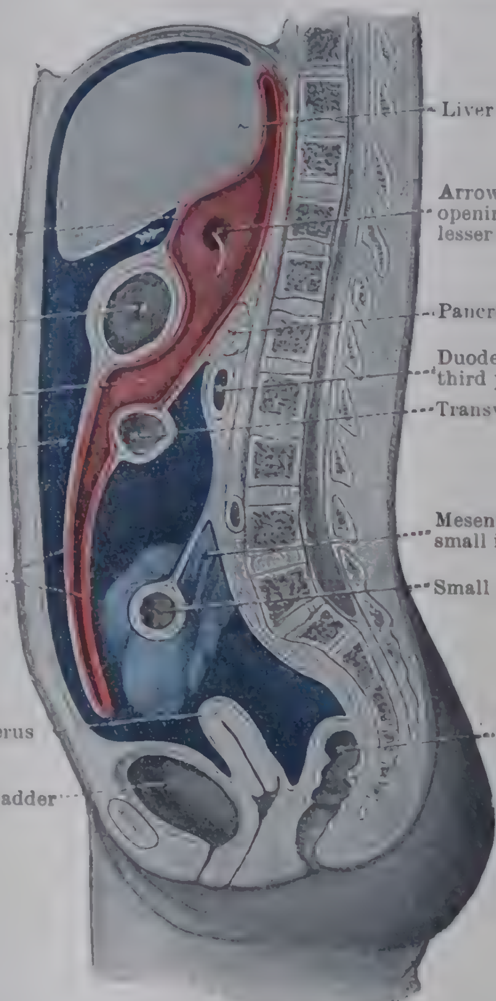

FIG. 513.—DIAGRAMMATIC MEDIAN SECTION OF FEMALE BODY TO SHOW ABDOMINO-PELVIC CAVITY AND PERITONEUM ON VERTICAL TRACING. The greater sac of peritoneum is blue and the lesser sac is red; both are represented much larger than in nature.

As the walls of the two regions are markedly different, the boundaries will be considered separately.

Boundaries of Abdomen Proper.—The **abdominal cavity proper** is limited *above* by the vault of the diaphragm, which presents a right and a left cupola separated by an intervening flatter portion which is slightly convex downwards. On the upper surface of each cupola is placed the base of the corresponding lung, whilst between them, on the flatter portion, rests the inferior surface of the heart.

During expiration the diaphragm ascends almost to the level of the right nipple and may reach the upper border of the fifth rib or even the middle of the fourth intercostal space; on the left side it is half an inch to an inch (12-25 mm.) lower; and in the median plane it is opposite the xiphi-sternal joint.

Whilst the circumference of the diaphragm is attached to the lower part of the thoracic framework anteriorly and laterally and to the lumbar vertebræ posteriorly, the central portion of the dome, formed by the central tendon, is placed high up, under cover of the ribs. As a result, the peripheral, muscular part slopes upwards and inwards from the circumference of the thoracic framework to the

central tendon and lies for a considerable distance in contact with the deep surface of the ribs; thus, the diaphragm not only comes to form the roof of the cavity but also enters into the formation of the sides, of the posterior wall, and, to a less extent, of the anterior wall; and *almost as much of the cavity of the abdomen as of the thorax lies under shelter of the ribs.*

The *anterior wall* is formed by the aponeuroses of the three pairs of wide abdominal muscles—obliquus externus, obliquus internus, and transversus abdominis—with the pairs of rectus and pyramidalis muscles alongside the median plane. Anteriorly, below the junction of abdomen and pelvis, lies the pubic symphysis. The body of the pubis looks upwards more than backwards, and supports the viscera contained within the anterior part of the abdominal cavity.

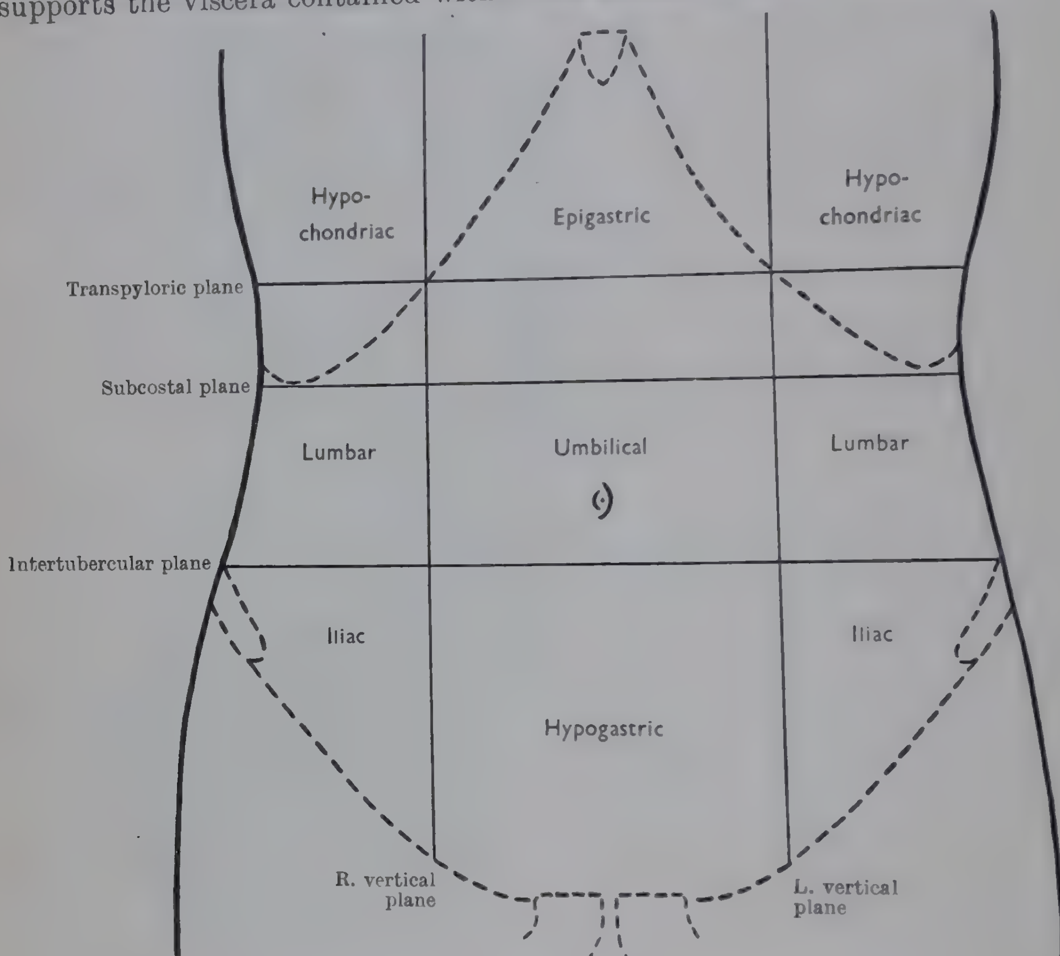

Fig. 514.—Planes of Subdivision of the Abdomen Proper, with the Names of the Nine Abdominal Regions.

The *side-walls* are formed by the muscular portions of the oblique and transverse muscles, and below by the iliac bones and the iliacus muscles.

The cavity is limited *posteriorly* by the lumbar portion of the vertebral column, with the crus of the diaphragm and psoas major muscle on each side, and the quadratus lumborum still more laterally. The iliac bones also enter into the formation of the inferior portion of the posterior wall.

The boundaries of the abdomen are formed chiefly of muscles which by contracting can alter the form and the size of the cavity. Its chief changes in form are due to the descent or elevation of the diaphragm, the contraction or relaxation of the anterior wall and the side-walls, and the raising or lowering of the pelvic floor.

The **pelvic cavity** is bounded ventrally and at each side by the portion of the hip bone below the level of the arcuate line, partly clothed by the obturator internus muscle and fascia down to the origin of the levator ani. The dorsal wall is formed by the sacrum and the coccyx in the middle, and on each side by the piriformis and coccygeus muscles covered with fascia. The floor is composed of the levatores ani. These muscles pass from the side-walls of the pelvis, down-

wards and medially towards the median plane, and present a concave superior surface towards the pelvic cavity.

The internal surfaces of the muscles immediately bounding the abdominal cavity proper and the pelvis are covered with a layer of fascia which separates them from the extraperitoneal areolar tissue and the peritoneum. That fascial layer is distinguished in different localities as: (1) the *transversalis fascia*, on the anterior wall and side-walls, lining the deep surface of the transversus abdominis muscle and continuous above with (2) the *diaphragmatic fascia* on the inferior surface of the diaphragm; (3) the *iliac fascia*, on the posterior wall, covering the psoas and iliacus muscles; and (4) the *fascia of the pelvic muscles* lining the pelvis.

Apertures.—Certain apertures are found in the muscular walls of the abdomen. They are: the three openings in the diaphragm for the passage of the inferior vena cava, the œsophagus, and the aorta; the apertures in the pelvic floor through which the rectum, the urethra, and, in the female, the vagina, reach the surface; the inguinal canal, through which the spermatic cord (or the round ligament) passes; and lastly, the femoral canal—a small passage which extends downwards from the abdomen along the medial side of the femoral vessels. The latter two, particularly, constitute weak points in the abdominal wall through which an inguinal or a femoral hernia may occur. Similar protrusions may occur at other points in the abdominal wall and also in the pelvic wall.

Extraperitoneal Tissue.—A considerable quantity of extraperitoneal areolar tissue more or less loaded with fat lies between the peritoneum and the fascia which covers the inner surfaces of the abdominal muscles. It is part of an extensive layer which lines the whole of the abdominal cavity, and may be regarded as divisible into a parietal and a visceral portion. The former lines the walls, whilst the latter passes between the layers of the peritoneal folds to the viscera. The extraperitoneal tissue contains a vascular plexus through which a communication is established between the vessels of the abdominal wall on the one hand and those of the contained viscera on the other, and also a network of nerve-fibres derived from sympathetic and cerebro-spinal nerves.

The *parietal portion* is thin and comparatively free from fat over the roof and anterior wall of the abdomen. In the pelvis the tissue is loose and fatty and is continued up for some inches on the anterior abdominal wall between the peritoneum and the transversalis fascia, and so permits of the ascent of the bladder during its distension. There also the median and lateral umbilical ligaments will be found passing up in its substance. On the posterior wall the tissue is large in amount and fatty, particularly where it surrounds the great vessels and the kidneys.

The *visceral expansions* are derived from the parietal portion in the form of prolongations around various branches of the aorta. These expansions are connected with the areolar coats of the blood-vessels and pass with them into the mesenteries and other folds of the peritoneum, and thus reach the viscera.

The chief uses of the extraperitoneal tissue are: (1) to unite the peritoneum to the fascial and muscular layers of the abdominal wall; (2) to connect the viscera to these walls and to one another in such a loose manner that their distension or relaxation may not be interfered with; (3) in addition, it is a storehouse of fat, forms sheaths for the vessels and nerves, and establishes, through its vascular plexus, communication between the parietal and visceral vessels.

Subdivision of Abdomen Proper.—Owing to the large extent of the area of the abdominal walls and the still greater size of the abdominal cavity, it is customary to subdivide the abdomen somewhat arbitrarily into nine regions. This is done by drawing two horizontal and two vertical lines on the surface, and by projecting the lines backwards as imaginary horizontal and sagittal planes in order to define various regions of the cavity. The names of these regions are given in Fig. 514, and they are of considerable practical value in locating the general position of the abdominal organs, and in describing and charting the situation of injuries, pain, tenderness and other abnormalities. (See also Fig. 1220, p. 1498.)

The planes most generally adopted and the lines at which they intersect the surface are the following :—

1. The *Subcostal Plane* (Cunningham, 1893). This corresponds to a surface line drawn round the trunk at the level of the lowest part of the costal margin seen or felt when the body is examined from the front. As a rule it passes through the most dependent parts of the tenth costal cartilages, at the level of the upper border of the third lumbar vertebra.

2. The *Transpyloric Plane* (Addison, 1899, 1900, 1901). This plane is of special practical value, and it may be used as an alternative to the subcostal plane in subdividing the abdomen. Its level is the mid-point of a line drawn, on the surface of the trunk, from the upper border of the sternum to the upper border of the pubic symphysis. This plane passes approximately midway between the xiphi-sternal junction and the umbilicus, at the level of the lower border of the first lumbar vertebra.

3. The *Intertubercular Plane* (Cunningham, 1893). This plane corresponds to a line joining the tubercles of the iliac crests, and lies at the level of the fifth lumbar vertebra. It should be noted that although the tubercle of the crest of the ilium is the most prominent lateral landmark in this region, it is not situated at the highest part of the iliac crest, which lies farther back at the level of the fourth lumbar vertebra.

4. The *Vertical Planes*. These are sagittal planes and correspond to vertical lines drawn on each side of the anterior median line midway between the anterior superior iliac spines and the median line. Each of these planes passes through the ninth costal cartilage near its tip, and through the inguinal ligament about ½ an inch (12 mm.) medial to its mid-point.

Contents of Abdomen.—The following structures are found within the abdomino-pelvic cavity :—

1. The greater part of the *alimentary canal*, viz., stomach, small intestine, and large intestine.
2. *Digestive glands:* the liver and pancreas.
3. *Ductless glands:* the spleen and the suprarenal glands.
4. *Urinary apparatus:* the kidneys, ureters, bladder, and part of urethra.
5. The internal *generative organs*, according to the sex.
6. *Blood-vessels* and *lymph-vessels* and *lymph-glands.*
7. The abdominal portions of the *cerebro-spinal* and *autonomic nervous systems.*
8. Certain *fœtal remains.*
9. The *peritoneum*—the serous membrane which lines the cavity, and is reflected over most of its contained viscera.

PERITONEUM

The **peritoneum** is the serous membrane which lines the abdominal cavity and invests most of the abdominal viscera to a greater or less degree. The cavity within this complicated serous sac is called the *peritoneal cavity.* Like other serous membranes, the peritoneum is composed of a thin layer of fibro-elastic tissue, covered with flattened endothelial cells. Like other serous sacs, also, the peritoneal cavity in the male is a completely closed sac, but in the female the *pelvic opening* of each uterine tube is a breach in it, whilst the *uterine opening* of that tube communicates with the interior of the uterus, and thus, indirectly, with the exterior of the body. Normally the membrane secretes only sufficient moisture to lubricate its surface; otherwise the sac is empty, and its opposing walls lie in contact, thus practically obliterating its cavity.

The serous lining of the abdomen permits of the movements of the contained viscera during any changes in size or form which they may undergo, and the stomach and intestines are free to move with a minimum of friction.

The peritoneum which covers an organ is termed *visceral peritoneum*; and it is united so intimately to many of the viscera that it appears at first sight to be a superficial layer of these organs rather than a separate membrane. Peritoneum which lines the walls or forms folds connected with viscera is termed *parietal peritoneum.*

In the adult the arrangement of the peritoneum is complicated by the changes which occur in the form and position of many of the viscera during their development, and it is necessary to explain briefly some of the changes which modify its original simple arrangement.

The peritoneum represents the smooth lining membrane of the abdominal part of the body-cavity or cœlom. Some of the abdominal viscera as, for example, the kidneys, lie dorsal to the membrane on the posterior body-wall, with only their ventral surfaces in contact with the lining membrane. The greater part of the intestinal tube, on the other hand, projects forwards, carrying the peritoneum with it, into the peritoneal cavity; but it remains connected with the dorsal wall by extraperitoneal tissue, containing nerves, blood-vessels and lymph-vessels. These

structures are covered on each side by a thin peritoneal membrane, continuous in front with the peritoneum which surrounds the intestine, and behind with that surrounding the peritoneal cavity.

Organs that show the first relationship are said to lie "behind" the peritoneum, or to be "partly invested" by it, while those of the second relationship are said to be "completely invested" and to have a 'mesentery' which connects them to the abdominal wall.

The intestine originally has a continuous dorsal mesentery, and, in addition, its proximal portion is connected to the ventral wall above the level of the umbilicus by a ventral mesentery; but as it develops it alters in position and form, and the mesenteries grow or become stretched.

The liver, for example, enlarges within the ventral mesentery, and the spleen makes its appearance and grows within the original dorsal mesentery of the stomach; and so the original ventral mesentery passes from the stomach to the liver and from the liver to diaphragm, and the dorsal mesentery of the stomach passes from stomach to spleen and from spleen to left kidney (Fig. 572, p. 677).

Mesenteries are sheets of extraperitoneal tissue (covered on each side with peritoneum) which unite portions of the intestine to the posterior abdominal wall and convey to them their vessels and nerves. There are several mesenteries, viz., the *mesentery proper*, which connects the jejunum and ileum to the posterior abdominal wall, the *transverse mesocolon* (mesentery of the transverse colon), the *pelvic mesocolon* (mesentery of the pelvic colon), mesentery of the appendix vermiformis, and occasionally others (see p. 604).

The term **omentum** is applied to two folds of similar structure derived from the embryonic ventral and dorsal mesenteries of the stomach, which in the adult pass from the stomach, one to the liver—the *lesser omentum*—and the other to the transverse colon—the *greater omentum*.

Greater Omentum.—The greater omentum, a large apron-like fold of peritoneum, usually more or less loaded with fat, is attached to the greater curvature of the stomach and hangs down in front of the intestines to a variable extent. When the abdomen is carefully opened without disturbing the viscera, it is rare to find the greater omentum evenly spread over the front of the intestines. More commonly it is folded in between some of the coils of intestine or is tucked into the left hypochondrium; or perhaps it is carried upwards in front of the stomach by a distended transverse colon. The greater omentum extends between the greater curvature of the stomach above and the transverse colon below, not taking the shortest course from the one to the other but hanging down as a loose fold and containing between the anterior and posterior sheets a part of the lesser sac of peritoneum (Figs. 503, 506).

The greater omentum consists of two sheets, each formed of two layers of peritoneum enclosing fat and areolar tissue. The **anterior** or **descending sheet** begins at the greater curvature of the stomach, where it is formed by the meeting of the layers from the anterior and posterior surfaces of that organ. Thence it descends across the front of the transverse colon (to which it is often adherent, either in part or as a whole). Leaving the colon (see Fig. 503), the two layers proceed to the lower border of the omentum, where, turning back, they pass up as the **posterior** or **ascending sheet**, which runs upwards until it meets the transverse colon. There its two layers separate to enclose that colon—and the greater omentum, properly so called, ceases. The two layers, however, unite at the upper margin of the colon to form the **transverse mesocolon**, which is continued upwards and backwards to the lower border of the pancreas. There, the layers of the transverse mesocolon again separate—the upper running upwards over the anterior surface of the pancreas to the posterior abdominal wall behind the cavity of the lesser sac; the lower passing downwards on the posterior abdominal wall from which it is again reflected as the mesentery.

The greater omentum is continued to the right for a short distance (one inch) along the lower border of the first part of the duodenum. At the left end it shortens very much, and is directly continued into the gastro-splenic ligament; the spleen, as it were, being introduced between the two layers instead of the colon.

The greater omentum contains, between the two layers of its anterior sheet, the greater part of the right and left gastro-epiploic arteries and their accompanying veins, as well as lymph-vessels and nerves. The special interest of the upper part of this sheet is that through it access may be obtained to the part of the lesser sac which is behind the stomach.

The amount of fat contained between its layers is variable, and may be very large in adipose subjects, and almost none in spare ones. It is often fenestrated and may be a fine lace-like net. On its surface there may be milk-like spots formed by accumulations of a special variety of lymphoid cells termed *histiocytes*.

Functions of Greater Omentum.—Numerous uses have been assigned to the greater omentum; the chief seem to be: (1) To act as a movable and easily adjustable packing material, capable of filling all spaces produced temporarily in the abdomen. In this respect it may be compared with the fatty pads in joints. (2) It probably, to some extent, prevents the passage of the small intestines up into the stomach-chamber and helps to keep them from becoming entangled there. (3) It is a storehouse of fat. (4) It is said to be "the great protector against peritoneal bacterial invasions"; being freely movable, it can pass to almost any part of the abdomen, and there "build up barriers of exudations to check infection".

Lockwood (1889) made the interesting observation (in connection with the contents of herniæ), that in bodies under forty-five years of age the omentum can rarely be drawn down below the level of the pubic tubercle; in older bodies the reverse is the rule.

Lesser Omentum.—The lesser omentum is a peritoneal membrane which passes from the inferior and posterior surfaces of the liver to the stomach and duodenum (Fig. 525). Its structure, contents, and attachments are as follows:—

The portion that lies to the left is thin, translucent, and sometimes fenestrated, and it extends from the lesser curvature of the stomach to the left end of the porta hepatis and to the fissure for the ligamentum venosum. It contains the right and left gastric arteries and accompanying veins and lymph-vessels, some lymph-glands, and filaments from the anterior gastric nerve which go to the liver. The right portion is thicker and stronger and passes from the first part of the duodenum to the porta hepatis. On the right it ends in a rounded margin. Traced downwards, the layers of peritoneum which form it clothe the commencement of the duodenum on two sides. In it lie the hepatic artery, the portal vein, and the bile-duct, with lymph-vessels and nerves.

The lesser omentum occasionally extends still farther to the right and forms a thin membrane that connects the gall-bladder to the transverse colon and right flexure of the colon. This portion is termed the *hepato-colic ligament*.

The **gastro-splenic ligament** is a short fold attached by one margin to the fundus and greater curvature of the stomach, and by the other to the gastric surface of the spleen immediately in front of the hilum. Between its two layers the short gastric branches of the splenic artery pass from the spleen to the stomach. Below and in front, its layers are continued into the corresponding layers of the greater omentum; above and behind, they separate at the "bare area" of the stomach (Fig. 538, p. 630).

The **lieno-renal ligament** is a short fold that stretches from the front of the left kidney to the hilum on the visceral surface of the spleen (Fig. 517, p. 608). Its medial layer becomes continuous there with the medial layer of the gastro-splenic ligament; and its lateral layer is continuous with the peritoneal covering of the spleen. The splenic vessels and nerves lie between its layers.

The **gastro-phrenic ligament** is a short fold reflected from the under surface of the diaphragm on the left side of its œsophageal opening to the posterior surface of the fundus of the stomach. It is merely a fold on the peritoneum which passes from the diaphragm to this part of the stomach.

The **mesentery** is described on p. 634.

The **mesentery of the vermiform appendix** is a small triangular fold attached by one margin to the whole length of the appendix, by another to the under surface of the mesentery close to the termination of the ileum, while the third margin is free. The vessels to the appendix are found in it.

The **transverse mesocolon** is a typical mesentery containing a considerable thickness of extraperitoneal tissue as well as the middle colic vessels and branches from the right and left colic vessels and nerves and lymph-vessels. Its root extends horizontally over the posterior abdominal wall from the right to the left colic flexure across the second part of the duodenum and the head of the pancreas and along the lower border of the body of that organ.

The **pelvic mesocolon** is described on p. 647.

Other folds, specially named, but described elsewhere, are the right and left gastro-pancreatic folds (p. 617) and the ligaments of the liver (p. 659).

Peritoneal "Adhesions" and Variations.—In addition to the peritoneal folds which have been mentioned, many other peritoneal bands and folds are sometimes found. (1) The gall-bladder is often united to the first part of the duodenum by a dense, strong layer of fibrous tissue which blends with the lateral part of the lesser omentum. (2) The duodeno-jejunal junction is occasionally firmly joined by similar bands to the transverse mesocolon. (3) Around the cæcum, vermiform appendix, terminal part of the ileum, and lower part of the ascending colon, it is common to find bands of fairly dense tissue passing (*a*) from the colon to the lateral abdominal wall, (*b*) from the terminal portion of the ileum to the cæcum, (*c*) from the cæcum itself to the parietes. Such bands are usually ascribed to "peritonitis". (4) The greater omentum may be united to the anterior surface of the ascending colon. (5) Fibrous bands often pass from the left side of the lower part of the descending colon to the parietes. They have been ascribed to faults in development, to peritonitis, and to mechanical traction; but it is not possible to state definitely the exact mode and cause of their origin.

Peritoneal Folds and Recesses.—In certain places there are small folds of peritoneum which bound recesses or pockets of the peritoneal cavity (pp. 631, 642, 647). Some of these may become the seat of an 'internal' or retroperitoneal hernia.

CAVITY OF PERITONEUM

The peritoneal cavity is described as consisting of two portions—the general peritoneal cavity or **greater sac** and the **lesser sac**. The greater sac is opened when the anterior abdominal wall is removed or incised; the lesser sac is chiefly behind the stomach and in the greater omentum, and it is much smaller. The two sacs are not separate cavities, for the lesser sac is merely a recess of the greater sac, formed by changes that take place in the position of the viscera and their mesenteries during development. If the general peritoneal cavity is compared to a bag, the lesser sac might be represented as a pocket lying behind it and opening into it by a narrow orifice.

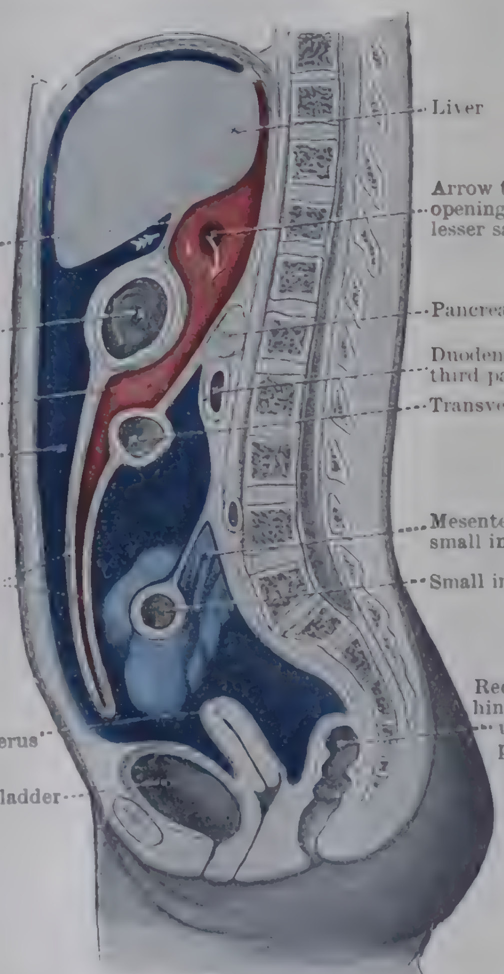

Fig. 515.—Diagrammatic Median Section of Female Body to show Abdomino-Pelvic Cavity and Peritoneum on vertical tracing. The greater sac of peritoneum is blue and the lesser sac is red; both are represented much larger than in nature.

Greater Sac of Peritoneum.—The general peritoneal cavity is placed between the parietes anteriorly and the abdominal viscera posteriorly. It is bounded anteriorly by the parietal peritoneum on the posterior aspect of the anterior abdominal wall, and posteriorly partly by the visceral peritoneum covering the viscera and partly by the parietal peritoneum on the posterior abdominal and pelvic walls.

Anterior Wall of General Peritoneal Cavity.—The anterior abdominal wall is covered completely with parietal peritoneum from the diaphragm to the pelvis. Over the greater part of its extent it is connected to the wall by a small amount of fatty extraperitoneal

areolar tissue; but below, near the pubic region, the fat is more abundant and the connexion between the two becomes much looser.

In this tissue there are five cord-like structures—one in the median plane, and two at each side. They are (*a*) the **median umbilical ligament** (*urachus*)—the remains of the allantois of the fœtus—which in the adult is a slender fibrous band connected to the umbilicus above and to the apex of the bladder below, where it usually becomes much stouter. At the sides of the median ligament, and some distance from it (Figs. 556, p. 651, and 625, p. 744), (*b*) a pair of stouter fibrous cords—the **lateral umbilical ligaments**—pass upwards and medially. They become more slender as they approach the median ligament, along with which they are connected to the umbilicus. Below, they grow thicker, and each can be followed backwards along the side-wall of the true pelvis to the internal iliac artery, which they join. The lateral umbilical ligaments are obliterated portions of the **umbilical arteries**, by which in the fœtus blood passes from the internal iliac arteries to the placenta. (*c*) More laterally still, the **inferior epigastric arteries** run upwards and medially from the external iliac trunks.

When the anterior abdominal wall is examined from behind, it will be seen that the five structures form five more or less distinct peritoneal ridges, known as the *median* and *lateral umbilical folds* and the *folds of the epigastric arteries*

Three pairs of shallow peritoneal fossæ are associated with these folds—one lateral to each fold. The most lateral of them—the one lateral to the epigastric artery—corresponds to the position of the deep inguinal ring. At its bottom, a dimple-like depression of the peritoneum indicates the point from which the processus vaginalis passed down during the descent of the testis.

Between the epigastric artery laterally, the margin of the rectus abdominis muscle medially, and the inguinal ligament below, there is a small triangular region called the **inguinal triangle.** The lateral umbilical ligament, in passing upwards, crosses this triangle and divides it into a lateral and a medial part; the intermediate one of the three fossæ mentioned above corresponds to the lateral division of the triangle.

Still another fossa of the peritoneum is seen in that region, just beneath the medial part of the inguinal ligament, corresponding to the position of the femoral ring; the vas deferens crosses its lateral part and the lateral umbilical ligament its medial part.

Near the median plane, above the umbilicus, the peritoneum is carried back from the anterior abdominal wall and diaphragm to the parietal surface of the liver in the form of a crescentic fold—the **falciform ligament** of the liver—which is described with that organ. The fold lies a little to the right of the median plane, and extends almost as low as the umbilicus. It consists of two layers of peritoneum between which, in the lower border of the fold, runs the round ligament of the liver—the remains of the umbilical vein of the fœtus.

Posterior Wall of General Peritoneal Cavity.—The peritoneum of the anterior abdominal wall is continued on to the inferior surface of the diaphragm. Thence it is reflected on to the superior surface of the liver, covers the anterior surface, turns round its inferior border, and is continued backwards on its inferior surface as far as the attachment of the lesser omentum, where it is reflected, as the anterior layer of the lesser omentum, to the stomach and the duodenum (Fig. 515).

Having reached the lesser curvature of the stomach, it passes down over the front of that organ to the greater curvature. From that curvature it descends as the most anterior layer of the greater omentum. Arrived at the lower border of the greater omentum, the membrane returns on itself, and passes upwards towards the transverse colon, forming the most posterior layer of the omentum. After covering the posterior surface of the transverse colon it is continued, as the posterior layer of the transverse mesocolon, to the posterior abdominal wall, which it reaches at the lower border of the pancreas (Fig. 515).

From the lower border of the pancreas it is continued downwards again, clothing first the lower surface of the pancreas, then the front of the third and fourth portions of the duodenum, and, below that, the posterior abdominal wall. But it is soon carried forwards again by the branches of the superior mesenteric vessels passing to the small intestine. Running out along those, it forms the right layer of the mesentery (Fig. 552): on reaching the small bowel at the border of the mesentery, it invests that tube, giving it its serous coat, and then returns—as

the left layer of the mesentery—to the posterior abdominal wall, on which it runs down, covering the great vessels near the median plane and the psoas major muscle and ureter at each side, to enter the pelvis.

Pelvic Peritoneum.—The arrangement of the peritoneum in the true pelvis is different in the two sexes, and is described in connection with the pelvic viscera.

Transverse Tracing of Peritoneum.—If the peritoneum is followed transversely around the abdomen just above the level of the iliac crest (Fig. 518), few difficulties will be encountered. From the anterior abdominal wall it passes round on each side to the back, lining the sides and the posterior wall. Passing medially on the posterior wall, it meets the colon—ascending on the right side, descending on the left—over which it is carried, in each case covering the bowel in front and at the sides only and leaving the posterior surface bare as a rule. Sometimes, however, the covering is complete and a short mesentery is formed. It is next

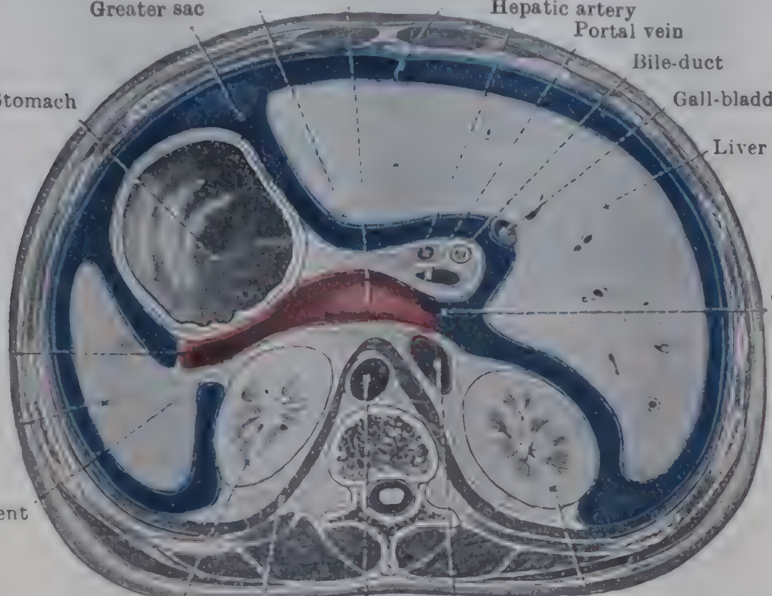

Fig. 516.—Transverse Section of Abdomen at Level of Opening into Lesser Sac of Peritoneum.

continued *medially* over the psoas muscle, the ureter, and the great vessels, on the front of which it meets the superior mesenteric artery and vein. From both sides it passes forwards on those vessels, forming the right and left layers of the mesentery; and finally, having reached the intestine, it clothes it completely, and the two portions become continuous on the bowel.

Transverse tracings at a higher level would include the lesser sac; it will therefore be well if we describe this portion of the peritoneal cavity before directing attention to such tracings.

Lesser Sac of Peritoneum.—The lesser sac is behind the stomach, lesser omentum and part of the liver, and in the greater omentum; and it communicates with the greater sac by a narrow mouth, on the right side, just below the liver, called the opening into the lesser sac. From the opening the lesser sac can be traced towards the left behind the lesser omentum and stomach as far as the spleen, upwards behind the caudate lobe of the liver, and downwards behind the stomach and into the greater omentum.

The **opening into the lesser sac** is situated just below and behind the porta hepatis. It is bounded *in front* by the right, free border of the lesser omentum passing up from the first part of the duodenum to the porta hepatis and containing between its two layers the portal vein, hepatic artery, and bile-duct. *Behind* lies the inferior vena cava, covered, of course, with peritoneum. *Above* is placed the caudate process of the liver. And *below* lies the first part of the duodenum with

the hepatic artery running forwards and to the right before turning up into the lesser omentum. It should be remembered that, normally, the various boundaries of the opening are in contact with one another, and that its cavity can be said to exist as such only when its walls are drawn apart.

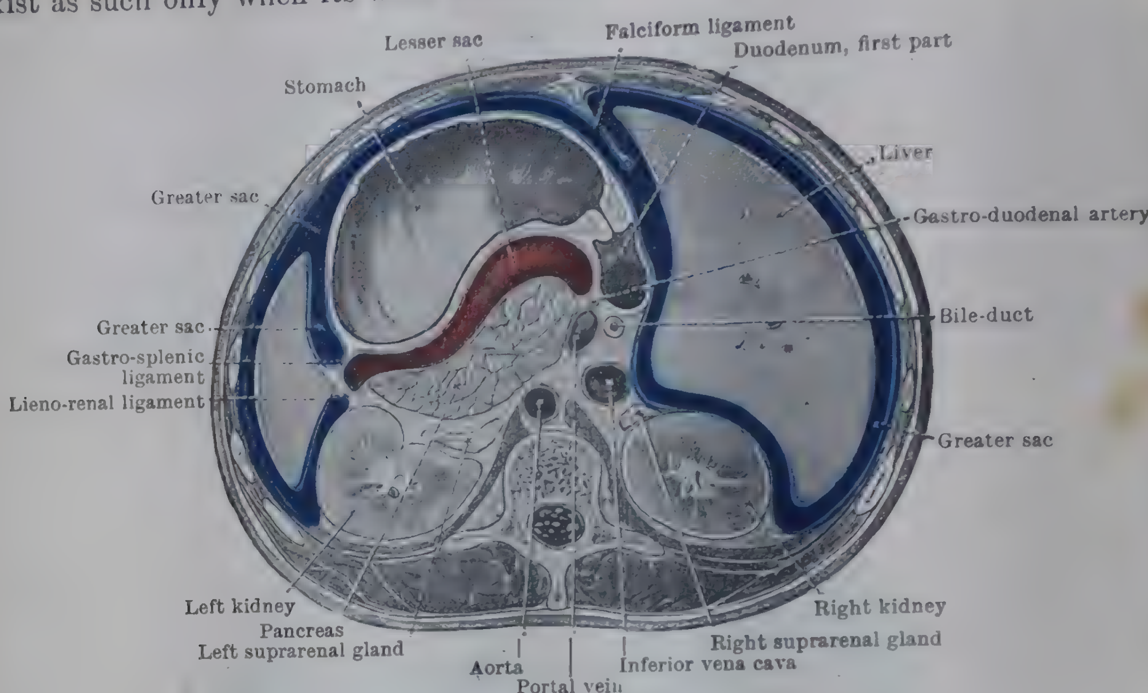

FIG. 517.—TRANSVERSE SECTION OF ABDOMEN IMMEDIATELY BELOW OPENING INTO LESSER SAC OF PERITONEUM.

To the left of the opening, there is a small portion of the lesser sac, termed the *vestibule*, which lies below the caudate process of the liver and above the first part of the duodenum and the head of the pancreas. The anterior wall of that portion is formed by the hepato-duodenal part of the lesser omentum, with the bile-duct, hepatic artery, and portal vein.

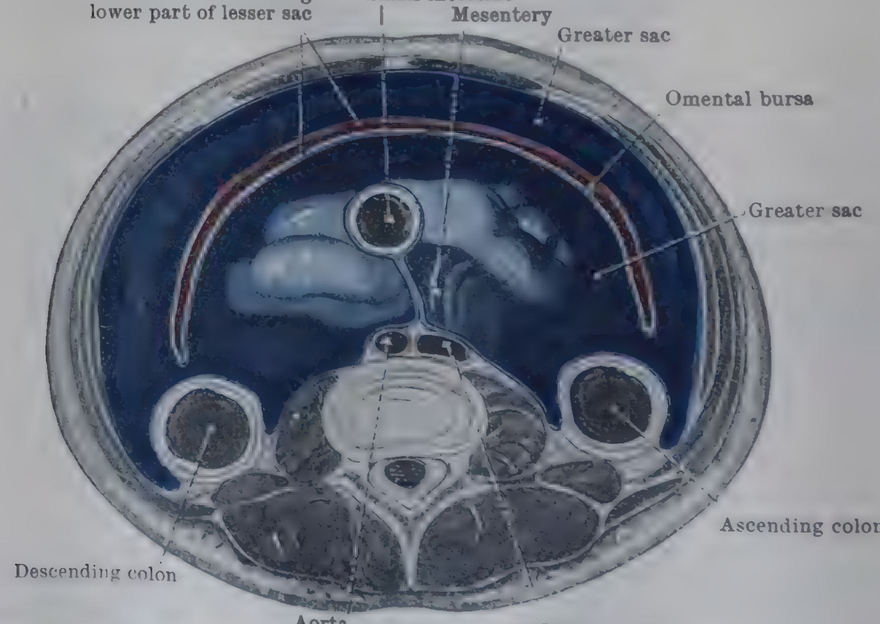

FIG. 518.—TRANSVERSE SECTION OF ABDOMEN THROUGH FOURTH LUMBAR VERTEBRA.

The vestibule is continued into the true lesser sac, which presents two recesses—upper and lower. The **upper recess** passes from the vestibule upwards behind the porta hepatis and the caudate lobe, in front of the diaphragm. The **lower recess** passes in front of the pancreas and behind the stomach towards the spleen (Fig. 517).

The lower recess and the vestibule of the lesser sac communicate with each other by a rounded orifice which is constricted by the sickle-shaped, forward-projecting *gastro-pancreatic*

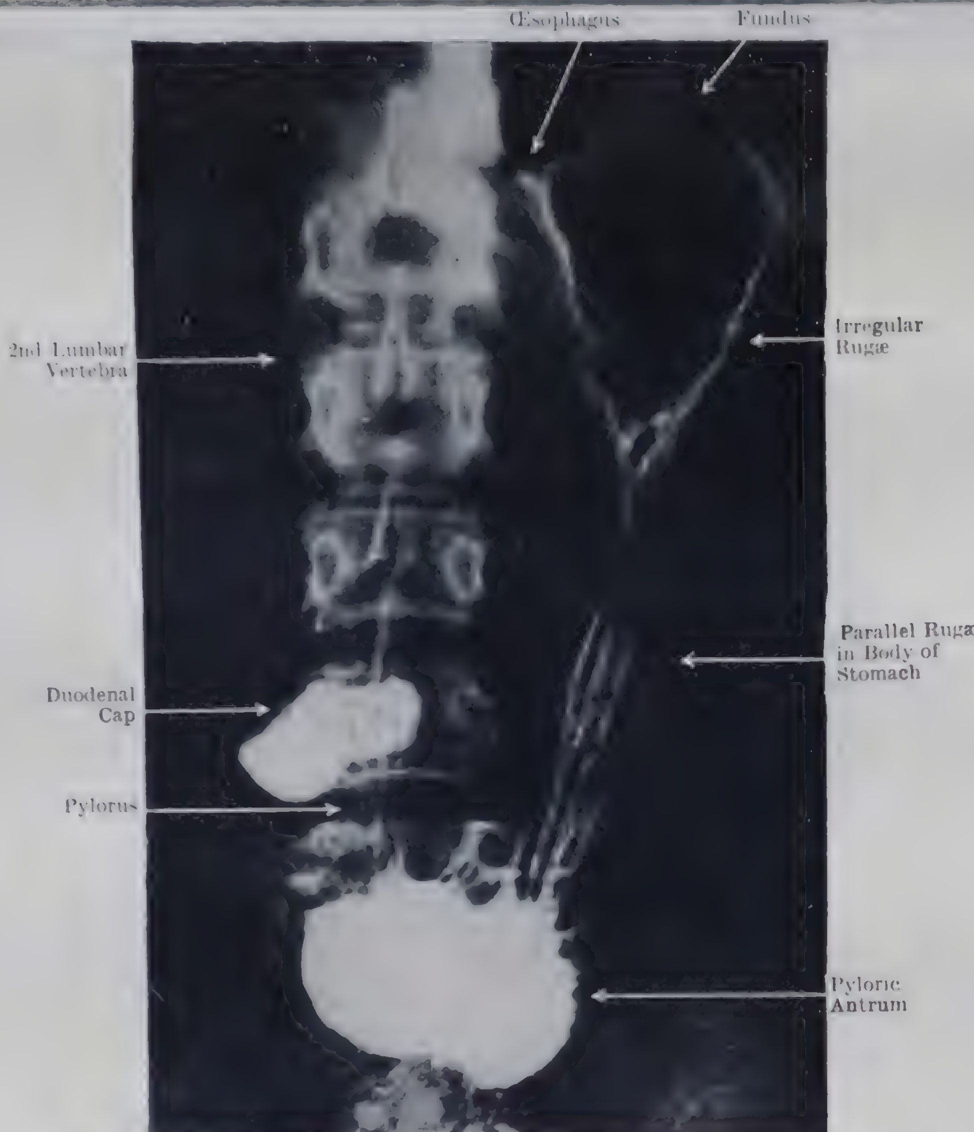

FIG. 1.—RADIOGRAPH OF NORMAL J-SHAPED STOMACH (WOMAN, AGED 39), SHOWING THE GASTRIC RUGÆ MADE EVIDENT BY A SMALL AMOUNT OF BARIUM.

Note the tubular appearance of the body of the stomach with parallel rugæ, the collection of barium in the most dependent part of the stomach, and that some of it has passed into the small intestine to form a well-defined duodenal cap.

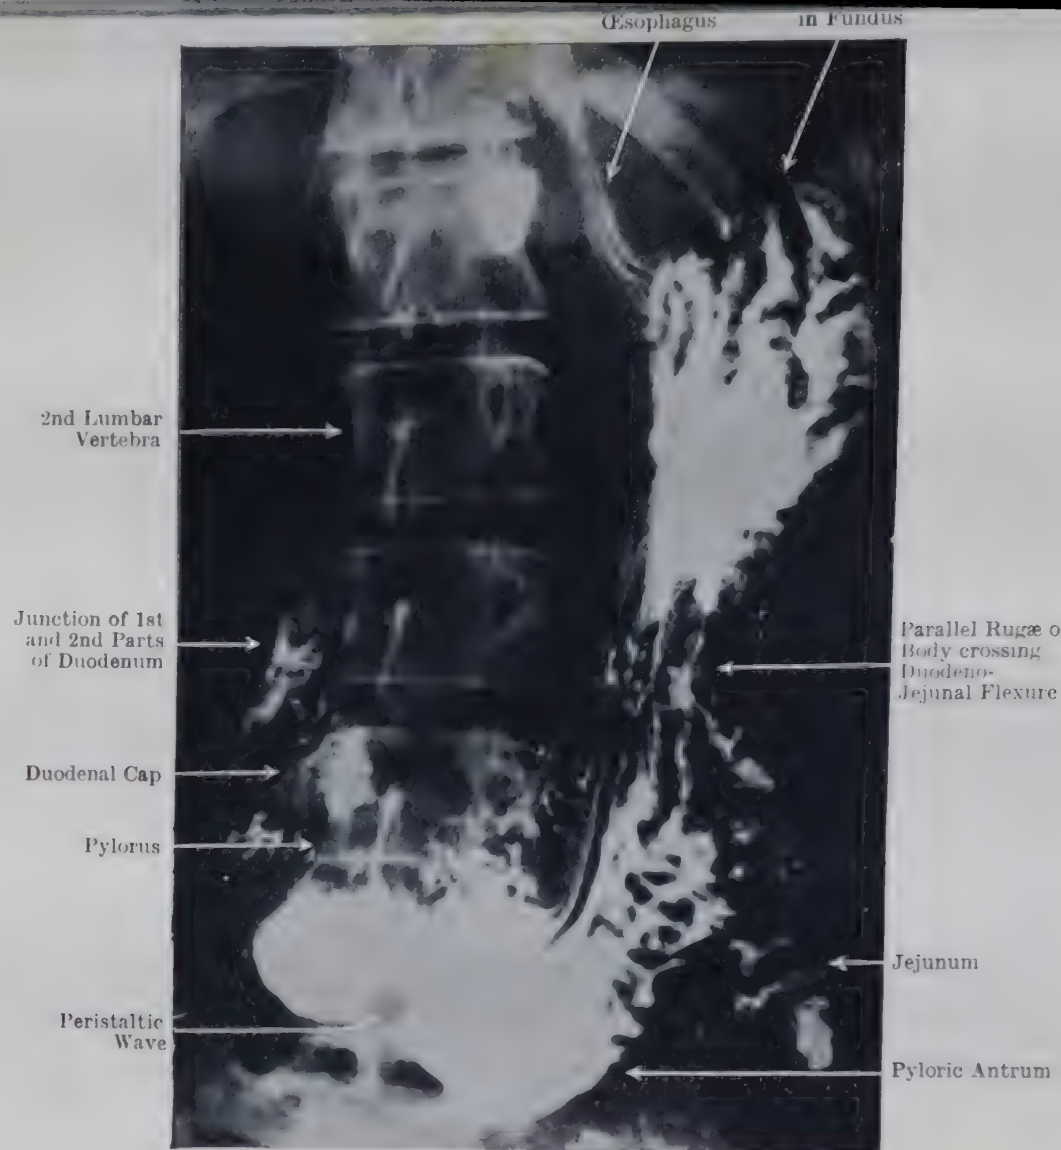

FIG. 2.—RADIOGRAPH OF NORMAL J-SHAPED STOMACH (WOMAN, AGED 41) WITH MORE BARIUM THAN IN FIG. 1.

Note the irregularity of the rugæ in the fundus, the irregular outline of the greater curvature in the lower part of the body, and the presence of a peristaltic wave.

[Facing p. 608

PLATE LII

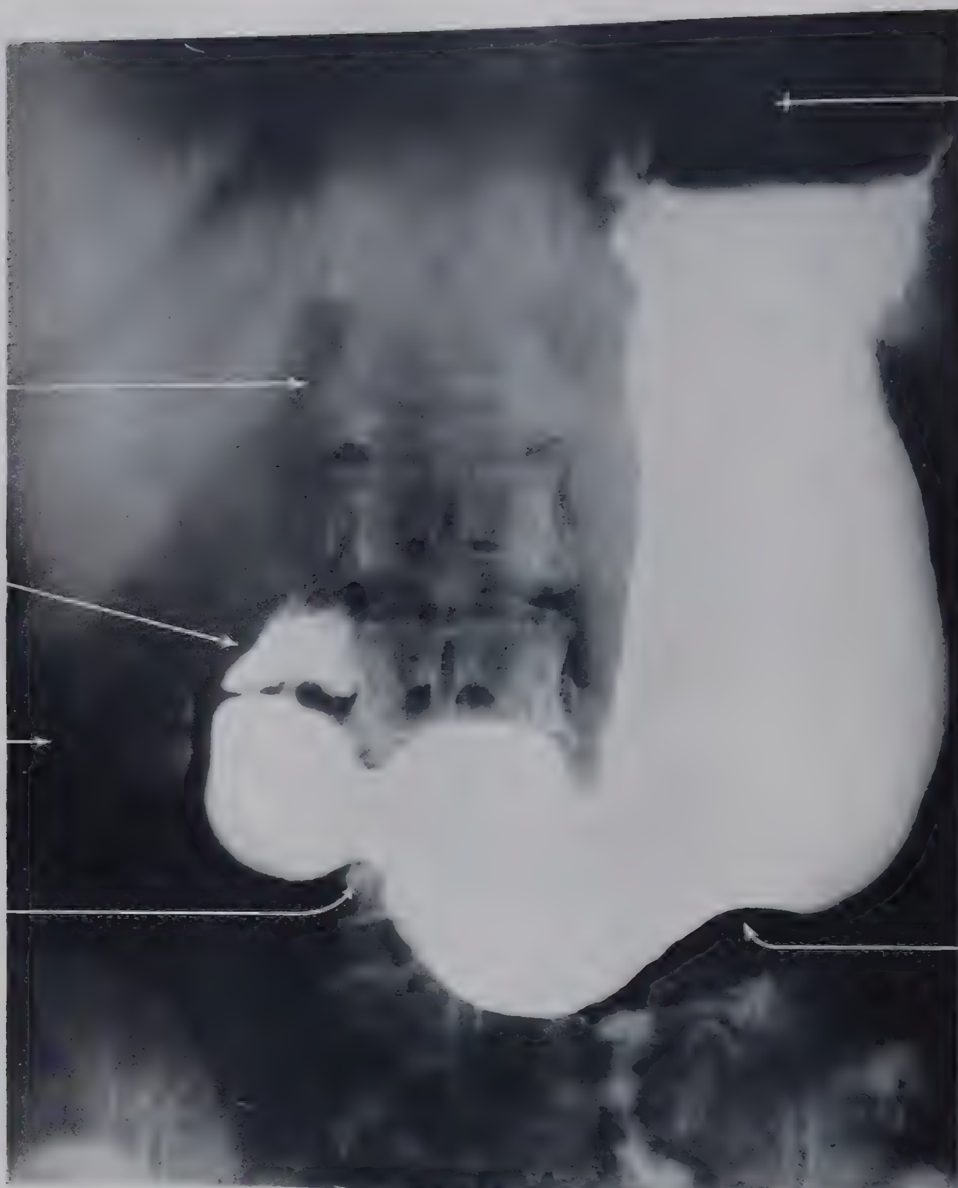

PLATE LII.—RADIOGRAPH OF J-SHAPED STOMACH OF WOMAN AGED 62, TAKEN IN THE ERECT POSTURE A FEW MINUTES AFTER AN OPAQUE MEAL.

Note the low position of the Greater Curvature and of the Pylorus. Cf. Plates LIII and LIV, p. 612. The Gall-Bladder, intercepting the X-Rays because of calcification in its wall, is seen in relation to the Pylorus. For the position of the gall-bladder see also Plate LX, p. 649.

folds. Those folds are elevations of the peritoneum of the posterior wall of the lesser sac raised up by the left gastric and hepatic arteries as they pass forwards from the posterior wall to the stomach and duodenum respectively (p. 617). The nature and variation of these folds (which may even, though rarely, be continuous, thus dividing the lesser sac) have been studied by Crymble (1913); whilst Reid (1913) has given an account of their disposition in the human fœtus.

As the peritoneal wall of the lesser sac is described in two main parts—an anterior and a posterior—it will be necessary to follow each of them separately. The peritoneum which forms the **anterior wall** clothes the caudate lobe of the liver; it then passes down from the posterior margin of the porta hepatis and the fissure for the ligamentum venosum to the lesser curvature of the stomach and the duodenum as the posterior layer of the lesser omentum. It then clothes the posterior surface of the stomach as far as the greater curvature, with the exception of the small "bare area" below and to the left of the cardiac orifice (Fig. 538). On the left, it is reflected from the back of the stomach to the spleen as the deeper layer of the gastro-splenic ligament. From the greater curvature of the stomach it is continued down as the posterior layer of the anterior sheet of the greater omentum, and, at the inferior part of the omentum, it meets and becomes continuous with the posterior wall of the lesser sac.

The peritoneum which forms the **posterior wall of the lesser sac** clothes the front of the inferior vena cava (Fig. 516), covers the cœliac artery, and passes upwards to cover the diaphragm behind the caudate lobe of the liver. Passing to the left, it covers the anterior surface of the pancreas, the suprarenal gland, and a portion of the left kidney, from which it is reflected to the spleen as the deep layer of the lieno-renal ligament (Fig. 517). From the pancreas it is prolonged downwards—as the anterior layer of the transverse mesocolon—to the transverse colon (Fig. 515). Thence it is continued down as the anterior layer of the posterior sheet of the greater omentum almost to its inferior border, where it becomes continuous with the anterior wall of the lesser sac already described.

Transverse tracings at the levels of the opening into the lesser sac and of the pylorus are shown in Figs. 516 and 517 and can be easily followed without any further description.

STOMACH

The **stomach** (gaster) is a receptacle in which food accumulates after its passage through the œsophagus, and in it take place some of the earlier processes of digestion, resulting in the conversion of the food into a viscid fluid known as *chyme*. The chyme escapes through the pylorus into the small intestine, where the digestive processes are continued.

The form and the position of the stomach present great variations not only among different people but also in the same person at different times. The degree to which it is filled, the size and position of adjacent organs, the condition of the abdominal walls, and even the assumption of the erect or the recumbent attitude can influence its shape and relations.

General Shape.—In shape, the stomach is irregularly piriform, with a wide end that lies deeply in the hollow of the left cupola of the diaphragm, and a narrow tapering extremity which passes downwards and forwards and is bent over to the right side in the epigastric region.

The long axis of the organ forms a spiral curve directed downwards, forwards and to the right, and finally backwards.

The stomach has two surfaces—an anterior directed forwards, upwards, and to the left, and a posterior which looks backwards, downwards, and also to the right. These surfaces meet above and to the right at the **lesser curvature**, and below and to the left at the **greater curvature**. The œsophagus enters the stomach at the upper end of the lesser curvature, at the cardiac orifice, whilst at the lower end the stomach passes into the duodenum at the pyloric orifice. The dome-shaped portion above and to the left of the œsophagus is the **fundus**, and the remainder of the stomach is divisible into the **body** and the **pyloric portion**.

Cardiac Orifice.—The cardiac orifice is at the upper end of the lesser curvature, to the right of the fundus, and more on the anterior than the posterior surface of the stomach. The orifice is oval or angular rather than round, being compressed from side to side. Around the opening the muscular walls of the œsophagus and its mucous membrane become continuous with corresponding coats of the stomach-wall. The longitudinal muscular coat passes onwards into a longitudinal set of fibres, and the circular œsophageal fibres pass into the circular and oblique layers. The whitish stratified squamous epithelium of the œsophagus is continuous with the pinkish-coloured columnar epithelial wall of the stomach, and the junction is marked by a sharp, irregular line around the margin of the opening.

To the right of the orifice, the right margin of the œsophagus merges with a slight curve into the lesser curvature of the stomach, while on the left side there is a deep notch—the **cardiac notch**—between the end of the œsophagus and the fundus, in which lies a projecting ridge of the right crus of the diaphragm.

The cardiac notch on the outer surface produces a fold in the interior of the stomach, which may assist in closing the œsophageal opening, and that, with the decussating fibres of the diaphragm and the strengthened circular fibres of the lower end of the œsophagus, forms a kind of sphincter for this orifice which serves to prevent regurgitation from the stomach under ordinary conditions.

The cardiac orifice is very deeply placed—about four inches behind the seventh left costal cartilage—and is about one inch from the median line. Posteriorly it corresponds to the level of the body of the tenth thoracic vertebra.

Owing to the fixation of the œsophagus by its passage through the diaphragm, and the close connexion between the stomach and the diaphragm near the cardiac orifice where the peritoneum is absent, this is the most fixed part of the whole stomach.

Pyloric Orifice.—By the pyloric orifice the cavity of the stomach communicates with that of the duodenum. It is placed at the distal (right) extremity of the stomach, which is cylindrical in shape, and it is surrounded by a ring of thick muscle tissue named the **pyloric sphincter**. The term **pylorus** is applied to the area of the stomach which contains this sphincter.

The position of the pylorus is indicated to sight by a slight annular constriction on the external surface termed the *pyloric constriction*, and also by an arrangement of blood-vessels which is nearly constant. On the peritoneal surface a thick vein passes upwards from the lower side somewhat more than half-way on the anterior surface, and from the upper border a second vein (pre-pyloric vein) reaches downwards in the same line, nearly, if not quite, meeting the first (Mayo, 1908). The pylorus is also evident to touch—the thickening of the wall produced by the sphincter being readily distinguishable from the thinner wall of the pyloric canal on the proximal side and of the duodenum on the distal.

When the sphincter is in a state of contraction, the lumen of the outlet is a stellate fissure. A section through this part of the stomach (Fig. 521) shows that the mucous membrane which covers the sphincter slopes gradually into the lumen of the pylorus on the gastric side and abruptly or steeply at its duodenal end.

Viewed from the interior of the duodenum, the sphincter when contracted forms a dome-shaped elevation covered by the mucous coat and bulging into the duodenum, the centre of the dome being perforated by a narrow cylindrical depression—the pyloric orifice.

At the pylorus the peritoneal covering of the stomach is continued on to the first part of the duodenum, and the longitudinal fibres of the stomach are in part continued onwards into the longitudinal fibres of the duodenal coat, but many of them bend inwards into the thickened ring around the opening and spread out in diverging bundles which interlace with the circular fibres, and some of them reach and terminate in the subjacent submucosa (Cunningham, 1906).

The circular muscular fibres of the stomach are not continuous directly with those of the duodenum. On the contrary, at the pylorus they become very much increased in number, and they form the sphincter, which is separated from the circular muscular coat of the duodenum by a fibrous septum. The sphincteric ring is thus sharply marked off from the duodenum, but there is no sharp line of

demarcation on the gastric side, for it gradually merges into the circular muscular coat of the pyloric canal.

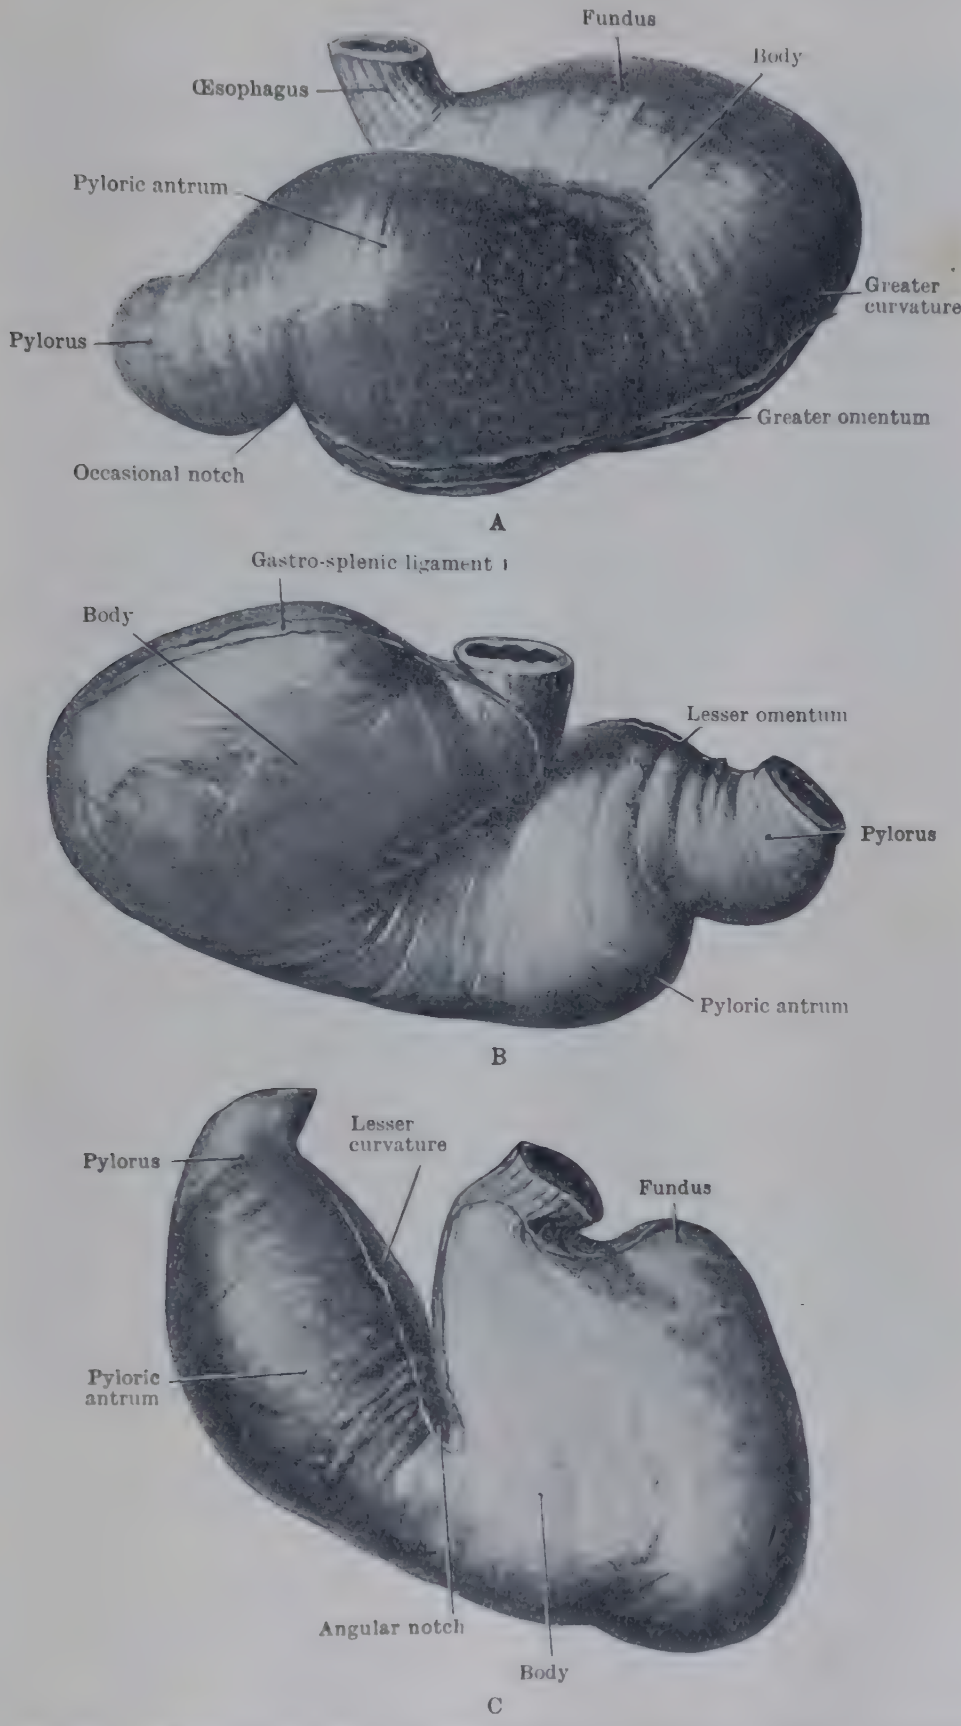

Fig. 519.—Three Views of a Stomach fixed by Formalin Injection *in situ*.
A. From the front. B. From the back. C. From above.

The orientation of the stomach was determined by the insertion of long pins into it in the sagittal, coronal, and transverse planes. These views show the comparatively horizontal position assumed by the stomach when the body lies supine. They also show the partial division into chambers produced by temporary constriction of the stomach wall fixed by the action of formalin.

The gastric mucous membrane (mucous coat), which is considerably thickened where it covers the sphincter muscle, is continued into the duodenum without any

alteration visible to the naked eye. When examined post mortem in the ordinary way, the gastro-duodenal aperture, viewed from the duodenal side, is more or less oval in form. When seen from the opposite side, it presents a stellate appearance, owing to the fact that the rugæ of the gastric mucous membrane are continued as far as the orifice.

The orifice is directed horizontally backwards and to the right. When the stomach is full, however, it looks almost directly backwards.

The pylorus rests on the neck of the pancreas below and posteriorly, and it is overlapped by the liver above and anteriorly. When the stomach is empty the

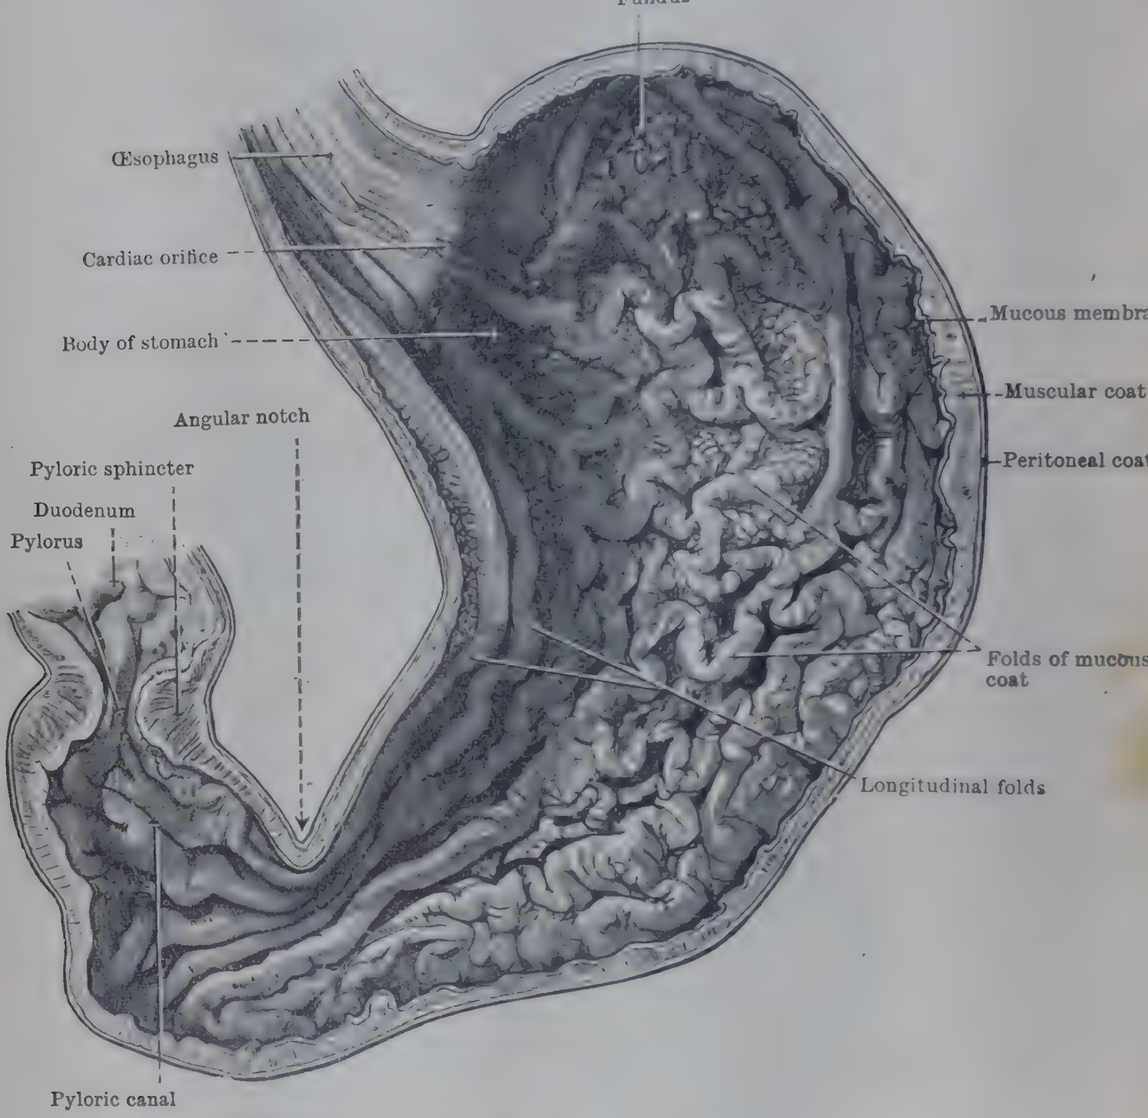

FIG. 520.—INTERIOR OF STOMACH, SHOWING ITS MUCOUS COAT AND ITS PARTS WHEN MODERATELY FILLED.

pylorus usually lies at the level of the transpyloric plane (p. 602) near (*i.e.*, within half an inch of) the median plane, below the left lobe of the liver or sometimes below the quadrate lobe. During distension it is pushed over beneath the quadrate lobe for a variable distance, but very rarely more than 1½ or 2 inches to the right of the median plane.

During the earlier stages of gastric digestion the pyloric sphincter is strongly contracted and the aperture firmly closed, but it opens intermittently to allow the passage of properly digested portions of the food.

The lumen of the pylorus is stated to be about half an inch in diameter, but that represents neither its full size nor its calibre when at rest. Foreign bodies with a diameter of almost an inch have been known to pass through the pylorus without giving rise to trouble, even in children. On the other hand, when at rest, with an empty stomach and duodenum, the aperture is closed.

PLATE LIII

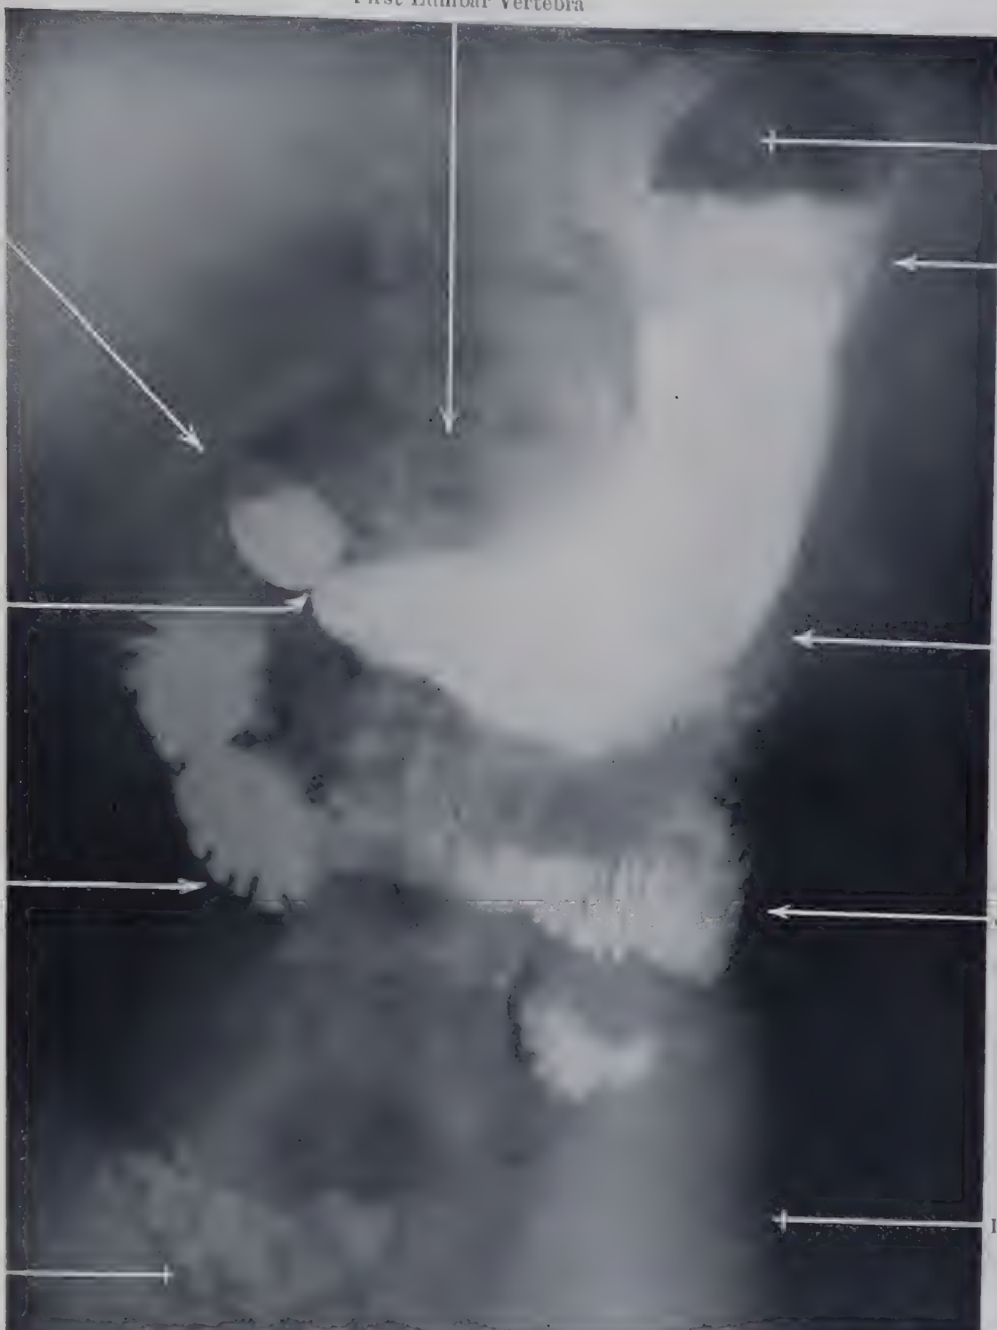

PLATE LIII.—RADIOGRAPH OF STOMACH OF MAN AGED 28 IN THE ERECT POSTURE AFTER OPAQUE MEAL, SHOWING THE INTERMEDIATE FORM (see p. 621, and compare with Plates LII, p. 609 and LIV).

The Body and the Pyloric Portion of the Stomach exhibit a more continuous curvature than those of the J-shaped Stomach in Plate LII, the Pyloric Canal is horizontal rather than vertical, and the Pylorus lies high in the abdomen. A previous opaque meal, taken three hours before, is seen in the Ileum. Compare also with Plate XLVIII, p. 559, in which the same stomach is seen half-filled.

PLATE LIV

FIG. 1. RADIOGRAPH OF "STEER-HORN" STOMACH OF MALE ADULT.

The Stomach lies almost transversely, high in the abdomen; the Pylorus and Duodenal Cap are hidden by the Pyloric Portion. The position of the air in the Fundus shows that the radiograph was taken in the erect posture. Cf. Plates LII, p. 609 and LIII.

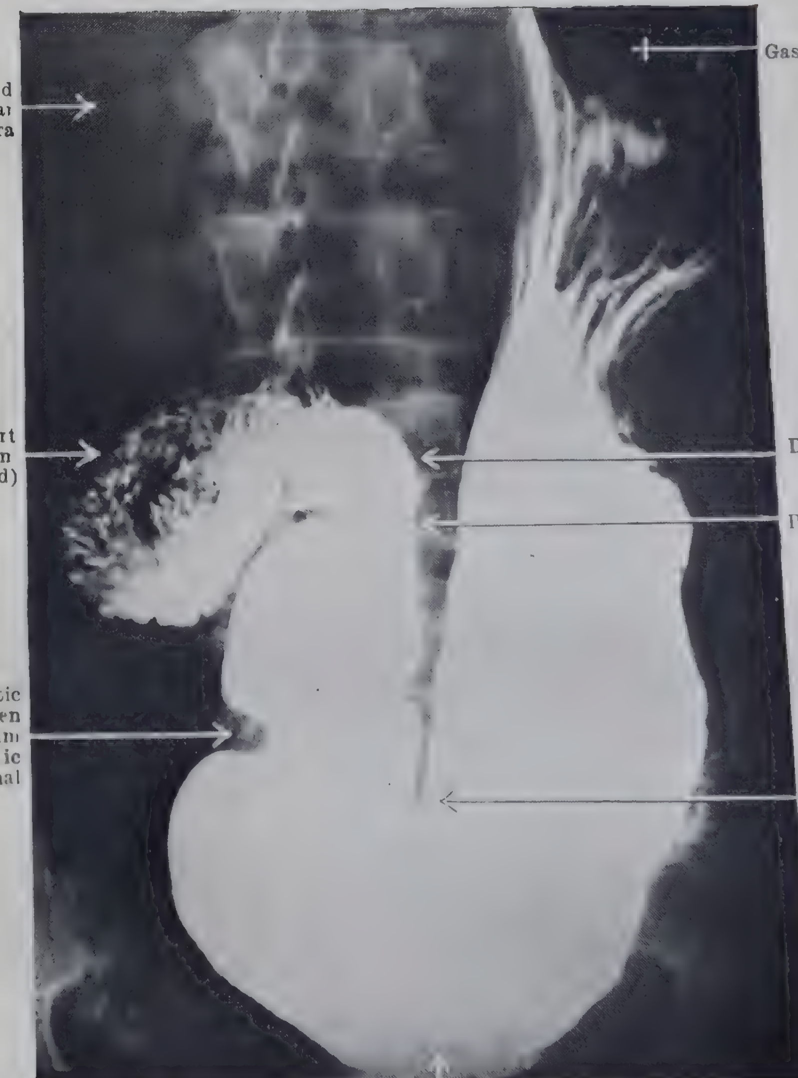

FIG. 2.—RADIOGRAPH OF STOMACH IN VISCEROPTOSIS.

The J-shape of the stomach is greatly exaggerated; the pylorus is at the level of the fourth lumbar vertebra; and the greater curvature descends into the pelvis.

[Facing p. 6

Surfaces and Chief Relations of Stomach.—The **anterior surface of the stomach** is more convex and more extensive than the posterior. When the stomach is distended, it is in contact with the inferior surface of the left lobe of the liver medially, the vault of the diaphragm laterally, and the anterior abdominal wall below. When the stomach is empty, on the other hand, the transverse colon may rise in front of it, and separate its anterior surface from the liver and diaphragm and abdominal wall.

The **posterior surface of the stomach** is more flattened than the anterior, owing to the contours of the structures upon which it rests. Towards the left, the body and fundus are in contact with the diaphragm and the spleen. To the right of the fundus the upper portion of the posterior surface is in contact with the left kidney, the left suprarenal gland and the diaphragm; and the lower portion, more horizontal, is in contact with the pancreas, with the splenic artery as it runs along the upper border of the pancreas, and with the transverse mesocolon and transverse colon below the pancreas. Those structures form what is known

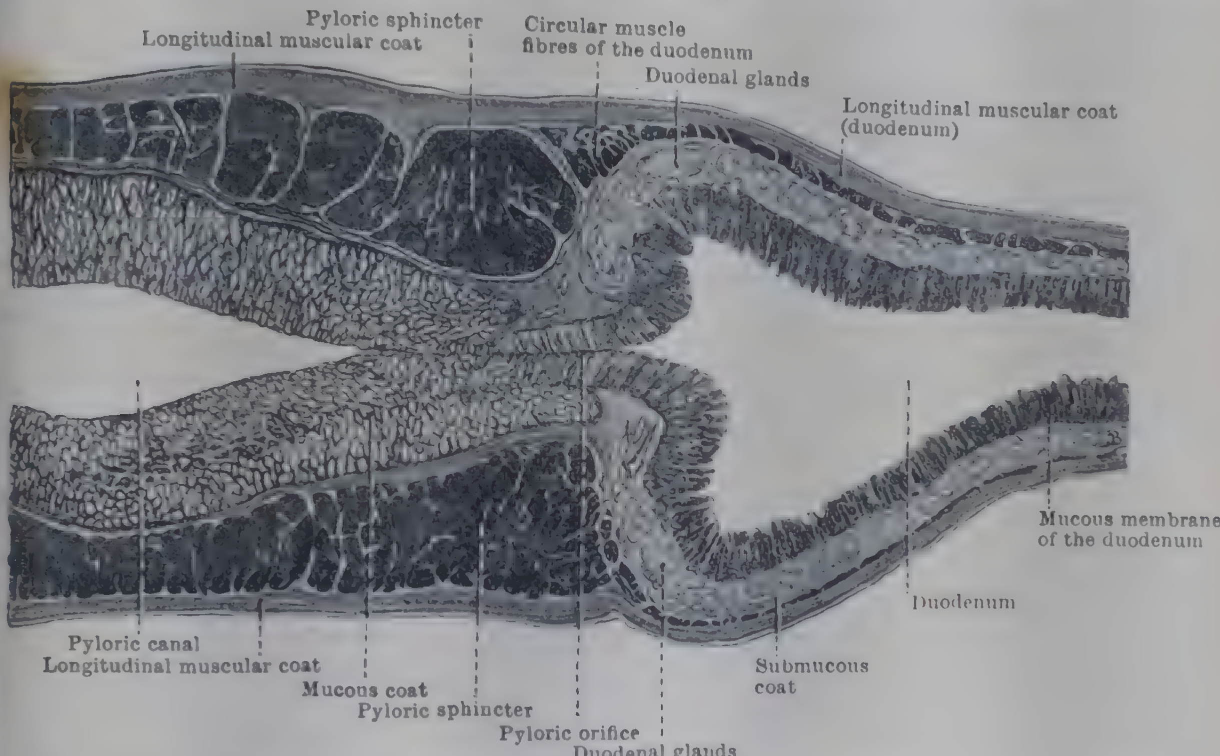

FIG. 521.—LONGITUDINAL SECTION THROUGH PYLORIC CANAL AND FIRST PART OF DUODENUM IN NEW-BORN CHILD.

as the **stomach-bed**, and, excepting the spleen, they lie immediately behind the posterior wall of the lesser sac of the peritoneum, which separates them from the stomach.

Curvatures of Stomach.—The **lesser curvature**, directed towards the liver, and attached to it by the lesser omentum, is on the whole concave. It consists of two portions which meet at the deepest part of the concavity to form a sharp angle called the **angular notch**. The upper or left portion, the longer of the two, is nearly vertical and continues the direction of the right margin of the œsophagus; the lower or right portion may be horizontal or even directed upwards to the pylorus. The angular notch is situated at the junction of the body with the pyloric portion of the stomach; and its position, its depth and the acuteness of its angle vary with the degree of distension of the stomach. When the pyloric portion of the stomach is full, the lower portion of the lesser curvature becomes convex in outline. The lesser curvature as a whole measures some three or four inches in length.

The **greater curvature** is convex, often with indentations upon it, and is usually over three times as long as the lesser curvature. But its length depends to a greater degree than that of the lesser curvature upon the physiological state of the stomach. It corresponds to a line drawn from the cardiac notch over the

summit of the fundus (Fig. 519) and along the most projecting part of the stomach as far as the pylorus. It is attached to the spleen by the gastro-splenic ligament and to the transverse colon by the greater omentum.

Divisions of Stomach.—The stomach may be divided into a *cardiac* and a *pyloric* portion. The cardiac portion, lying to the left side, is wider in diameter than the pyloric, and comprises the *fundus* and the *body* of the stomach.

The **fundus of the stomach** is the rounded or dome-shaped portion which lies above a horizontal plane drawn through the œsophageal opening. Its shape seldom alters, whatever the condition of the stomach may be, and it is usually filled with air.

The **body of the stomach** extends from the base of the fundus along the long axis of the stomach and merges into the pyloric portion. The junction of the

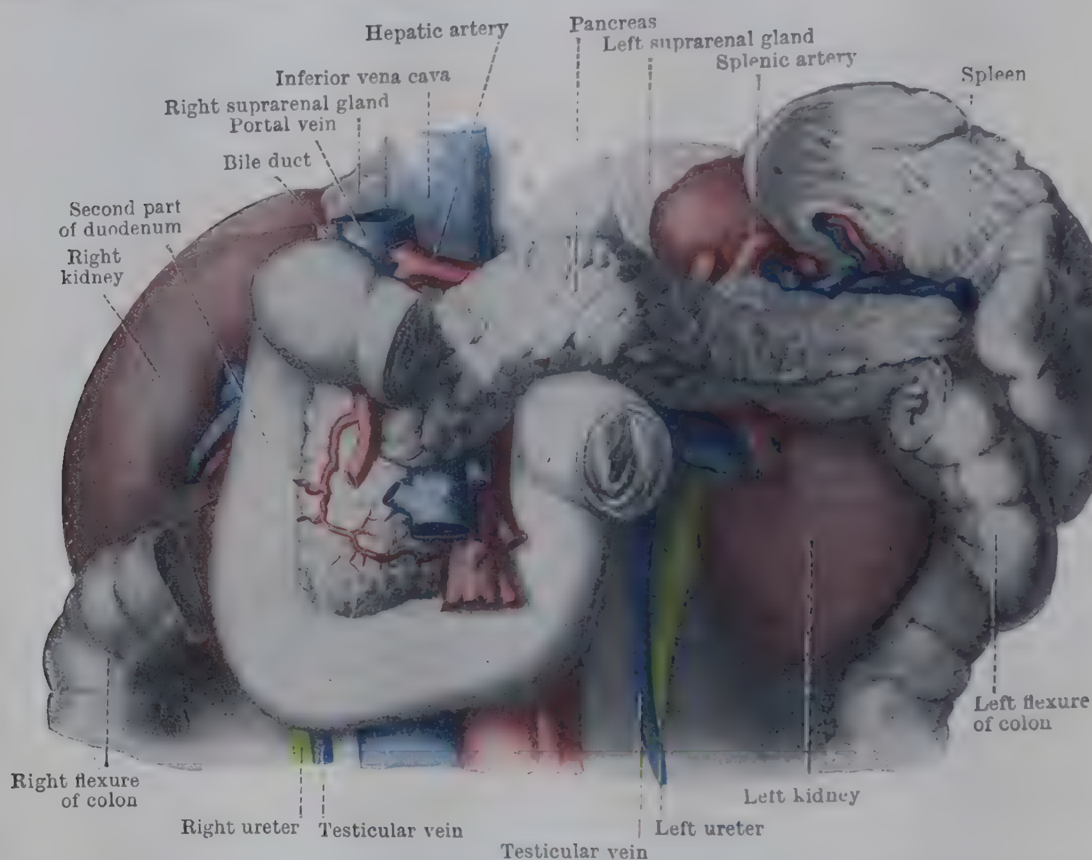

FIG. 522.—DISSECTION TO SHOW POSTERIOR RELATIONS OF STOMACH. The stomach has been cut close to the pylorus and removed. The transverse colon has been taken away, and the small intestine has been cut across close to the duodeno-jejunal flexure. (From a model by Birmingham.)

two parts is marked on the lesser curvature by the angular notch, but is not distinctly marked off on the greater curvature by any permanent notch. There is usually, however, on the greater curvature a slight notch due to a localized contraction of some of the circular muscular fibres which marks the junction of the two portions. The body of the stomach forms a rounded chamber, capable of great distension, but when the stomach is empty it contracts to a narrow tube-like structure. As the stomach is seldom completely empty, the body usually tapers from the fundus to the proximal end of the pyloric portion (Fig. 520).

The **pyloric portion of the stomach** extends from the angular notch in the lesser curvature, and a variable and inconstant notch on the greater curvature, as far as the pyloric orifice (Figs. 519, 520).

It differs from the body of the stomach in being more tubular in shape, and possessing thicker walls. It has been divided anatomically into the *pyloric antrum* and the *pyloric canal.*

The **pyloric canal** is the distal, short, more or less tubular portion which ends in the pyloric sphincter. The proximal portion, called the **pyloric antrum**, is more expanded. It is not clearly demarcated from the body of the stomach by any

constant line of division on the greater curvature. On the lesser curvature it extends from the angular notch to the pyloric canal.

Hour-Glass or Bilocular Stomach.—This is a condition of the stomach in which the organ is more or less completely separated into two divisions—a cardiac and a pyloric—the normal arrangement in certain rodents and other animals. As a rule the former division is the larger, but occasionally the two are nearly equal, or the pyloric portion may exceed the cardiac in size. Sometimes the condition is temporary, and the result of a vigorous contraction of the circular muscular fibres at the seat of constriction. In other cases it is permanent, and may be due to cicatricial contraction after gastric ulcer, or to some other pathological condition. The condition is more frequent in women than in men, and it is rarely found in the fœtus or child.

Size and Capacity of Stomach.—Probably no organ in the body varies more in size within the limits of health than the stomach. Moreover, as its tissues change so

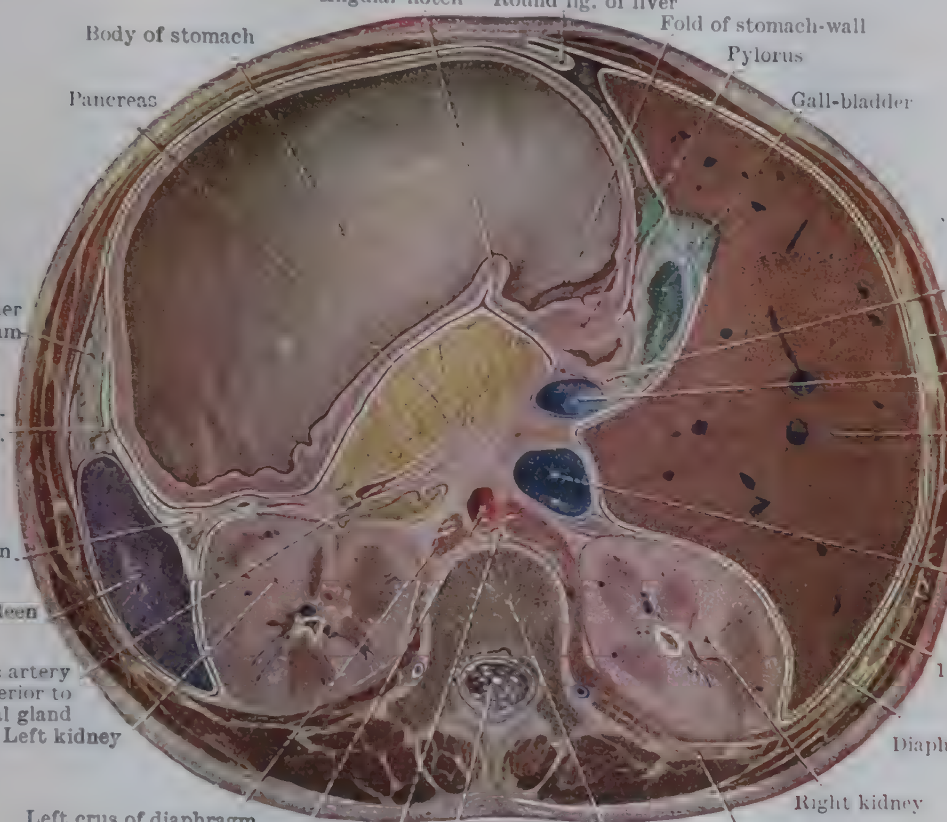

FIG. 523.—TRANSVERSE SECTION OF TRUNK AT LEVEL OF FIRST LUMBAR VERTEBRA.
Showing relations of stomach, pancreas, kidneys, etc. From a subject ten years old.

rapidly after death, measurements made on softened and relaxed organs are not only worthless but quite misleading.

The *length* of the stomach in the fully distended condition is about 10 to 11 inches (25 to 27·5 cm.), and its greatest *diameter* not more than 4 to 4½ inches (10 to 11·2 cm.); whilst its *capacity* in the average state rarely exceeds 40 ounces or 1 quart.

The distance in a direct line from the cardiac to the pyloric orifice varies from 3 to 5 inches (7·5 to 12·5 cm.), and that from the cardiac orifice to the summit of the fundus from 2½ to 4 inches (6 to 10·0 cm.).

As regards the *weight*, the average of twelve wet specimens freed from their omenta was found to be 4¾ oz. (135 grms.), with a maximum of 7 oz. (200 grms.) and a minimum of 3½ oz. (100 grms.).

In the **new-born child** the stomach is scarcely as large as a small hen's egg, and its capacity is about 1 oz. (28 c.cm.). In shape it corresponds fairly closely to that of the adult, and the fundus is well developed. It is vertical in position.

Position of Stomach.—*In the cadaver*, lying horizontally, the stomach, if empty or nearly so, is found in the upper left quadrant of the abdominal cavity, with its fundus in the hollow of the diaphragm, its long axis lying almost

horizontally and its pyloric part running to the right to join the duodenum. In that state the whole organ is narrow and tubular, particularly the pyloric part, which is contracted, and resembles a piece of thick-walled small intestine.

When the stomach is *distended*, both the cardiac and pyloric parts are full and rounded (Fig. 519). It extends down below the subcostal plane. As a result of the general increase in length which takes place during distension, the pylorus is moved a variable distance to the right beneath the quadrate lobe of the liver, and at the same time the long axis of the whole organ becomes much more vertical, running forwards, downwards, and to the right.

When the stomach has been removed, after the body has been hardened, a chamber or recess is exposed, known as the **stomach-chamber** (Figs. 522 and 524). It is a space in the upper and

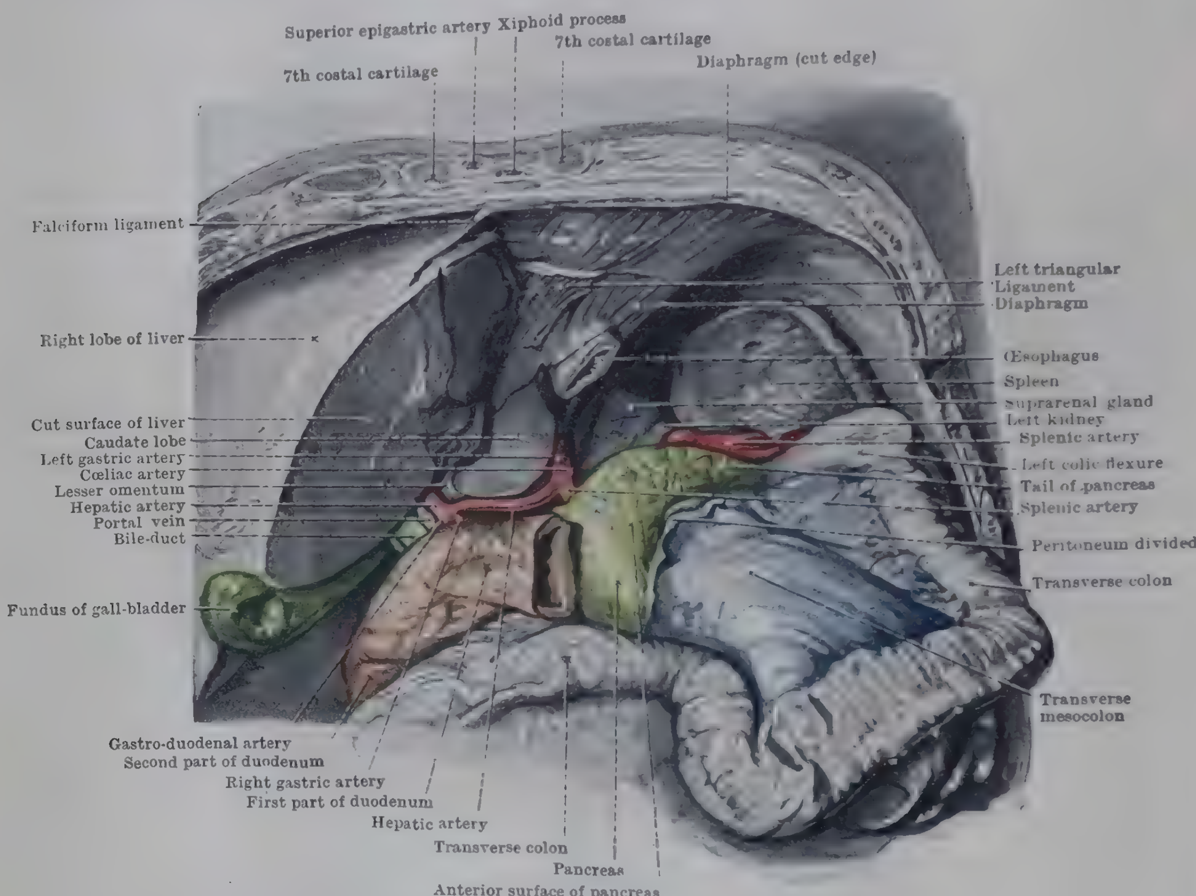

FIG. 524.—STOMACH-CHAMBER VIEWED FROM THE FRONT AND FROM BELOW.
From the specimen figured in Fig. 525, after removal of the stomach and lesser omentum.

left portion of the abdominal cavity with an arched roof, and an irregularly sloping floor. The *roof* is formed by the visceral surface of the left lobe of the liver and by the left cupola of the diaphragm.

The *floor* or "*stomach-bed*" (Fig. 524) is formed behind by the upper end of the left kidney (with the suprarenal gland) and the gastric surface of the spleen; and in front by the anterior surface of the pancreas and the transverse mesocolon.

Peritoneal Relations.—The stomach is almost completely covered with peritoneum—the anterior surface being clothed with that of the general peritoneal sac, and the posterior surface by the anterior wall of the lesser sac. The layers of peritoneum that clothe the front and the back of the stomach meet at the lesser curvature and extend to the liver as the two layers of the *lesser omentum.* They meet also along the greater curvature and pass away from the stomach as a wide fold, to different parts of which different names have been given—(1) the anterior two layers of the *greater omentum*, (2) the two layers of the *gastro-splenic ligament*, and (3) a small peritoneal fold, known as the *gastro-phrenic ligament*, which runs from the stomach up to the diaphragm along the left side of the œsophagus.

A small irregularly triangular area (about 2 inches wide and 1½ inches from above downwards during moderate distension of the stomach, on the posterior surface below and to the left of the cardia) is not covered with peritoneum, and over it the organ is in direct contact with the diaphragm, occasionally also with the upper end of the left kidney and the suprarenal gland (Fig. 538). From the left angle of that "bare area" the attachment of the gastro-splenic ligament starts; and at the right angle a fold begins through which the left gastric artery passes to the stomach. That fold is called the *left gastro-pancreatic* fold.

The *right gastro-pancreatic* fold of peritoneum passes from the right extremity of the upper border of the pancreas to the first part of the duodenum. It encloses the hepatic artery.

Structure of Stomach.—The wall of the stomach is composed of four coats—from without inwards: (1) serous, (2) muscular, (3) submucous, and (4) mucous (Fig. 526).

The **serous coat** is formed of the peritoneum, the relations of which to the stomach have already been described. It is closely attached to the subjacent muscular coat, except near the curvatures, where the connexion is more lax.

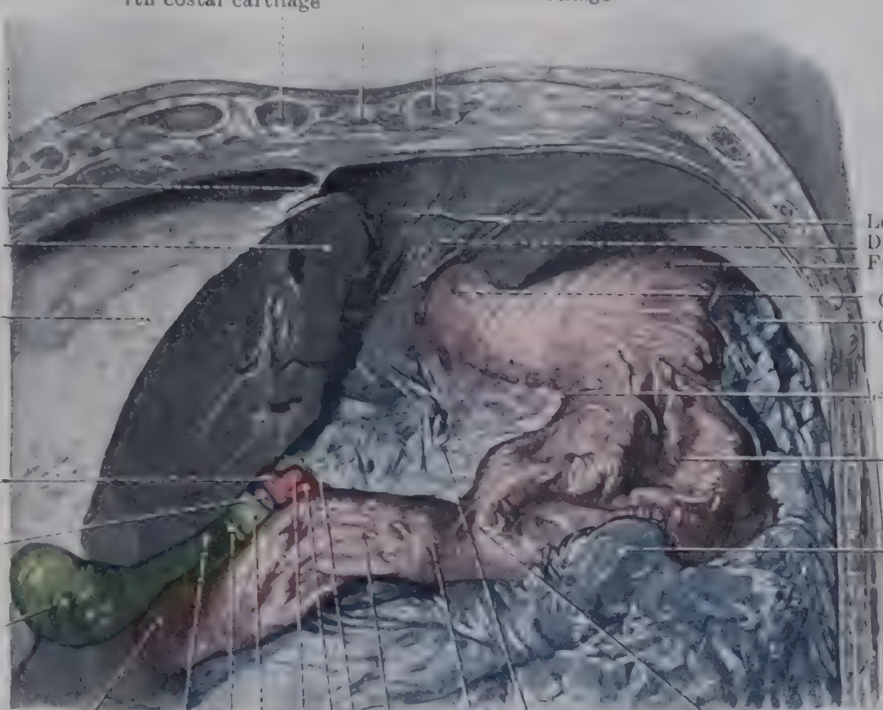

FIG. 525.—STOMACH WITH GREATER AND LESSER OMENTA *IN SITU*.

The left lobe of the liver has been removed, and also the anterior layer of the duodenal part of the lesser omentum. The view is taken looking upwards as well as backwards.

The **muscular coat**, composed of plain muscle, thinnest in the fundus and body, and thicker in the pyloric portion, is responsible for the production of the gastric movements in digestion. It is made up of three complete or almost complete layers:—an external longitudinal, a middle circular, and an internal oblique layer.

The *longitudinal layer*, continuous with the longitudinal fibres of the œsophagus, sweeps from the cardiac orifice along and on each side of the curvatures, particularly the lesser curvature, but is almost or entirely absent on the central parts of the anterior and posterior surfaces. On each side of the lesser curvature it forms two strong bands, many of whose marginal fibres turn aside and terminate, at intervals, in the deeper layers. Towards the pylorus the longitudinal fibres become much thicker, and also much tougher and more closely united, and they take part in the formation of the **pyloric sphincter** (see p. 610).

A specially condensed band of these can often be made out both on the front and back at the pyloric antrum, the form of which is said to be due to their presence. These bands are known as the *pyloric ligaments*.

The *circular layer*, continuous with the more superficial of the circular fibres of the œsophagus (Fig. 528), is a more complete layer; its fibres encircle the body from the

lesser to the greater curvature, and they are absent only from the fundus. In the wall of the pyloric canal they increase in thickness and pass into the pyloric sphincter. A marked thickening of the circular layer in this region is found in the condition known as congenital hypertrophic pyloric stenosis.

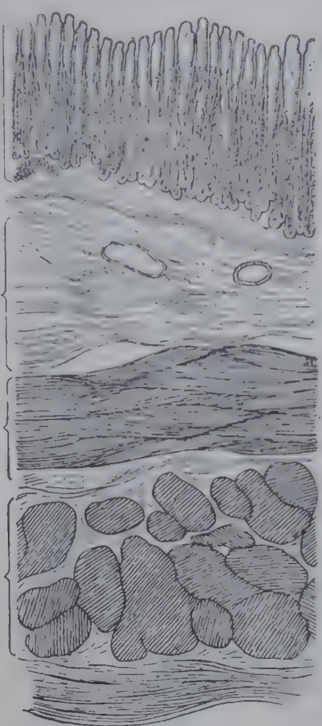

FIG. 526.—TRANSVERSE SECTION OF WALL OF HUMAN STOMACH IN REGION OF PYLORIC ANTRUM. (Diagrammatic.)

The *oblique fibres* form the inner layer and are continuous above with the deeper circular fibres of the œsophagus. They are arranged in U-shaped bundles which loop over the stomach immediately to the left of the cardia and run very obliquely downwards on both surfaces of the organ as far as the angular notch (Fig. 528). The looped fibres, as they pass to the left, gradually become less oblique, and they finally form circles around the wide end of the stomach as far as the fundus. These last fibres are sometimes ascribed to the circular layer.

The **submucous coat** is a layer of strong but loose areolar tissue which lies between the muscular and mucous coats and unites them (Fig. 526). It is more loosely attached to the muscular and more closely to the mucous coat, and it forms a bed in which the vessels and nerves break up before they enter the mucous membrane.

In the fresh state the **mucous coat** is of a reddish-grey colour and of moderate consistence. After death, the colour turns to a darker grey, and the whole membrane becomes softer and more pulpy. It is thicker (over 2 mm.) and firmer in the pyloric part than elsewhere, and it is thinnest at the fundus. When the stomach is empty the mucous coat is thrown into numerous prominent folds or *rugæ* which project into the interior. They are, in general, longitudinal in direction, with numerous cross branches.

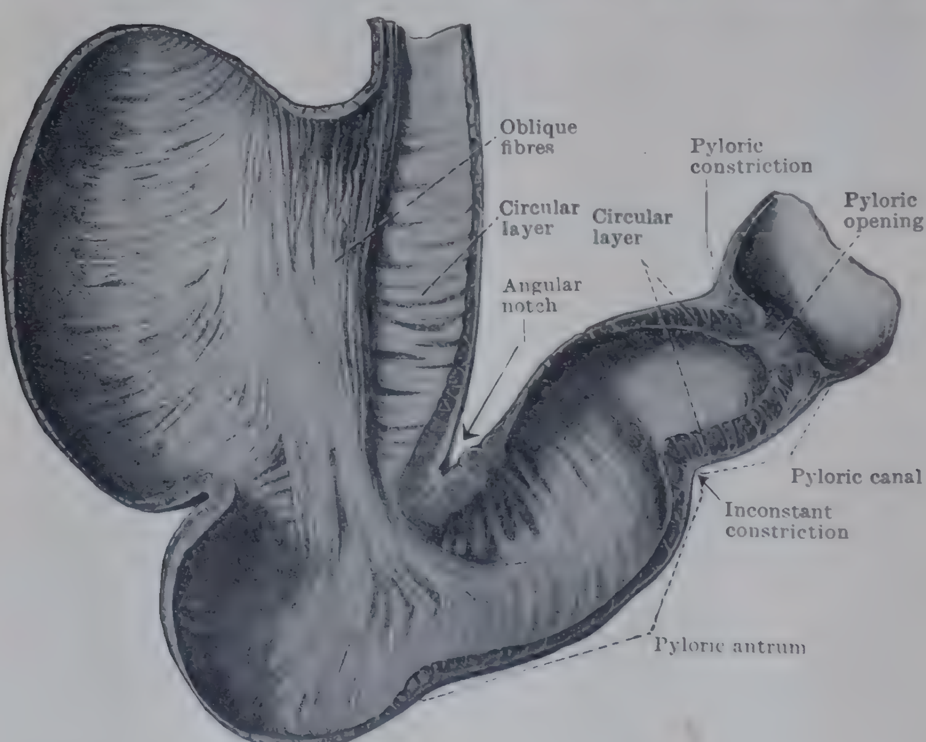

FIG. 527.—MUSCULAR COAT OF STOMACH, SEEN FROM WITHIN AFTER REMOVAL OF MUCOUS AND SUBMUCOUS COATS. (Cunningham, 1906.) The anterior half of the stomach is shown, viewed from behind.

They disappear when the stomach is distended. Along the lesser curvature there are three or four long, narrow, very constant ridges which pass without a break from the œsophageal orifice towards the pyloric part of the stomach (Fig. 520). They are parallel to one another, and are apparently never completely obliterated. Between them are deep

furrows which lead from the cardiac orifice to the pyloric portion of the stomach, and thus occupy the position of the 'gastric canal' of the foetus (Lewis, 1912). The view once held (Jefferson, 1915) that these mucosal gutters constitute a functional 'gastric canal', which is reinforced by the action of the oblique muscle fibres (Fig. 527), is no longer accepted (see p. 621).

When the surface of the mucous coat is examined in a *fresh* stomach, it is seen to be marked out into a number of small, slightly elevated polygonal areas by numerous linear depressions; the mucous membrane is consequently said to be mamillated (Fig. 529, A). These little areas, which measure from 1 to 6 mm. in diameter, show numerous small pits, about ·2 mm. wide, which are the mouths of the gastric glands, and they are so closely placed that the amount of surface separating them is reduced (particularly in the pyloric portion, where the gland-mouths are widest) to a series of elevated ridges that resemble villi on section. Although the gland-mouths cannot be seen with the naked eye, a very slight magnification is sufficient to show them clearly; it is also possible to see the gland-tubes leading off from the bottom of each (Fig. 529, B).

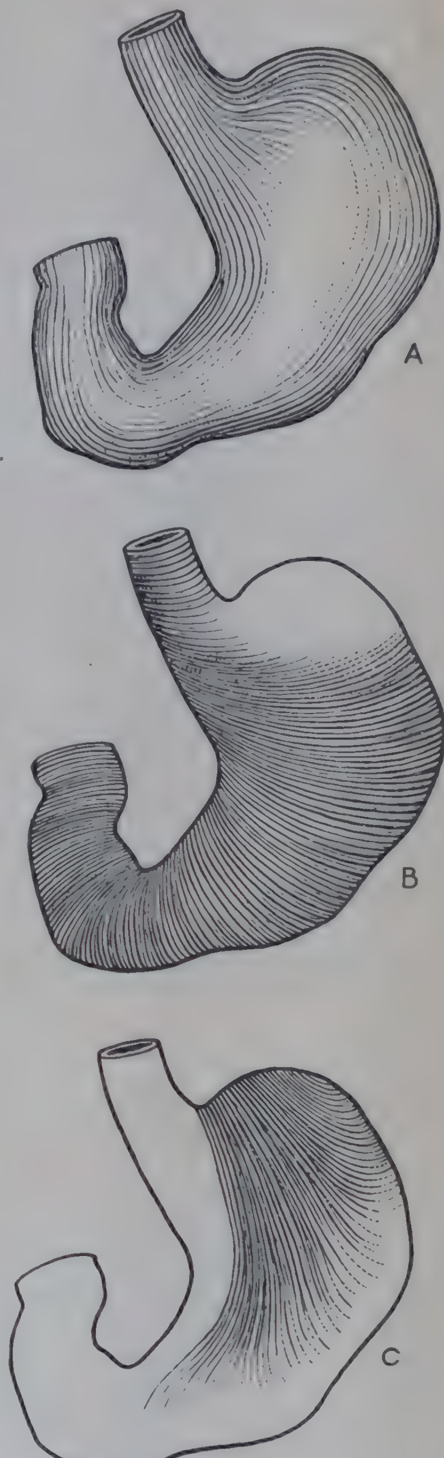

Fig. 528.—Three Diagrams of the Muscular Coats of the Stomach, to show Extent and Direction of Fibres composing them. A. Longitudinal layer whose fibres form an incomplete investment and are specially developed along the lines of the curvatures, especially the lesser. B. Middle circular layer, which forms a complete investment for the body and pyloric portion of the stomach. C. Oblique fibres which run obliquely to those of the other layers from the notch between the cardiac orifice and fundus on the anterior (and posterior) surfaces of the stomach and form an incomplete layer.

Minute Structure of Mucous Coat.—The mucous coat consists of an epithelial covering composed of long columnar cells, and of numerous tubular glands which are prolonged outwards and are enclosed in a delicate stroma of areolar tissue mingled with some small lymph-nodules. The bases of the glands reach outwards to the lamina muscularis mucosæ—a layer consisting of an external longitudinal and an internal circular layer of plain muscle-fibres.

Gastric Glands.—Each gastric gland consists of one or more secreting tubules which terminate in a duct. The duct is lined with columnar epithelial cells similar to those which cover the surface of the mucous membrane. Three varieties of glands are found in different regions of the stomach, and they are named from their position :—

(1) **Cardiac Glands** are situated close to the œsophageal opening. The duct of each ends in a single, long tubule lined with short columnar, granular cells.

(2) **Fundal Glands** are found in the fundus and body of the stomach. The duct of each ends in one or more tubules lined with polyhedral cells termed the *chief* or *central cells.* At intervals, between that layer of cells and the basement membrane, are placed large spheroidal cells, termed the *parietal* or *oxyntic* cells, which stain more deeply as a rule.

(3) **Pyloric glands** are found in the pyloric portion of the stomach. Each consists of a group of short but tortuous gland tubules which end in a short duct. The tubules are lined with short columnar or polyhedral cells similar to the central cells of the fundal glands.

Vessels and Nerves.—The **arteries** of the stomach are all derived ultimately from the *cœliac artery.* The *left gastric artery* arises from that trunk direct. Having reached the lesser curvature and given off an œsophageal branch, it divides into two branches which run along the front and the back of the lesser curvature and join with two similarly disposed arteries derived from the *right gastric* branch of the hepatic. From the two arches thus formed, four or five branches pass to each surface of the stomach and soon pierce the muscular coat. Along the greater curvature numerous branches reach the stomach from the *right and left gastro-epiploic arteries,* which are branches respectively of the gastroduodenal and the splenic; they run in the greater omentum close to its attachment to the

stomach. Finally, four or five *short gastric arteries*, branches of the splenic, are distributed to the fundus of the stomach, which they reach by passing forwards between the layers of the gastro-splenic ligament. At first the arteries lie beneath the peritoneum; very soon, however, they pierce the muscular coat, which they supply, and, reaching the submucosa, break up to form a close network of vessels. From these arise numerous small branches which enter the mucous membrane and form capillary plexuses around the glands as far as the surface.

The **veins** begin in the capillary plexuses around the glands; uniting, they form a network in the submucosa, from which branches arise that pierce the muscular coat and finally end in the following veins: the *right gastro-epiploic*, which joins the superior mesenteric; the *left gastro-epiploic* and four or five *short gastric veins*, which join the splenic; the *left gastric vein*, which runs along the lesser curvature from right to left, and ultimately joins the portal vein. These veins contain numerous valves which, though competent to prevent the return of blood in the child, are rarely so in the adult.

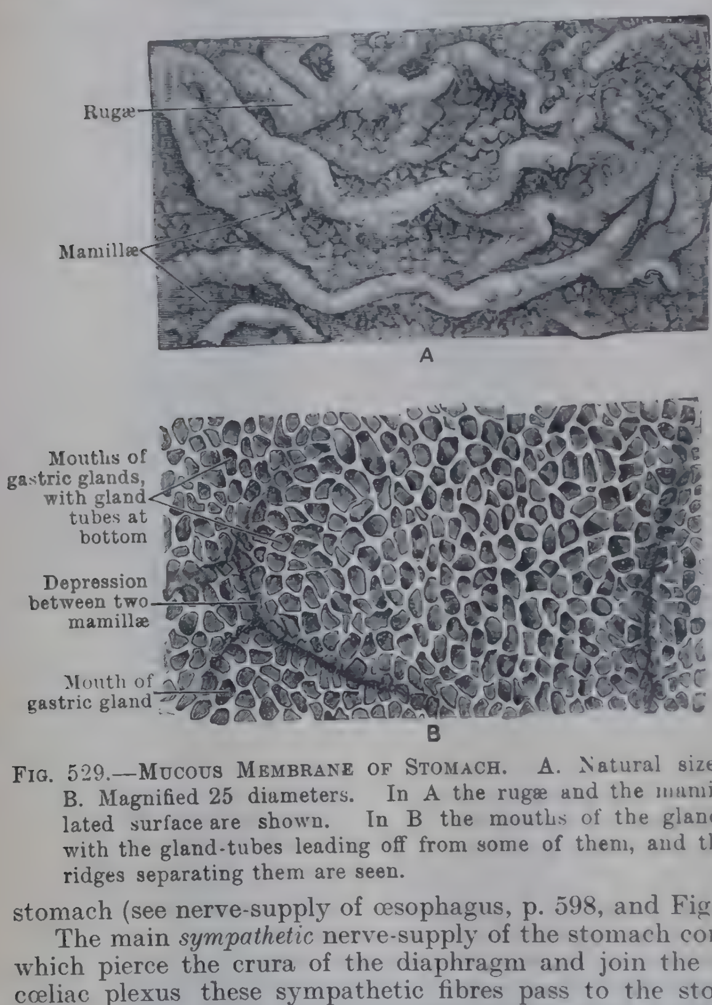

FIG. 529.—MUCOUS MEMBRANE OF STOMACH. A. Natural size; B. Magnified 25 diameters. In A the rugæ and the mamillated surface are shown. In B the mouths of the glands with the gland-tubes leading off from some of them, and the ridges separating them are seen.

The **lymph-vessels** of the stomach arise in an extensive plexus in the mucous membrane and join a subserous plexus from which efferent vessels arise. These are arranged in three main streams which pass to numerous glands situated on the branches of the cœliac artery.

The **nerves** are the *anterior* and *posterior gastric nerves*, which are distributed for the most part to the front and back of the stomach respectively. These nerves are derived from the œsophageal plexus, and the great majority of the fibres composing each of them are *parasympathetic* and come from both the right and left vagus nerves. A small number of *sympathetic* fibres also may come through the œsophageal plexus to the cardiac end of the stomach (see nerve-supply of œsophagus, p. 598, and Fig. 965, p. 1135).

The main *sympathetic* nerve-supply of the stomach comes through thoracic splanchnic nerves, which pierce the crura of the diaphragm and join the cœliac ganglia and plexus. From the cœliac plexus these sympathetic fibres pass to the stomach through finer extensions of this plexus which accompany the branches of the cœliac artery. These *left gastric, hepatic* and *splenic plexuses* also contain *parasympathetic* fibres which take a variety of routes to reach them (Dos Santos, 1931), but come for the most part from a branch of the posterior gastric nerve. This branch comes off the posterior gastric nerve soon after that nerve has entered the abdomen, and it runs down on the diaphragm to be distributed through the cœliac plexus.

For the manner in which the parasympathetic fibres are relayed in the *myenteric* and *submucous plexuses*, and for the terminal distribution of the sympathetic fibres see nerve-supply of the intestine, p. 624.

Radiographic Examination of Stomach.—Examination of the stomach by X-rays after a "barium meal" throws light upon its form and position and also upon the action of its muscular coats. This kind of examination has shown that there are permanent differences in the form and position of the stomach—especially in the level and direction of its pyloric portion—which seem to depend on the "bodily habitus" of the individual, as well as factors such as race, age, and sex. In addition, the stomach in its form reacts to the amount and character of an ingested meal, and to emotional and general health conditions. Fatigue and mental strain produce 'hypotony'—the greater curvature of the stomach showing a low position and less peristalsis (Wingate Todd, 1930). The form and position of the stomach are greatly influenced by the posture also, and are not the same when the person is standing or sitting up as when he is lying down, either supine or prone (Fig. 530).

The normal empty stomach is a contracted tubular organ with its walls in apposition except at the fundus, which always contains a bubble of air.

When a "barium meal" is taken, the barium first accumulates in the pyloric portion of the stomach and then the body becomes filled. With only a little barium the stomach appears

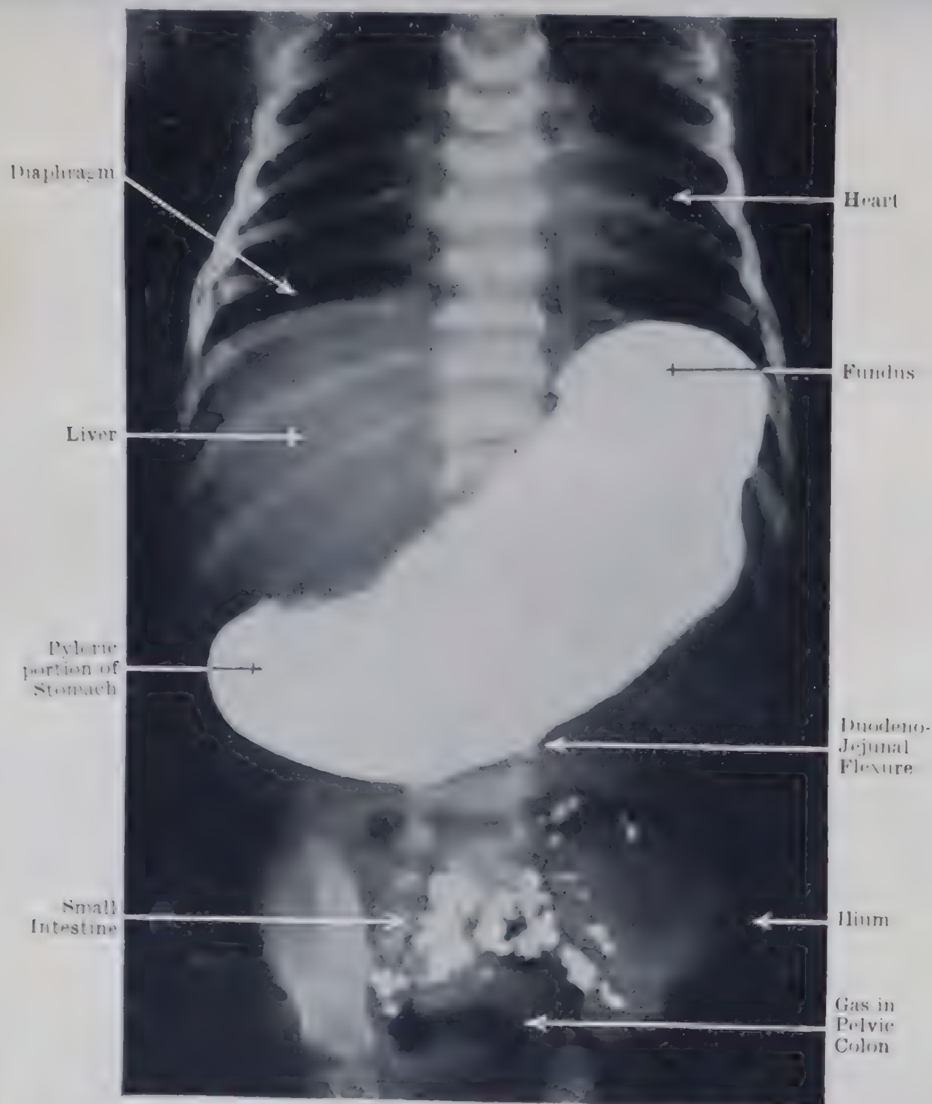

FIG. 1.—RADIOGRAPH OF STOMACH, FILLED WITH BARIUM, OF INFANT FIVE WEEKS OLD, SHOWING THE CHARACTERISTIC "STEER-HORN" FORM. (DR. G. G. ALLAN.) Compare with Fig. 2 and Plate LIV, Fig. 1, p. 613.

narrow and tubular, but as more barium is taken the whole organ becomes wider. If there is any secretion present, it forms in a layer above the barium. Above that again is the air-bubble, which is nearly always larger than before the meal because some air is usually swallowed with it. The air-bubble does not absorb X-rays, so that it appears black on the film.

If a patient with the usual J-shaped stomach is examined in the erect posture during the taking of the meal, the barium is seen to pass directly to the pyloric portion along the lesser curvature. It was believed at one time that this path taken by the barium is determined by the "gastric canal" mentioned on p. 619; but it is now accepted that it is due to gravity and that the musculo-mucosal arrangement in a longitudinal direction is functionally unimportant. If the stomach is moderately filled with water before the barium is taken, the barium still follows the lesser curvature while the patient remains in the erect posture. But if he inclines his body to the left, the barium is then seen to drop through the water—a proof that under these circumstances gravity determines its path.

In the barium-filled stomach peristaltic waves are clearly visible (Pls. LII, p. 609, LVI). They begin as shallow indentations of the greater curvature in the lower part of the body. They gradually deepen and involve the lesser curvature as they pass over the pyloric antrum and canal towards the pylorus. Preceding the ring of contraction there is a zone of relaxation; and, as peristalsis goes on, the pyloric orifice opens from time to time. Not every peristaltic wave forces barium through the pylorus, for the function of peristalsis is not merely to empty the stomach—it also serves to mix the digestive secretions with the food. The pyloric sphincter usually relaxes with every third or fourth peristaltic wave. The first sign that the pylorus is opening is the characteristic appearance of opaque material in the first part of the duodenum, known as the *duodenal cap* (Pl. LII).

In addition to the examination of the form and of the outline of the stomach, the mucosal folds or *rugæ* may be made evident by spreading a thin layer of barium over the mucous coat (Pl. LI, p. 608). In the fundus the rugæ form an irregular pattern, but in the body they run parallel to one another. Some of the folds pass from the posterior wall on to the anterior wall; and, as they turn over the greater curvature, they produce some irregularity of the outline of the stomach, especially if they are prominent.

The form and position of three well-recognized "types of stomach", as seen in the erect posture, may be studied in Plates LII, LIII, and LIV.

Plate LII represents the J-shaped stomach, by far the commonest "type of stomach" seen on the X-ray screen. On the lesser curvature, the angular notch is distinct, and on the opposite part of the greater curvature there is a wide, shallow temporary constriction produced by contraction of the circular muscle-fibres. Nearer the pylorus a peristaltic contraction is indicated by deep indentations opposite each other on the two curvatures. The position of the pyloric sphincter is shown by an abrupt interruption of the shadow of the barium. A thin streak passes through the sphincter and leads to a shadow, higher up, produced by opaque material in the first part of the duodenum —the *duodenal cap*.

Plates LIII and LIV, p. 612, represent two other "types of stomach" which are much less common but equally characteristic as seen on the X-ray screen. In both of them the body and the pyloric portion exhibit a more continuous curvature, and the pyloric canal is horizontal rather than vertical. Plate LIV, Fig. **1** is a radiograph of a stomach that lies almost transversely in the abdomen even in the erect posture: it is the so-called "steer-horn" type—see also Pl. LV, Fig. 2. In children, the stomach is characteristically of this type (Fig. **1**, Pl. LV). Plate LIII exhibits an intermediate form.

The lowest point of the body, the pylorus and the first part of the duodenum are at a much lower level in the J-shaped than in the other types of stomach. In the J-shaped the pylorus is often as low as the third lumbar vertebra and may be lower still; whereas in the intermediate and steer-horn types the pylorus is frequently in the "transpyloric plane" opposite the body of the first lumbar vertebra or the disc between the bodies of the first and second.

In the horizontal posture, the form and the position of the stomach are altered. The J-shaped stomach hangs less vertically, the lowest part of the greater curvature moves upwards, and the stomach comes to resemble the other types which even in the erect posture are more in the position shown in the cadaver (Fig. 525). The duodenal cap may be hidden by the rise of the pyloric portion of the stomach, which ascends in front of it, and the first part of the duodenum is horizontal instead of almost vertical as it is in the erect posture.

X-Ray examination shows that the position of the stomach is influenced also by the condition of the abdominal muscles. Contraction of these muscles can elevate the stomach as a whole and the change from the horizontal to the erect posture alters

the height of the inferior border. The sinking which occurs in the alteration from the horizontal to the erect posture accounts partly for the differences between the stomach seen in the post-mortem room or on the operating table and the stomach displayed by means of X-rays in the living person standing erect.

That the position of the digestive organs in healthy living persons is much more variable than might be supposed from their examination in the horizontal cadaver is illustrated by the observations made by Moody, van Nuys & Kidder (1929) on students in California

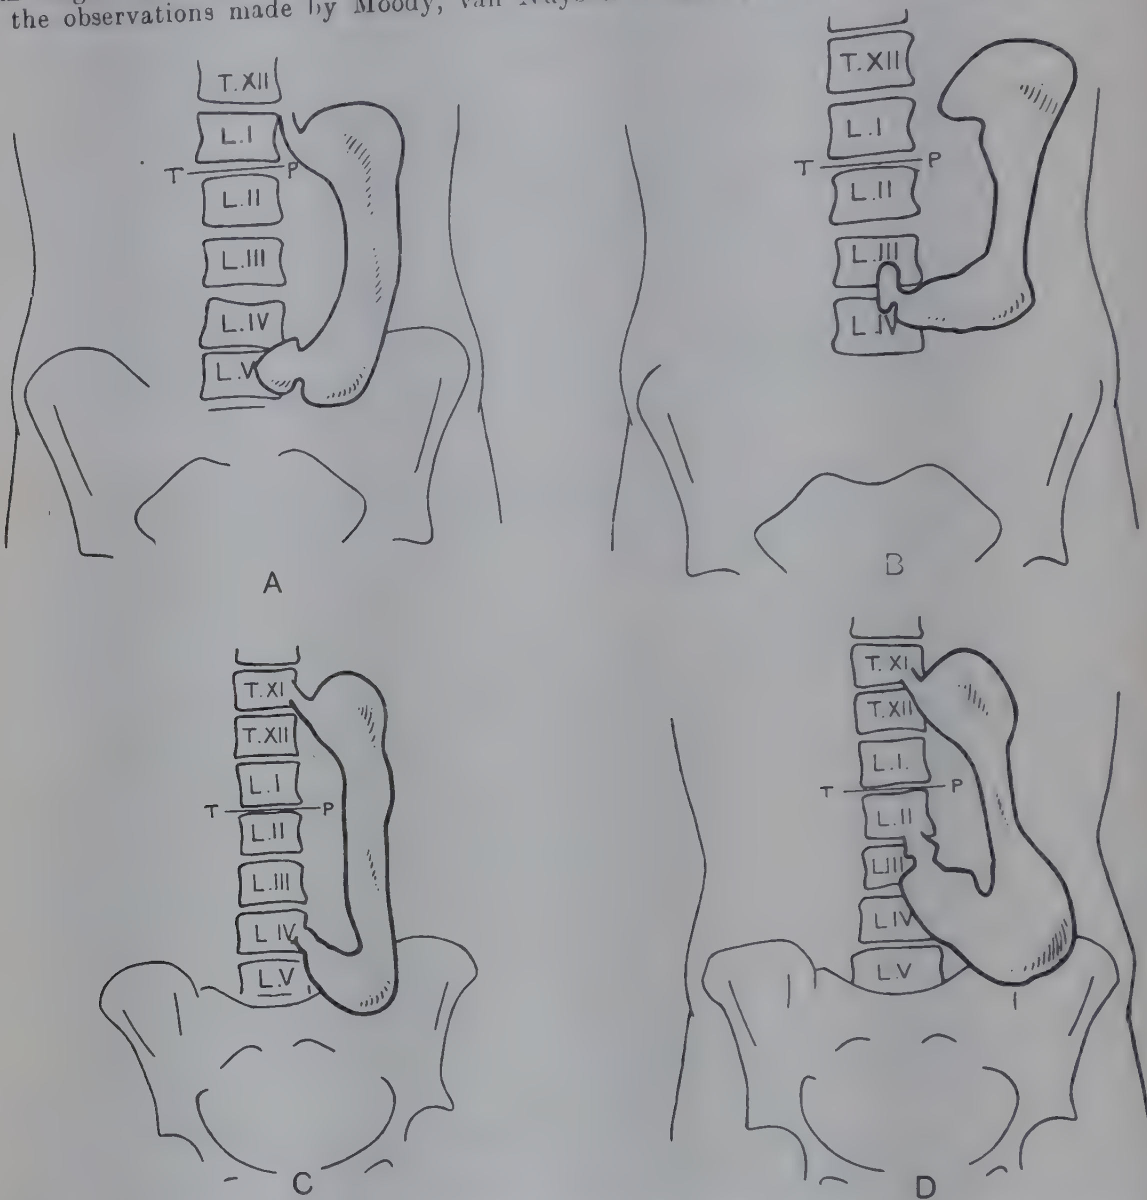

FIG. 530.—TRACINGS OF OUTLINES OF STOMACH AS DEFINED BY X-RAY EXAMINATION. (After Moody, Van Nuys, & Kidder, 1929.) A. Empty stomach, subject erect, the form of the stomach a 'reverse L', with short horizontal arm; lowest part of the greater curvature 5 cm. below the plane of the iliac crests opposite the upper half of the first sacral vertebra. B. Same stomach, subject prone. C. Empty stomach, subject erect, pylorus opposite the fourth lumbar vertebra. D. Same stomach, subject prone, pylorus opposite the third lumbar vertebra. (From the *Anatomical Record*, by permission of the Wistar Institute.)

and London. They confirm the view that in the living the form and position of the stomach vary in different people and in the same person with changes in posture, and that the individual variations which may occur are of wide range. The observations may be briefly summarized as follows:—The pylorus, for example, may lie as high as the upper half of the twelfth thoracic vertebra or as low as the upper half of the fifth lumbar vertebra, and it may lie below the 'inter-iliac line' or plane of the iliac crests, when the subject is erect, supine, or prone. It may lie in the median plane, or to the right or to the left of it, though the position to the left (as shown in Fig. 530) is uncommon. Similarly, the position of the greater curvature of the stomach varies widely, and it may be seen even in the pelvis (Pl. LIV, Fig. 2, p. 613).

Associated with those different positions of the pylorus there is a difference in the position of the first part of the duodenum and in its relation to the head of the pancreas.

Moody has found also that in the living subject standing erect, "the common position of the cæcum is not in the iliac fossa, but in the cavity of the true pelvis".

He finds a similar difference in the position and form of the liver in the living person, and

that its lower border extends below the inter-iliac plane in 50 per cent of males and in 34 per cent of females. Its position and vertical dimensions are greatly influenced by posture; the "excursion" or range of movement of the lower margin with change of posture is usually from 2 to 3 cm. but may be as much as 9 cm. He finds also that "there seems to be no definite relation between the position of the liver and that of the stomach; the liver may be low and the stomach high, or the liver high and the stomach low". (See also Barclay, 1936.)

INTESTINES

The remaining portions of the alimentary canal—from the stomach to the anus—are called the *intestines*, and are divided into two main parts called the small intestine and the large intestine. The **small intestine** succeeds the stomach and is disposed in coiled loops throughout the abdomen proper and the pelvis. It is divided into three parts: the *duodenum*, which is continuous with the pylorus, the *jejunum*, and the *ileum*, which joins the large intestine in the right iliac fossa. The **large intestine** begins in that fossa, takes an arched course round the coils of the small intestine, passes over the left side of the pelvic brim into the pelvis, and ends at the anus. Its commencement is called the *cæcum*, to which a small worm-like structure called the *vermiform appendix* is attached; the cæcum is succeeded by the *colon*, which is by far the longest part of the large intestine and is itself divided; it passes into the pelvis to become continuous with the *rectum*, which is succeeded by the *anal canal*—the terminal inch and a half of the bowel.

Though they have the contrasted designations of "small" and "large" because the small intestine is usually of narrower calibre than the large intestine, yet it is not invariably narrower, and it is very much longer. They have the same general structure of serous, muscular, submucous and mucous coats (see below), but there are certain obvious differences between them. The small intestine is uniformly smooth and, with the exception of the duodenum, has a complete coat of peritoneum. Its longitudinal muscular coat is uniformly distributed around its circumference. The greater part of the large intestine—in fact, the whole colon—is puckered and sacculated, and, excepting the cæcum and the middle and terminal parts of the colon, it has only a partial coat of peritoneum. Another obvious and characteristic difference from the small intestine is that all over the colon little pockets of peritoneum filled with fat hang from its surfaces; these are called *appendices epiploicæ*, and their significance is obscure.

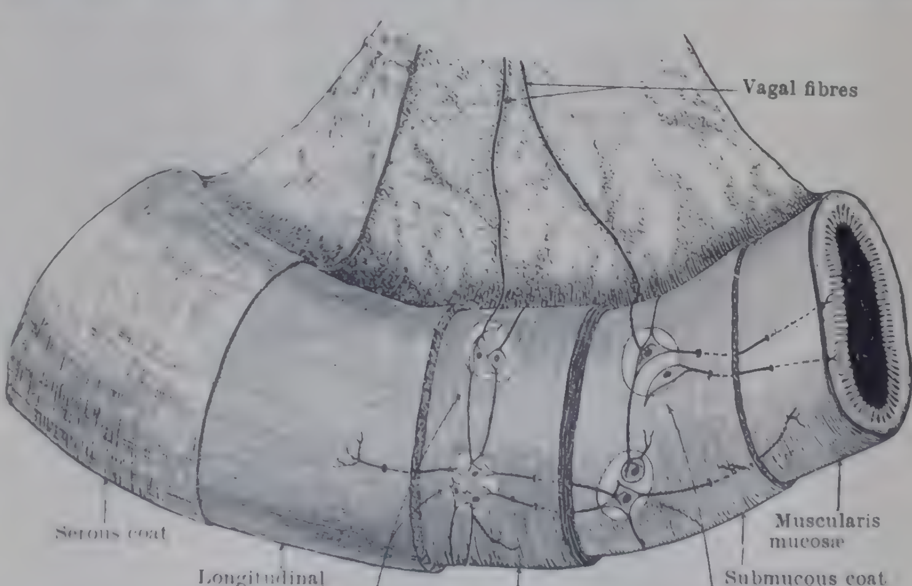

Fig. 531.—Diagram of Connexions and Distribution of the Enteric Plexuses. (After C. J. Hill, 1927.)

Characteristic of the large intestine, as far down as the rectum, is the arrangement of the bundles of longitudinal muscle. They are grouped into three obvious bands, termed the *tæniæ coli*, but in the intervals between these bands, according to Hamilton (1946), the longitudinal muscular coat is present as a definite layer "a little less than one-half the thickness of the circular coat".

The sacculated appearance is often well seen in radiographs of the abdomen, when the gut is filled with material opaque to X-rays (Pls. XLVIII, LVII, LVIII, LIX, LX, pp. 559, 648, 649).

Structure.—Both small and large intestines have four coats—serous, muscular, submucous, and mucous. The external *serous coat* forms a complete or a partial covering in different parts. The underlying *muscular coat*, formed of two layers of plain muscle—an outer longitudinal, and an inner, whose fibres are circular or ring-like—is separated by the submucous coat from the mucous coat, which lines the interior of the canal. It has been stated (Carey, 1921) that in the small intestine of many mammals the muscular layers are not truly circular or longitudinal, but are both spiral, the inner coat forming a close spiral and the outer a long one. In the inner coat one complete turn is made in every 0·5 to 1 mm. or less, while those of the outer coat which are spiral make a complete turn in every 200 to 500 mm. or more. The *submucous coat* consists of a layer of loosely arranged but strong areolar tissue. The *mucous coat* shows three layers of component tissue, viz., internally a layer of columnar epithelium, which may be more than one layer of cells in thickness and rests on a thin layer of loose areolar tissue, external to which there is a thin sheet of plain muscle called the *lamina muscularis mucosæ*. The internal surface of the mucous coat shows the openings of an enormous number of *intestinal glands*—small straight tubular glands—whose closed ends lie in the deeper part of the mucous coat. The internal surfaces of the small and large intestines differ from one another in many respects, and especially in that the mucous coat of the

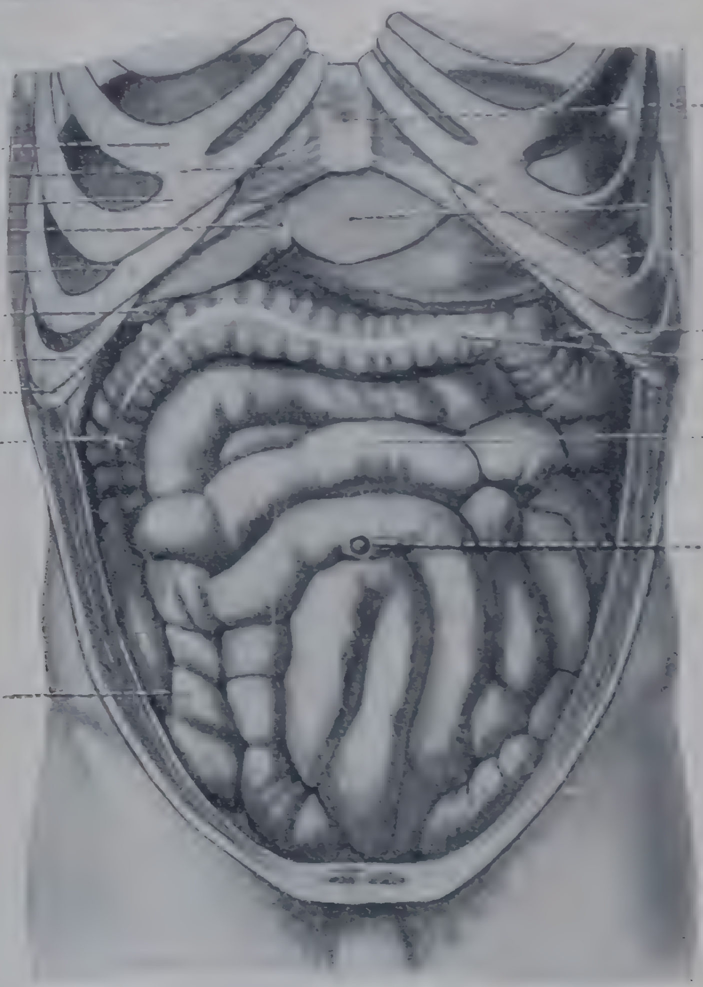

FIG. 532.—ABDOMINAL VISCERA, AFTER REMOVAL OF GREATER OMENTUM.
The oblique position of the stomach and the high position of the transverse colon are largely due to the fact that the subject was fixed in the horizontal position.

small intestine is covered with villi, is thrown into permanent folds, and has in its substance aggregated as well as solitary lymphatic nodules.

Nerves.—The intestine has a rich supply of nerves belonging to the sympathetic and parasympathetic systems. *Sympathetic* fibres are distributed to the whole of the intestine as far as the rectum through the cœliac, the superior and the inferior mesenteric plexuses, and along finer extensions from these major networks which accompany the branches of the blood-vessels. The source of the sympathetic fibres which run through the cœliac and superior mesenteric plexuses, namely the thoracic splanchnic nerves, is supplemented for the lower part of the colon mainly by splanchnic branches from the upper two lumbar ganglia of both sides. These run downwards and forwards to join the inferior mesenteric plexus, and they are probably more important than other fibres which may reach the inferior mesenteric plexus through the hypogastric and pelvic plexuses from ganglia of the sympathetic trunks at a lower level (Telford and Stopford, 1934).

The sympathetic fibres are accompanied in their course through the plexuses by *parasympathetic* vagal fibres which pass to the cœliac plexus from the posterior gastric nerve (see nerve-

upply of stomach p. 620). Other parasympathetic fibres reach the inferior mesenteric plexus rom the pelvic splanchnic nerves (S. 2 and 3, or 3 and 4) by ascending through the pelvic and ıypogastric plexuses.

The nerves to the intestine thus constituted do not all follow the blood-vessels slavishly, nd Mitchell (1935) has described, in particular, a number of branches from the pelvic and hypogastric plexuses which take an upward, independent course across the lower left colic vessels o the descending and pelvic colons. These nerves communicate with the perivascular plexuses, nd he considers that they are probably important parasympathetic pathways to the distal colon.

On reaching the intestine the *parasympathetic fibres*, which are preganglionic and of uniform liameter, pierce the longitudinal muscle coat and some of the fibres end by synapsing round he cells of the ganglia of the *myenteric plexus*, whilst other fibres continue onwards and form imilar connexions in the *submucous plexus*. From the cells of the myenteric plexus postganglionic fibres run through the network and eventually end on the muscle-fibres of both the ongitudinal and the circular muscle coats (Fig. 531). From the cells of the submucous plexus ostganglionic fibres reach the lamina muscularis mucosæ and muscle-fibres in the villi; some f these vagal fibres also reach the intestinal glands.

The *sympathetic fibres*, on the other hand, are postganglionic when they reach the intestine, ıaving been relayed in the cœliac and other ganglia of the plexuses, and they are varicose and hinner than the vagal fibres. According to Hill (1927), whose work was done on rabbit and uinea-pig material, the majority of the sympathetic fibres are distributed to the blood-vessels f the intestinal walls. In the case of the stomach and colon, a few fibres pass to a special plexus mmediately internal to the myenteric plexus; and, in the case of the small intestine, some join the ıyenteric plexus itself, where they become indistinguishable from the postganglionic vagal fibres.

Other sympathetic fibres form fine, scattered plexuses in the subserous and submucous layers, eaching from the latter into the subepithelial layer of the villi (Fig. 533). These are probably ensory in nature. The stimuli to which they respond are stretching of the gut, strong musclecontraction, and probably also the toxins and tensions of inflammation. These stimuli may xcite reflexes, or they may give rise to painful sensations, referred for the most part to that egion of the abdominal wall which has a somatic nerve-supply corresponding segmentally to hat of the part of the intestine affected by the stimulus. The whole of the intestine, however, xcept the anal canal, is quite insensitive to other stimuli which, when applied to most of the ther parts of the body, give rise to pain.

SMALL INTESTINE

The **small intestine** (intestinum tenue) commences at the pylorus and ends at he ileo-colic valve by joining the large intestine. It occupies the greater portion f the abdominal cavity below the liver and stomach (Fig. 479), and part of it ies in the pelvic cavity.

In *length*, the small intestine usually measures some 20 to 22 feet. In form it s cylindrical, with a *diameter* that varies from nearly two inches (47 mm.) in the uodenum to a little over an inch (27 mm.) at the end of the ileum; there is thus gradual diminution in its size from the pylorus to the ileo-colic valve.

The small intestine is relatively longer in the child than in the adult; at birth it is to the total eight of the child as 7 to 1, whilst in the adult the proportion is as 4 to 1. It is generally eld that the small gut is relatively longer in the male than the female.

While the entire length of the intestine in its most extended form after death, when muscular onus has disappeared, may be 20 to 22 feet as stated, it is probable that during life the length s not so great. The muscular coats, both longitudinal and circular, are more or less contracted, nd probably the total length during life may be estimated as 15 to 17 feet.

In formalin-hardened bodies the small bowel rarely measures more than 12 or 13 feet in ength. Similarly its diameter is often reduced in places to ½ or ¾ inch (12 to 18 mm.), lthough the greater part of the gut may retain its usual width: these narrow parts have pparently been fixed in a state of contraction.

The small intestine is divided into three parts—(1) the **duodenum** (Fig. 537), onstituting the first ten inches, distinctly marked off from the rest by its xation and the absence of a mesentery; (2) the **jejunum**, which comprises the pper two-fifths of the remainder, and (3) the **ileum**, the lower three-fifths. The ejunum and ileum pass imperceptibly into each other, and the line of division etween them is artificial. Typical parts of the two—namely, the beginning of he jejunum and the end of the ileum—differ in size and in the appearance resented by their lining mucous membrane, and they can be distinguished from ach other without difficulty (see p. 635).

The characteristic features of the small intestine are found on its inner surface n special developments of its mucous coat: they are (1) intestinal villi; (2) ircular folds; and (3) aggregated lymphatic nodules.

Intestinal Villi.—The mucous coat of all parts of the small intestine has a soft, velvety appearance (Fig. 534, B) which is due to the presence of an enormous number of minute processes known as villi.

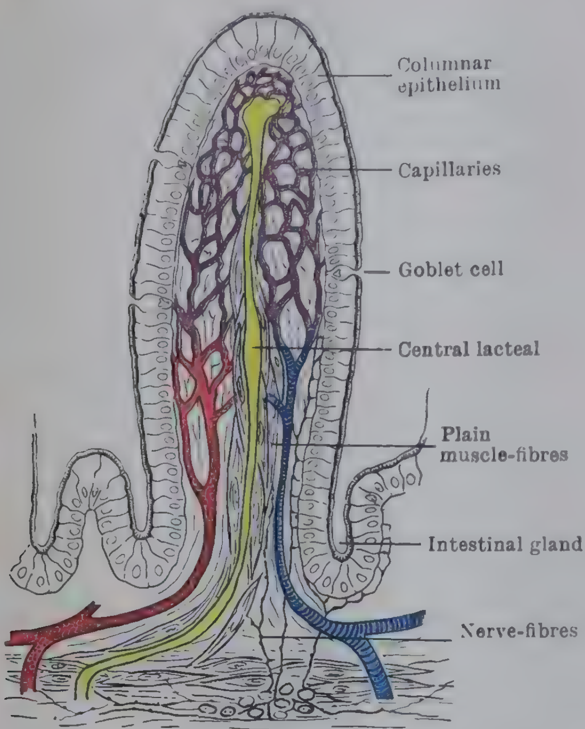

FIG. 533.—STRUCTURE OF AN INTESTINAL VILLUS. (Diagrammatic.)

They are minute, cylindrical or finger-like projections of the mucous coat (Fig. 535) about $\frac{1}{20}$th to $\frac{1}{50}$th of an inch (1·2 to 0·5 mm.) in height, barely visible to the naked eye. They begin at the edge of the pyloric orifice and are broad and short in the duodenum, but grow narrower as they are followed down through the intestine to the ileo-colic valve, at the edge of which they cease. They are found not only on the general surface of the mucous membrane but also on the circular folds, and, while they are not present over the solitary lymphatic nodules, they are found on the surface of the aggregated nodules.

Structure of Villi.—Each villus is covered by a layer of columnar cells set upon a basement membrane. These cells have a finely striated border, and goblet cells are interspersed amongst them. The core of a villus has a fine reticulum of connective tissue cells and fibres, with strands of smooth muscle-fibres that run parallel to the axis of the villus and have their origins in the muscularis mucosæ (Fig. 533).

In the centre of each villus there is a channel lined with flattened endothelium, known as the *central lacteal*, which drains into the lymph-vessels of the mucosa ; there may be several lacteal vessels within the larger villi. One or more arteries enter the base of the villus and break up into a dense capillary network which lies under the epithelium and surrounds the whole surface of the structure. The venous drainage is into the submucous plexus. A subepithelial nerve-plexus and nerve-fibres running from the submucous plexus to the muscle-cells have been described by Hill (1927).

Dilatation of the blood-vessels causes enlargement of the villus, while contraction of the muscle-layer diminishes its height and serves to assist in emptying the lacteal into the lymph-vessels. The villi thus play an important part in the absorption of the products of digestion. According to Spanner (1931) there is an arterio-venous anastomosis in each villus which acts as a by-pass when absorption is not active.

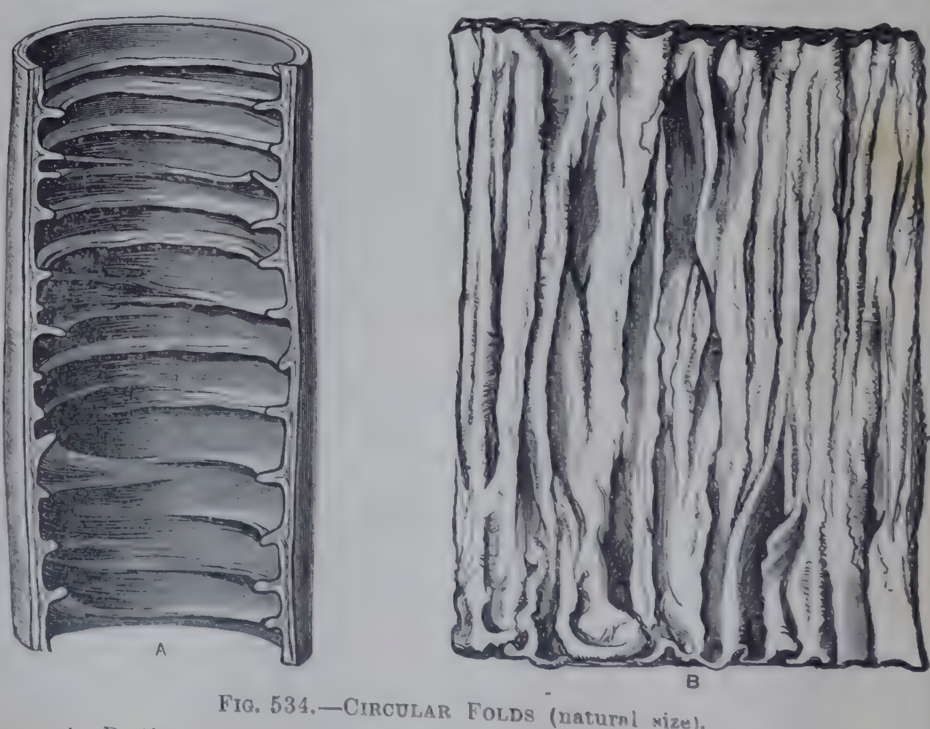

FIG. 534.—CIRCULAR FOLDS (natural size).
A. Portion of jejunum which has been filled with alcohol and hardened ;
B. Portion of fresh intestine spread out under water.

Circular Folds.—When the intestine is empty and contracted, its mucous membrane is thrown into folds which disappear on distension. In addition to

these, there are in certain portions of the small intestine a series of large, permanent folds, known as circular folds (Fig. 534). They are usually more or less crescentic folds of the mucous coat, with a prolongation from the submucous coat, and resemble a series of closely placed shelves running transversely around the gut. They rarely form more than two-thirds of a circle; sometimes, however, they present a spiral arrangement, the spiral extending little more than once round the tube, as a rule. Occasionally they bifurcate at one or both ends; sometimes, too, short irregularly directed branches pass off from them. They are usually about 2 to 3 inches (5 to 7·5 cm.) in length, and their height, that is, their projection into the cavity, may be as much as $\frac{1}{3}$ of an inch (8 mm.), whilst in thickness they measure about $\frac{1}{8}$ inch (3 mm.).

They increase the amount of surface available for secretion and absorption.

Circular folds begin at a distance of from 1 to 2 inches (2·5 to 5 cm.) beyond the pylorus. At first they are small, irregular, and scattered; but they are larger lower down, and at the opening of the bile-duct (4 inches from the pylorus) they are distinct and prominent. In the rest of the duodenum, and in the upper half of the jejunum, they are highly developed, being large, broad, and closely set. In the lower half of the jejunum they become gradually smaller and fewer. In the ileum they become still smaller and more irregular, and, as a rule, they practically cease a little below its middle, but though much reduced in size they can be traced to within a short distance of the ileo-colic valve.

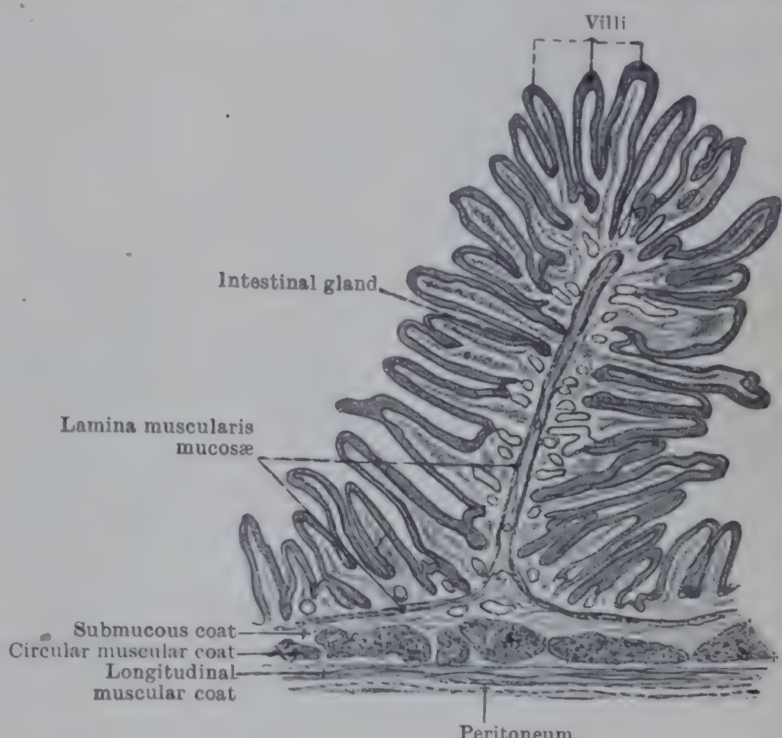

Fig. 535.—Longitudinal Section of Wall of Small Intestine passing transversely through a Circular Fold.

Lymphatic Nodules.—The **solitary lymphatic nodules** are minute masses of lymphoid tissue, opaque and of a whitish colour, which project on the surface of the mucous membrane throughout the whole length of both the small and the large intestine.

Isolated lymph-cells are found in abundance scattered through the areolar tissue layer of the intestinal mucous membrane generally; in places these cells are gathered together to form little nodules, supported by a framework of reticular tissue and surrounded by a lymph-space which communicates externally with the lymph-vessels of the submucous coat. Such a collection of lymph-cells constitutes a solitary nodule. They are usually of a rounded or oval shape (Fig. 536), the deep surface resting in the submucous coat, the nodule itself piercing the lamina muscularis mucosæ, and the free surface projecting slightly above the general surface of the mucous membrane. In size they vary from $\frac{1}{40}$th to $\frac{1}{8}$th of an inch (0·6 to 3·0 mm.), but their average bulk is about that of a small grain of sago, to which they bear some resemblance. They are particularly abundant in the vermiform appendix and the cæcum.

The **aggregated lymphatic nodules** consist of a large number of minute lymphatic nodules grouped closely together and forming a slightly elevated area, usually of an oblong form, on the surface of the mucous membrane (Fig. 536). In length they vary from half an inch (12 mm.), or less, to three or four inches (100 mm.), and in width they commonly measure from a third to half an inch (8 to 12 mm.). Their number is variable, but in the average condition about

20 or 30 are found. They are best marked in young subjects, where they form considerable elevations above the general surface and may be as many as 45 in number. After middle life they atrophy, and in old age, although usually present, they are indistinct. Occasionally their positions are marked by little more than a dark discoloration of the mucous membrane. They are situated along the surface of the intestine opposite the line of mesenteric attachment, with their long axis corresponding to that of the bowel.

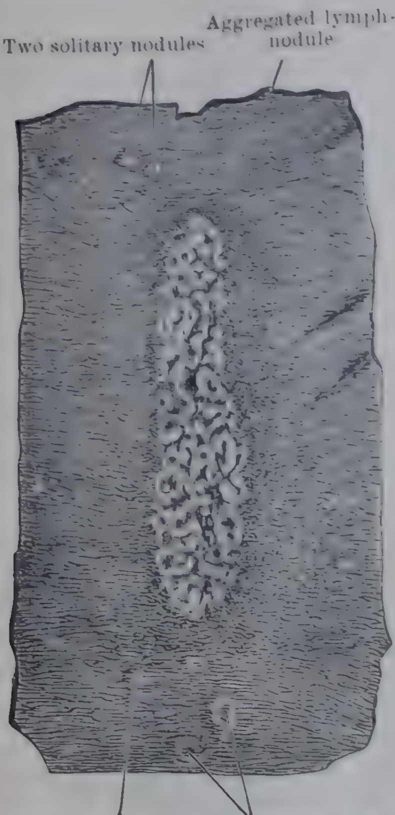

FIG. 536.—SOLITARY and AGGREGATED LYMPHATIC NODULES FROM ILEUM OF CHILD TWO YEARS OLD (natural size).

Near the lower border are seen a few small patches made up of two or three lymphatic nodules; they are marked "intermediate form".

The aggregated nodules are confined to the small intestine, being largest and most numerous in the ileum, particularly in its distal part, where they usually assume an oblong shape; in the distal half of the jejunum they are small, circular, and few in number; in its proximal part they are much less numerous: and in the duodenum only a few can be found.

The circular folds stop at the margins of the aggregated nodules, and are not continued across them; but villi are found on the surface of the aggregated nodules, in the intervals between the individual nodules.

The chief bowel lesion in typhoid (enteric) fever is found in the nodules—both aggregated and solitary.

When the surface of one of those nodules from a child's intestine (in which these structures are particularly well developed) is carefully examined, it is seen to be made up, not of a series of separate, rounded nodules grouped together but rather of a number of wavy, irregular, and branching ridges connected with one another by cross-branches, the whole recalling in miniature the appearance of a relief map of a very mountainous district in which the chief chains run irregular courses and are joined to one another by connecting ridges.

Small patches, intermediate in form between solitary and aggregated nodules, and consisting of two or three lymphatic nodules, are also found.

DUODENUM

The **duodenum** is the first part of the small intestine, and it differs from the rest of the tube in that, having no mesentery, it is fixed to the posterior abdominal wall. The ducts of the liver and pancreas open into it, and some distinctive glands, termed the *duodenal glands*, are found in its wall.

Position, Shape, and Dimensions.—The duodenum begins at the pylorus about the level of the first lumbar vertebra, and it ends at the **duodeno-jejunal flexure** on the left side of the second lumbar vertebra (Fig. 537). It lies on the posterior wall of the abdomen opposite the upper three lumbar vertebræ, and, with the exception of its terminal part, it lies to the right of the median plane.

It forms an irregular horseshoe-shaped curve, with the opening directed upwards and to the left, and the ends reaching to within about two inches of each other. Within the concavity of the curve lies the head and neck of the pancreas.

The duodenum is about 10 inches (25·0 cm.) in length, and it has a diameter of from $1\frac{1}{2}$ to 2 inches (3·5-5·0 cm.).

Various Forms of Duodenum.—Three different types of duodenum have been described—(1) the **annular,** in which the curves separating the various parts are open, and the two extremities come fairly close to one another; (2) the **U-shaped,** in which the third part is very long, and the fourth part is nearly vertical; and (3) the **V-shaped** duodenum, in which the third part is very short or absent.

Divisions and Relations.—For descriptive purposes the duodenum is divided into four parts, viz. :—(1) A *first* part, which passes from the pylorus obliquely backwards, to the right and slightly upwards. (2) A *second* part, which descends vertically. (3) A *third* part, which is directed horizontally from right to left. (4) A *fourth* part, which ascends vertically or with a slight obliquity to the left to end in the duodeno-jejunal flexure.

First Part.—The first part is about 2 inches (5·0 cm.) long, and it has a considerable degree of mobility. Its commencement is sometimes indicated by a slight groove, and there is always a sudden transition that can be felt between the thick walls of the pylorus and the thin walls of the duodenum. For the first inch of its course, the first part of the duodenum has the same peritoneal relationships as the pyloric part of the stomach. Thus, it is suspended from the liver by the lesser omentum, whilst from its

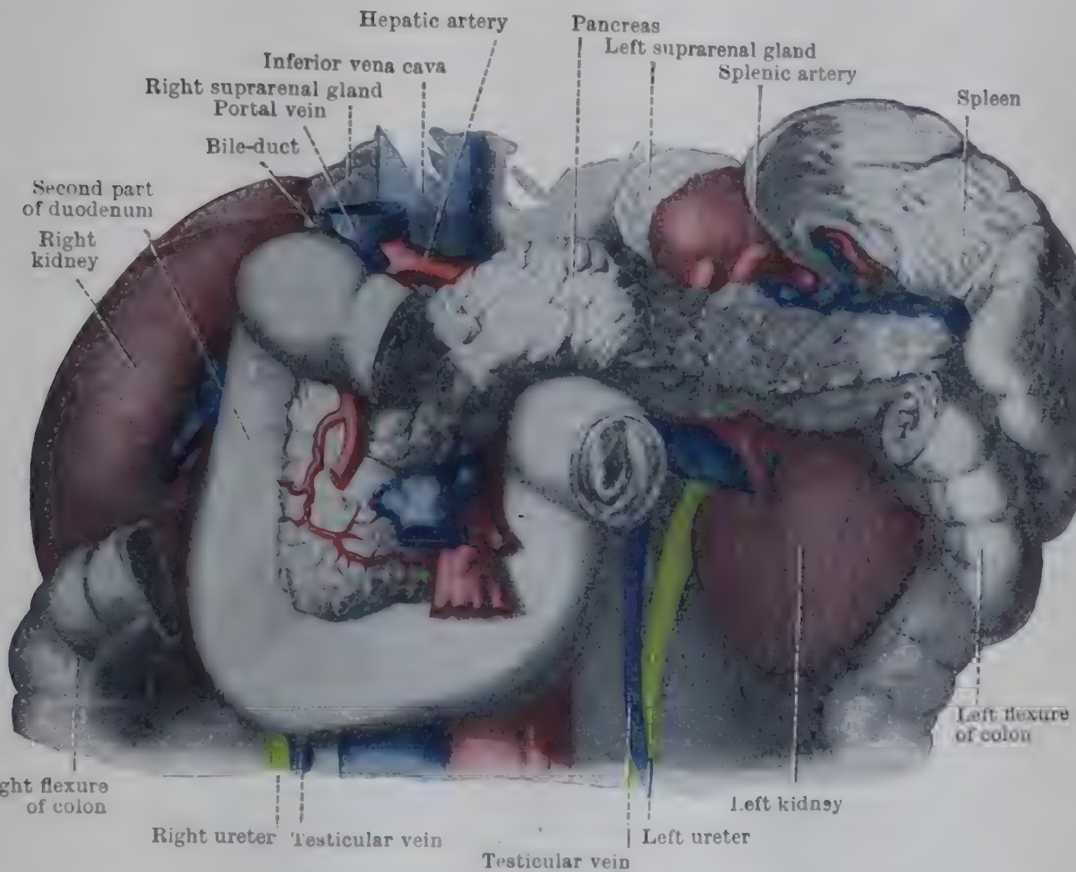

FIG. 537.—DISSECTION TO SHOW RELATIONS OF DUODENUM. The stomach has been cut and removed close to the pylorus. The transverse colon has been taken away, and the small intestine has been cut across close to the duodeno-jejunal flexure. (From a model by Birmingham.)

lower border hangs the right edge of the greater omentum. The *anterior surface* is covered with peritoneum and looks into the greater sac, where it comes into relation with the quadrate lobe of the liver and the body of the gall-bladder. The closeness of this contact is often indicated in the cadaver by a staining of the duodenum with bile which has escaped through the walls of the gall-bladder. The *posterior surface* of the first inch also is covered with peritoneum, and it looks backwards into the lesser sac, which separates it from the neck of the pancreas.

The second inch or so of the first part of the duodenum curves backwards and is covered with peritoneum on its superior and lateral surfaces only. Its medial surface is directly related to the portal vein, bile-duct, and gastro-duodenal artery (Fig. 537), and its inferior surface rests on the head of the pancreas. The lateral surface is related to the neck of the gall-bladder and the superior surface is the lower boundary of the opening into the lesser sac, which separates it from the caudate process of the liver. In order to enter the attachment of the right border of the lesser omentum the hepatic artery runs horizontally forwards above the pancreas but below the opening into the lesser sac and on the medial side of the duodenum. As the hepatic artery enters the lesser omentum it gives off the right gastric artery, which runs forwards and to the left along the upper border of the first part of the duodenum in the lower attachment of the lesser omentum. The gastro-duodenal artery on the other hand, descends vertically behind and to the left of this part of the duodenum.

Here it is accompanied by the bile-duct on its right and by the portal vein behind it. On reaching the lower border of the duodenum the gastro-duodenal artery gives off the right gastro-epiploic branch which runs forwards along the lower border of the duodenum in the attachment of the greater omentum.

Second Part.—The second part measures about 3 inches (7·5 cm.) in length, and it descends from the region of the neck of the gall-bladder opposite the upper part of the first lumbar vertebra to the level of the third lumbar vertebra. In its descent it lies on the posterior abdominal wall to the right of the vertebral column and the inferior vena cava, and it is crossed in front by the transverse colon.

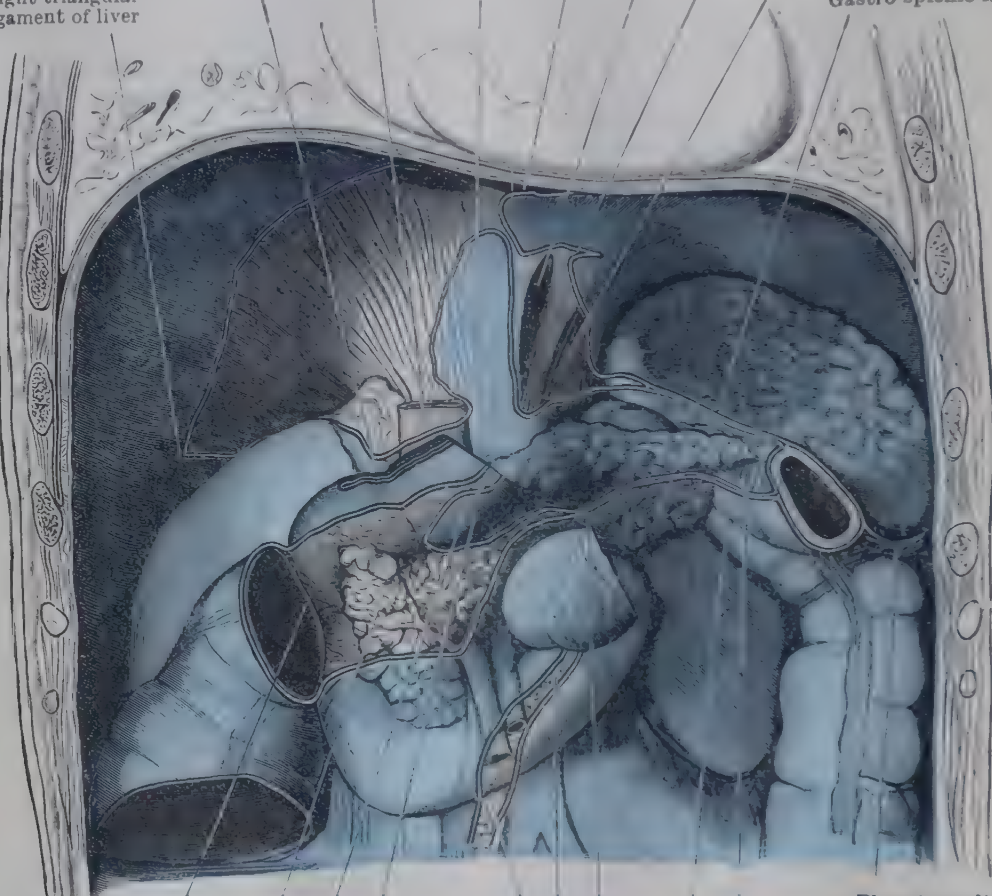

FIG. 538.—PERITONEAL RELATIONS OF DUODENUM, PANCREAS, SPLEEN, KIDNEYS, ETC.
From a body hardened by injections of formalin. When the liver, stomach, and intestines were removed the lines of the peritoneal reflexions were carefully preserved. The peritoneum is coloured blue.

At its commencement it is related *posteriorly* to the right suprarenal gland, and below this to the right kidney near its hilum, to the right renal vessels, to the pelvis of the right ureter, and to the right psoas major muscle.

The *anterior* and *lateral surfaces*, above and below the transverse colon, are covered with peritoneum. Above the colon, these surfaces of the duodenum look into the upper compartment of the general peritoneal cavity and form a bulging which accounts for the duodenal impression on the right lobe of the liver. Below the colon they look into the lower compartment of the cavity and are related to coils of the jejunum. These two peritoneal-covered areas are separated by the attachment of the root of the transverse mesocolon or by the transverse colon itself when the layers of the right part of the mesocolon shorten and separate to leave the back of that part of the colon bare.

The *medial surface* of the second part is in contact with the head of the pancreas, which

occasionally overlaps it anteriorly and posteriorly; and the anastomosis formed by the superior and inferior pancreatico-duodenal arteries is between the duodenum and pancreas.

The bile-duct, after passing down behind the first part of the duodenum, descends between the head of the pancreas (usually embedded in its substance) and the second part, nearly as far as its middle. There, it is joined by the pancreatic duct, and the two, piercing the wall of the duodenum obliquely, open into it by a common orifice $3\frac{1}{2}$ or 4 inches (8·5 to 10 cm.) beyond the pylorus.

Third Part.—This part runs more or less transversely to the left for a distance of about 3 inches (7·5 cm.). As it crosses the posterior abdominal wall it is separated from the vertebral column by the right ureter, the right psoas major, the right testicular or ovarian vessels, the inferior vena cava, and the aorta.

The *anterior* and *inferior surfaces* are covered with peritoneum and are in relation to coils of the jejunum. Near its termination the superior mesenteric vessels pass in front of it in the root of the mesentery. The *superior surface* is in close relation to the head of the pancreas.

Fourth Part.—The fourth part of the duodenum is about 2 inches (5·0 cm.) in length, and it ascends along the left side of the aorta to the level of the second lumbar vertebra to terminate by bending abruptly forwards into the duodeno-jejunal flexure.

As it ascends it lies in front of the left sympathetic trunk, the left psoas major, and the left testicular or ovarian artery.

The root of the mesentery begins on the front of this part of the duodenum at the duodeno-jejunal flexure; thence, it runs obliquely down to the right, and finally leaves the third part of the duodenum near its union with the fourth part. The *front* and *lateral side* of the fourth part are covered with peritoneum and are in contact with some coils of the jejunum; the *medial side* is closely applied to the uncinate process of the pancreas and the aorta.

Duodenal Peritoneal Recesses.—In the neighbourhood of the fourth part of the duodenum there may be four peritoneal pockets—the superior and inferior duodenal, the paraduodenal, and the retroduodenal recesses (Fig. 539). These fossæ and the peritoneal folds guarding them are of considerable interest, because they are situated in a region where developmental failures may occur that require surgical interference. Thus one or other of the recesses may present itself as the sac of an 'internal' or retroperitoneal hernia (p. 1502). These herniæ are now regarded as essentially congenital in nature, and the result of defects in the normal developmental rotation of the intestine and its mesentery around the axis of the superior mesenteric artery as described on page 677. In such cases the greater part of the small intestine may be found imprisoned behind the mesentery of the colon, and the neck of the sac may or may not have large mesenteric vessels constricting it according to its position. For a more detailed account of the anatomy and mechanism of production of these recesses and herniæ see Treves (1885), Moynihan (1906), Andrews (1923) and Longacre (1934).

When the fourth part of the duodenum is drawn medially, two triangular folds of peritoneum will generally be found passing from the duodenum to the abdominal wall (Fig. 539). Each fold is attached by one border to the duodenum and by another to the parietal peritoneum at the left side of the duodenum, whilst the third margin is free and bounds the opening of a small pouch which lies behind the fold. Of these folds, the *upper* is situated near the termination of the duodenum with its free margin directed down. It sometimes contains a portion of the inferior mesenteric vein. Behind it lies the **superior duodenal recess**, whose opening looks downwards and will usually admit

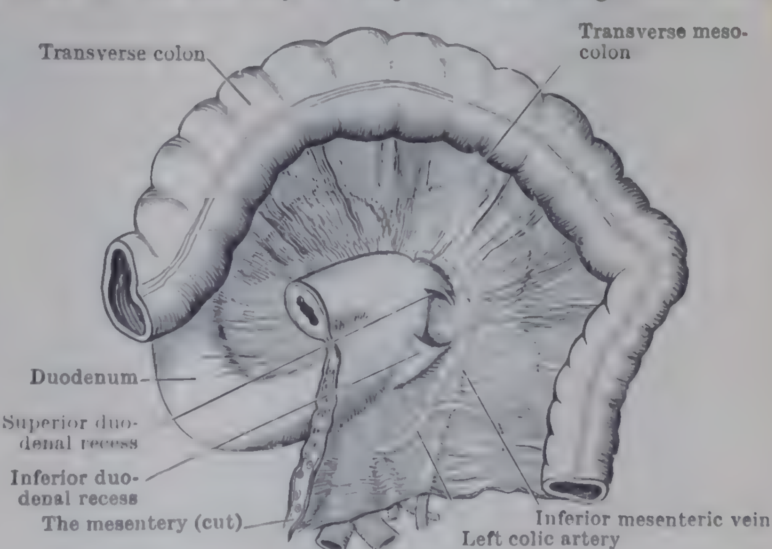

Fig. 539.—Duodenal Folds and Recesses.

The transverse colon and mesocolon have been thrown up, and the mesentery has been turned to the right and cut. The paraduodenal fossa is situated to the medial side of the inferior mesenteric vein, between it and the terminal part of the duodenum. It is not shown in the illustration.

the tip of a finger (Fig. 539). The second fold is placed lower down. Its free border is directed upwards, as is the mouth of the **inferior duodenal recess**, which lies behind it. The inferior recess is larger and more constant than the superior; it is present in 75 per cent of bodies, whilst the superior is present in 50 per cent (Jonnesco, 1895).

Paraduodenal Recess.—This recess, which is seen best in the infant, is placed to the left of the fourth part of the duodenum. It is produced by the inferior mesenteric vein raising up a fold of peritoneum termed the **paraduodenal fold** as it runs along the lateral side of the recess and then above it (see Fig. 539, where the vein, but not the fold or recess is shown). According to Moynihan (1906), this is the only recess to the left of the duodenum capable of developing into the sac of a hernia; and, when that occurs, the inferior mesenteric vein always lies in the anterior margin of the orifice of the sac (accompanied for some distance by the ascending branch of the superior left colic artery).

The **retroduodenal recess** is a small pocket that passes behind the fourth part of the duodenum from its left margin.

Interior of Duodenum.—No circular folds are found in the duodenum for an inch or two beyond the pylorus. They begin as low, scattered, and irregular folds which gradually become larger, more regular, and more numerous, and at the middle of the second part are of considerable size. In the third and fourth part of the duodenum the folds are large, prominent, and closely set.

Fig. 540.—Interior of Second Part of Duodenum (viewed from the Front) showing Duodenal Papilla and Opening of Accessory Pancreatic Duct.

On the postero-medial wall of the second part, about its middle—*i.e.*, 3½ or 4 inches (8·5 to 10 cm.) beyond the pylorus—there is a small papilla on which the bile-duct and pancreatic duct open by a common orifice (Fig. 567, p. 666); it is known as the **duodenal papilla**.

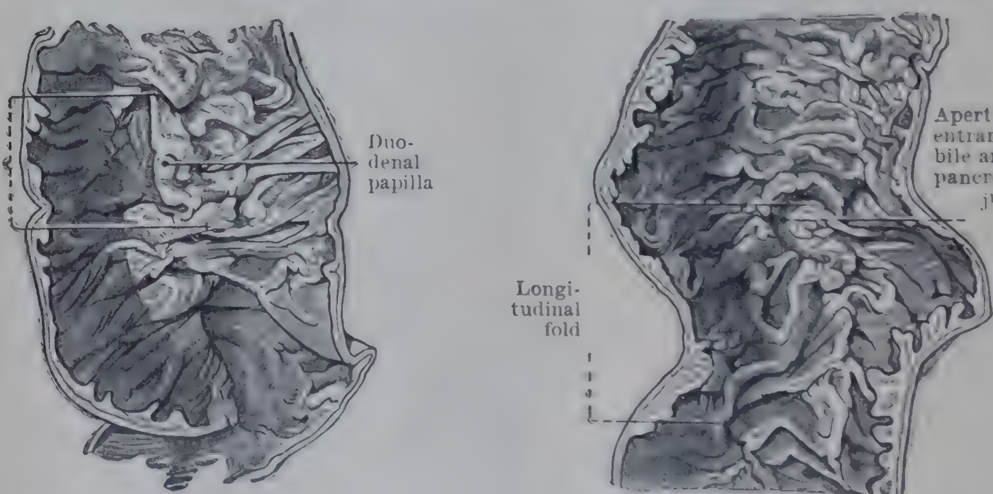

Fig. 541.—Variation of Duodenal Papilla.

A. At middle of longitudinal fold. B. Absent; the opening of the ducts is on the upper part of posterior face of longitudinal fold.

The papilla is placed beneath, and protected by, a hood-like circular fold. From its lower margin a ridge of the mucous membrane, called the *longitudinal fold of the duodenum*, descends for a considerable distance and acts as a frenum which fixes the papilla and directs its apex slightly downwards (Fig. 540). The common orifice of the bile-duct and pancreatic duct on the summit of the papilla is so narrow that it can admit only the point of a pencil.

The position of the papilla in relation to the longitudinal fold varies, and the papilla may even be absent (Fig. 541). For variations of the opening of the bile-duct, see p. 667.

Nearly an inch higher up, and on a slightly more ventral plane, there is a second and smaller papilla on whose summit the accessory pancreatic duct opens by a very small orifice. The second papilla seems to be constantly present, although sometimes so small that it may easily

escape detection unless carefully sought for. When well developed it may have a hood-like fold and a little frenulum like those of the duodenal papilla.

Structure of Duodenum.—The serous coat has been described with the several parts of the duodenum.

The **muscular coat** is well developed, and is pierced by the bile-duct and pancreatic duct. As these united ducts traverse the muscular wall they are surrounded by a sphincter-like group of fibres which extends into the papilla.

The **submucous coat** differs from that of the rest of the small intestine in that it contains, especially in the upper half of the duodenum, the **duodenal glands**. They are small acino-tubular glands that closely resemble the pyloric glands of the stomach; they lie in the submucous coat and send their ducts through the lamina muscularis mucosæ to open on the surface between the intestinal glands or, sometimes, into these glands themselves (Fig. 542). To naked-eye examination they are small, round or flattened masses of a reddish-grey colour, and vary in size from $\frac{1}{50}$th to $\frac{1}{12}$th of an inch in diameter (0·5 to 2·0 mm.). They form an almost continuous layer as far as the opening of the bile-duct; beyond that they diminish progressively, and they completely disappear near the duodeno-jejunal flexure.

The **mucous coat** is thicker in the duodenum than in any other part of the small intestine, and it is covered throughout with broad, short villi.

Vessels and Nerves.—The main **arteries** are the superior and inferior pancreatico-duodenal—branches of the gastro-duodenal and superior mesenteric arteries respectively; but the first part receives also a small branch from the right gastric artery, which is said to have little or no anastomoses with the others. The blood is returned by the **pancreatico-duodenal veins**, of which some pass downwards and to the left on the front of the head of pancreas and join the superior mesenteric vein (Fig. 568, p. 669); while others cross the back of the head of pancreas and open into the portal vein or the superior mesenteric vein.

The **lymph-vessels** for the most part follow the course of the blood-vessels and end in adjacent groups of lymph-glands.

The **nerves** come from the *cœliac* and *superior mesenteric plexuses* of the sympathetic.

Duodenal Diverticula.—Occasional diverticula are found passing from the duodenal wall in different directions. Such diverticula may be hernial protrusions of the mucous and submucous coats through the muscular wall, termed "false" diverticula, or they may be "true" diverticula, in which all the coats are represented, and they may contain pancreatic tissue in their wall. They are usually situated on the aspect of the duodenum which is in contact with the pancreas, and frequently in the neighbourhood of the orifice of the bile-duct. Some of them appear to be due to pressure from the interior of the duodenum, while others, including most of the true diverticula, are congenital in origin and are possibly associated with the diverticula which give rise to the liver and pancreas. The foregoing is a summary of the standard account of this condition by Baldwin (1911); for a later discussion and description of a case, see Maclean (1923).

Duodeno-Jejunal Flexure.—When the fourth part of the duodenum reaches the inferior surface of the body of the pancreas, at a point opposite the left side of the second lumbar vertebra, it turns abruptly forwards, downwards, and to the left, and passes into the jejunum. The abrupt bend is known as the **duodeno-jejunal flexure.** Unlike the rest of the duodenum, which is subject to considerable variations in position in different individuals, the duodeno-jejunal flexure is fixed by a thin band of muscle called the *suspensory muscle of the duodenum* (Treitz, 1853), which blends, at the flexure, with the muscular coat of the duodenum. Thence, it passes upwards behind the pancreas, is connected with the fibrous tunic around the cœliac artery, and is continued above into the right crus of the diaphragm (p. 452). For more details about this so-called *muscle of Treitz*, see Lockwood (1889), Low (1907), and Crymble (1910).

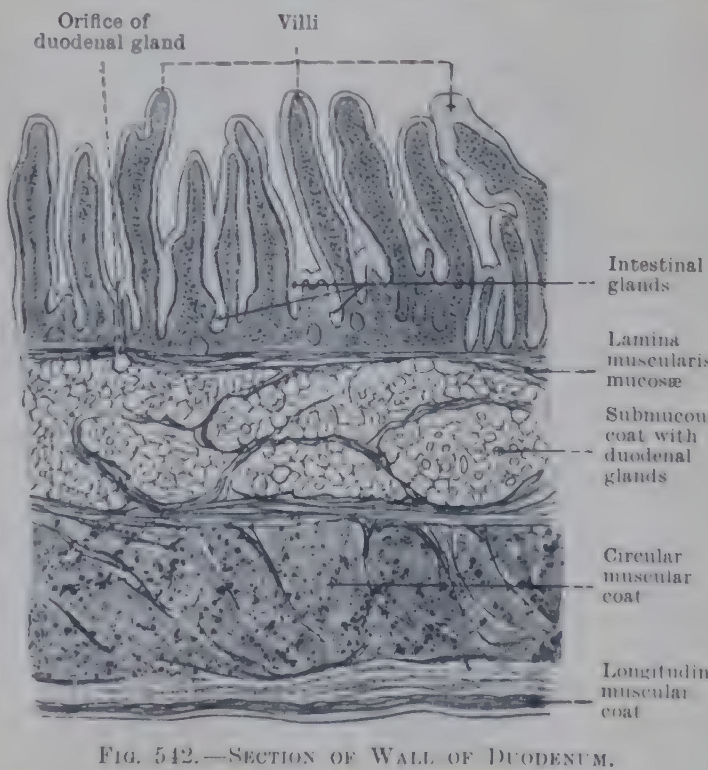

FIG. 542.—SECTION OF WALL OF DUODENUM.

The duodeno-jejunal flexure is occasionally directed to the right, and it lies at a variable distance from the root of the transverse mesocolon; when the attachment of the mesocolon is low, the duodeno-jejunal flexure is in contact with it.

Jejunum and Ileum

The **jejunum** and **ileum** are attached to the posterior wall of the abdomen by *the mesentery*, which is a lamina of fibro-areolar tissue covered on each side with peritoneum, and containing blood-vessels, lymph-vessels, lymph-glands, and nerves.

The part of the tube to which the mesentery is connected is known as the mesenteric or attached border; the opposite side is the free border.

The **mesentery** is a broad, fan-shaped fold which connects the small intestine to the posterior wall of the abdomen. The long, free border of the fold contains the intestine within it. The other (or attached) border, called the **root of the mesentery**, is comparatively short, being only 6 or 7 inches long; but it is much thicker than the part near the gut, for it contains between its layers a considerable

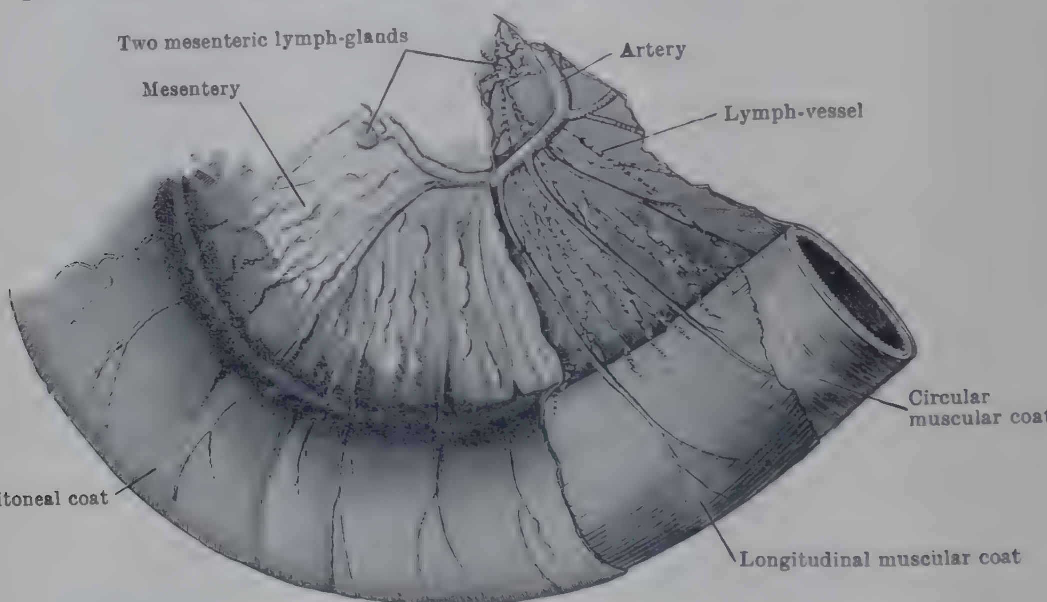

Fig. 543.—Portion of Small Intestine, with Mesentery and Vessels.
The peritoneal coat has been removed from the right half, and the two layers of the muscular coat exposed.

amount of fatty extraperitoneal tissue and the large vascular trunks that supply the intestine. **The root is attached to the posterior abdominal wall** along an oblique line which extends approximately from the left side of the second lumbar vertebra to the right sacro-iliac joint (Fig. 552). In that course the line of attachment passes from the duodeno-jejunal flexure down over the front of the third part of the duodenum, then obliquely across the aorta, the inferior vena cava, the right ureter, and psoas major muscle, to the right iliac region.

The unattached border of the mesentery is frilled out to an enormous degree, so that, while the root measures but 6 or 7 inches, the free border is extended to some 20 feet. The length of the mesentery, measured from its root to the attached edge of the intestine directly opposite, usually measures at its longest part about 6 inches (8 or 9 inches, Treves, 1885; and Lockwood, 1889). Its longest part goes to the portion of the small intestine situated between two points, one six feet, the other eleven feet from the duodenum (Treves, 1885).

Between the two layers of the mesentery (Fig. 543) there are:—(*a*) The jejunal and ileal branches of the superior mesenteric vessels, accompanied by nerve-plexuses and lymph-vessels; the nerves of the mesentery terminate, some in the intestinal wall, others in blood-vessels in the mesentery, and others form terminal plexuses with free nerve-endings; lamellated corpuscles also are occasionally present. (*b*) The mesenteric lymph-glands—between 100 and 200 in number. (*c*) A considerable amount of fatty fibro-areolar tissue, continuous with the extra-peritoneal areolar tissue. (*d*) The intestine itself.

The portion of the mesentery connected to the jejunum contains less fat than that of the ileum, and near the border of the jejunum there are oval or circular areas ("windows") where fat is absent and which are translucent. The mesentery attached to the ileum is usually fat-laden and opaque up to the margin of the intestine.

As a means of deciding which is the proximal and which the distal part of any particular loop of small intestine, it is helpful to note that the peritoneum from the right side of the mesentery is reflected laterally on the posterior abdominal wall to clothe the ascending colon. That of the left side, similarly, passes across the parietes to the descending colon.

The mesentery is of such a length that the coils are able to move about freely in the abdominal cavity, and consequently the position occupied by any portion of the tube, with the exception of the beginning of the jejunum and the ending of the ileum, can never be stated with certainty. Nevertheless, it may be said that, in general, the jejunum occupies the superior and left portions of the cavity below the stomach, the ileum the inferior and right divisions, its terminal part almost always lying in the pelvis just before it joins the large gut.

According to Mall (1898), the most usual arrangement is that the upper coils of the jejunum are on the left side and high up. The tube then crosses the vertebral column below the duodenum, and a few coils are placed on the right side. It then crosses to the left side again, and several coils are formed, some of which may descend into the true pelvis. Thence, it passes again to the right side, where it is coiled up, and then finally descends into the true pelvis.

The root of the mesentery pursues at its attachment an almost straight line from one end to the other, but, if cut across a very short distance from the posterior abdominal wall, it will there be found to form a wavy line. Farther away still, that condition becomes more and more marked; and, finally, if the mesentery is cut close to its attachment to the intestinal wall, it will be seen that its free edge is not only undulating but is frilled or goffered to an extreme degree. When shown in that way, it is found that the folding is not quite indiscriminate but that the main folds, of which there are usually six, run alternately to the right and left. As a rule, the first fold runs to the left from the duodeno-jejunal flexure and goes to a coil of jejunum which lies under the transverse mesocolon and helps to support the stomach. The second fold passes to the right, the third to the left, and so on up to the fifth and sixth, which are usually small. From the margins of the primary folds secondary folds project in all directions, and from those again even a third series may be formed.

The order is of course by no means constant, but if the intestine is removed from a hardened body without disturbing the mesentery, the mesentery will be found to be arranged with more or less regularity on some such plan as that indicated.

Structure (Fig. 531).—The **muscular coat** is thicker in the jejunum, and grows gradually thinner as it is traced down along the ileum. The **submucous coat** contains the bases of the solitary nodules, but otherwise calls for no special remark. The **mucous coat** is thicker and redder in the jejunum than in the ileum. It is covered throughout with villi, which are shorter and broader in the jejunum than in the ileum. In its whole extent it is closely set with intestinal glands, and numerous solitary nodules are seen projecting on its surface. Aggregated lymphatic nodules are particularly large and numerous in the ileum; they are fewer, smaller, and usually circular in the jejunum. Finally, the mucous membrane is thrown into *circular folds*, which are fully described on p. 626.

Vessels.—The **arteries**, on reaching the intestine, pass to one or other side of it and only occasionally bifurcate to give a branch to each side of the gut. They are at first under the peritoneal coat; soon, however, they pierce the muscular coat and form a plexus in the submucous coat from which numerous branches pass to the mucous coat, where some form plexuses around the intestinal glands whilst others pass to the villi. The **veins** are similarly disposed, and the blood from the whole of the small intestine beyond the duodenum is returned by the *superior mesenteric vein*, which joins with the splenic to form the portal vein.

The **lymph-vessels** of the small intestine (known as *lacteals*) begin in the villi, and also as lymph-sinuses around the bases of the solitary nodules; a large plexus is formed in the submucosa, a second between the two layers of the muscular coat, and a third beneath the peritoneum. The vessels from all these pass up in the mesentery, being connected on the way with the numerous *lymph-glands of the mesentery* and finally join the *gastro-intestinal trunk*, which opens into the cisterna chyli.

Differences between Jejunum and Ileum.—If the small intestine is followed down from the duodenum to the cæcum no noticeable change in appearance will be found at any one part of its course to indicate the transition from jejunum to ileum, for the one passes insensibly into the other. Nevertheless, a gradual change takes place, and if typical parts of the two, namely, the upper portion of the jejunum and the lower portion of the ileum, are examined, they will be found to present characteristic differences, which are set forth in the following table.

Jejunum.	Ileum.
Wider, $1\frac{1}{2}$ to $1\frac{1}{4}$ inches in diameter. Wall, thicker and heavier. Redder and more vascular. Circular folds, well developed. Villi, short and broad. Aggregated lymphatic nodules, few and small. Less fat in its mesentery and translucent areas present near the gut.	Narrower, $1\frac{1}{4}$ to 1 inch in diameter. Wall, thinner and lighter. Paler and less vascular. Circular folds, very small or absent. Villi, slender and filiform. Aggregated lymphatic nodules, large and numerous. Mesentery, fat-laden and opaque.

Diverticulum Ilei.—This is a short protrusion which springs from the lower part of the ileum in a little over 2 per cent of bodies. It is usually about 2 inches long and of the same width as the intestine. Most commonly it is found about $2\frac{3}{4}$ feet from the ileo-colic orifice and opposite the original termination of the superior mesenteric artery. As a rule, its end is free; but occasionally it is adherent either to the abdominal wall, the adjacent viscera, or the mesentery; and in such cases it may be the cause of strangulation of the intestine. This curious abnormality attracted the attention of earlier anatomists, but the younger J. F. Meckel (1808, 1812) was the first to explain it in terms of the normal development of the intestine; and it is still currently known as *Meckel's diverticulum.*

The diverticulum is due to the persistence of the proximal portion of the vitello-intestinal duct, which connects the primitive intestine of the embryo with the yolk-sac. In shape it may be cylindrical, conical, or cord-like, and it may present secondary diverticula near its tip in which, on microscopic examination, pancreatic tissue may sometimes be found. It arises most frequently from the free border of the intestine, but it sometimes comes off from the side. It runs at right angles to the gut most commonly, but it may assume any direction, and it is often provided with a mesentery. In 3302 bodies specially examined with reference to its existence, it was present in 73, or 2·2 per cent, and it appeared to be more common in the male than in the female. In 59 out of the 73 cases its position with reference to the end of the ileum was examined: its average distance from the ileo-colic valve was $32\frac{1}{2}$ inches measured along the gut, the greatest distance being 12 feet, and the smallest 6 inches. In 52 specimens the average length was 2·1 inches, the longest being $5\frac{1}{4}$ inches, the shortest $\frac{1}{2}$ inch. The diameter usually equals that of the intestine; but occasionally it is cord-like, or pervious only for a short way; on the other hand, it may attain a diameter of $3\frac{3}{4}$ inches. These data have been compiled from Thomson (Collective Investigation, 1891), Kelynack (1892), Mitchell (1898) and other sources.

Radiographic Examination of Small Intestine.—The small intestine, examined by X-rays after a "barium meal", has a characteristic appearance owing to the presence of the circular folds of its mucous coat. In the lower half of the duodenum and in the **jejunum**, where the folds are numerous and closely set, the barium is broken up into irregular transverse streaks and may be finely fragmented so that the intestine resembles an old-fashioned fur-boa; but in the **ileum** the shadow is more or less continuous (Pls. LIII, LIV, p. 620). This difference is sufficiently great to enable at least the upper coils of the jejunum to be distinguished easily from the ileum. The position of the coils is, of course, another help in identification (see p. 635).

The passage of the barium through the jejunum is rapid, but in the ileum the rate of progress is much slower; barium enters the cæcum usually about three hours after the meal has been taken.

The form and position of the **duodenum**, as seen in X-ray examination after a "barium meal", are shown in Pl. LIII, p. 620. With variations in the position of the pylorus, mentioned on p. 622, there is a corresponding alteration in the position of the first part of the duodenum. The characteristic appearance of the "duodenal cap", as barium begins to leave the stomach (p. 621), is well shown in Pl. LII, p. 609.

LARGE INTESTINE

The ileum is succeeded by the **large intestine** (intestinum crassum), which begins on the right side about $2\frac{1}{2}$ inches below the end of the small intestine. It comprises the following parts: **cæcum and vermiform appendix, ascending colon, right flexure of colon, transverse colon, left flexure of colon, descending colon, pelvic colon, rectum, and anal canal.** In its course the large bowel is arranged in an arched manner around the small intestine (Fig. 532 and Pl. LVII, p. 648).

In *length*, the large intestine measures about one-fifth of the whole intestinal canal, that is, 5 to $5\frac{1}{2}$ feet (1·5 m.). Its *breadth* is greatest at the cæcum, which

measures about 3 inches (75 mm.) in diameter when distended; and from there —with the exception of a dilatation at the rectum—it decreases to the anus. Functionally, there is a distinct difference between the ascending colon and transverse colon together and the descending colon; the descending colon is often found firmly contracted after death and measures only $1\frac{1}{2}$ inches or less in diameter.

The external appearances by which the large intestine, with the exception of the vermiform appendix and the rectum, may be distinguished from the small intestine are stated on p. 623. Two structures peculiar to the large intestine and visible on its external surface require further description.

The **tæniæ coli** are about $\frac{1}{4}$ inch (6 mm.) wide, begin at the root of the vermiform appendix, and run along the surface of the large intestine at nearly equal distances from one another as far as to the rectum. There, they spread out and form a layer of longitudinal muscular fibres which is continuous all round the tube (see p. 653). The tæniæ are about one-sixth shorter than the colon;

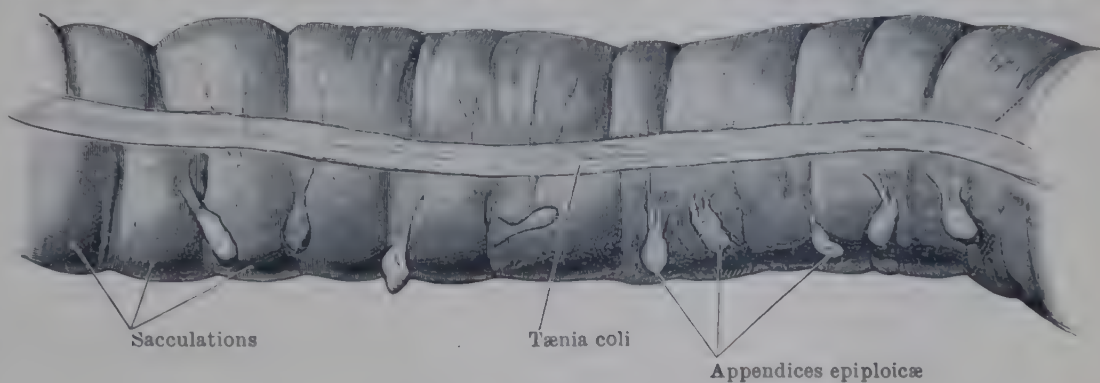

FIG. 544.—LARGE INTESTINE.

A piece of transverse colon from a child two years old. The three chief characteristics of the large intestine—appendices epiploicæ, tæniæ, and sacculations—are shown.

consequently, in order to accommodate it to the length of the tæniæ, the colon is puckered (Fig. 544), and three rows of **sacculations** are produced, along the length of the tube, between the tæniæ. If the tæniæ are dissected off, the sacculations largely disappear, the intestine becomes cylindrical, and at the same time about one-sixth longer.

The position of the three tæniæ on the colon is as follows: On the ascending and descending colon one tænia lies on the front of the gut and two on the back--one to the lateral side (postero-lateral) the other to the medial side (postero-medial). It is chiefly along the first of them (the anterior) that the appendices epiploicæ are found. On the transverse colon in the natural position, the anterior tænia of the ascending and descending colon becomes the posterior (or postero-inferior), the postero-lateral becomes anterior and the postero-medial becomes superior in position. The anterior and postero-lateral tæniæ of the descending colon pass on to the front of the pelvic colon and the longitudinal muscular coat, increasing in total bulk (Hamilton, 1946), forms two wide bands, one on the front and the other on the back of the rectum (p. 649).

When the interior of a piece of distended and dried large intestine is examined, its sacculations appear as rounded pouches separated by crescentic folds that correspond to the creases on the exterior. These folds are made up of mucous membrane containing the muscular coats of the intestine as well as areolar tissue, and each extends over only one-third of the circumference of the intestine, between the tæniæ.

The **appendices epiploicæ** are little pouches of peritoneum, generally more or less distended with fat, which project from the serous coat along the whole length of the large intestine, with the exception of the rectum. They are rudimentary in the appendix. The appendices epiploicæ can be seen as early as the seventh month in the fœtus, but at that time they contain no fat.

In formalin-hardened bodies portions of the large intestine, but particularly of the descending colon, are often found fixed in what appears to be a state of contraction, when they are reduced to a diameter of about $\frac{5}{8}$ or $\frac{3}{4}$ of an inch (16 to 19 mm.). Under similar conditions parts of the small intestine are found correspondingly reduced.

Structure of Large Intestine.—The **serous coat** is complete on the vermiform appendix, cæcum, transverse colon, and pelvic colon; incomplete on the ascending and descending colon and on the rectum. It will be described in detail with each of these portions of the intestine.

The **mucous coat** is of a pale or yellowish ash-colour in the colon, but becomes much

redder in the rectum. Unlike that of the small intestine, its surface is smooth, owing to the absence of villi, but it is closely studded with the orifices of numerous large intestinal glands. Solitary lymphatic nodules also are numerous, particularly in the vermiform appendix (Fig. 550).

Vessels and Nerves.—The arteries are derived from the *mesenteric arteries.* Branches of the superior mesenteric supply the large intestine as far as the left flexure of the colon, and branches of the inferior supply the remainder as far as the lower part of the rectum. The cæcum and vermiform appendix receive their blood from the *ileo-colic artery*; the ascending colon from the *right colic artery*; and the transverse colon from the *middle colic artery.* The descending colon is supplied by the *superior* and *inferior left colic*, and the pelvic colon by the *inferior left colic arteries.* The rectum derives its blood from the three *rectal arteries.*

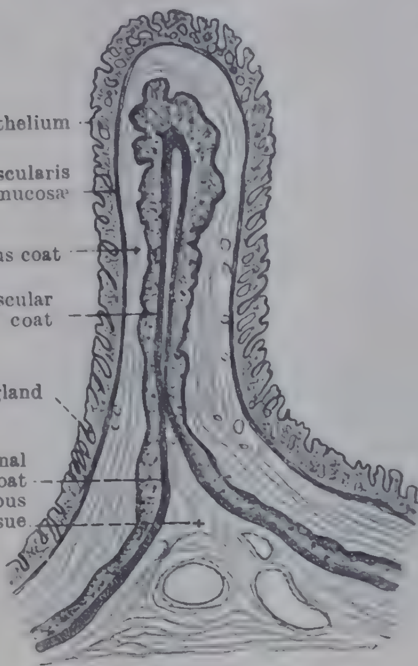

Fig. 545.—Transverse Section of a Crescentic Fold of the Colon.

The **veins** correspond largely to the arteries, and join the *inferior* and *superior mesenteric veins*, which send their blood into the portal vein.

The **lymph-vessels** of the large intestine arise from plexuses in the submucous and subperitoneal coats, as in other parts of the alimentary canal. Those from the cæcum and vermiform appendix run to the *ileo-colic glands.* The deeper vessels of the colon escape chiefly along the entering blood-vessels, those from the lateral aspects passing behind the intestine. The vessels pass first to a series of "*paracolic*" *glands* that lie along the medial border of the intestine; thence, they pass along the lines of the main arteries to *intermediate* and *main glands* disposed at intervals around those vessels (p. 1415).

The **nerves** come from the *superior and inferior mesenteric plexuses.* Their arrangement is described on p. 624.

CÆCUM AND VERMIFORM APPENDIX

Cæcum.—After leaving the pelvic cavity, as already described, the terminal portion of the ileum passes upwards, backwards, and to the right, in close contact with the cæcum, and opens very obliquely, by the ileo-colic orifice, into the large intestine some $2\frac{1}{2}$ inches from its lower end. The portion of the large gut which lies below the level of this orifice is known as the cæcum. *In shape* (Fig. 549) it is a wide, asymmetrical cul-de-sac furnished with tæniæ and sacculations. Its lower end is directed downwards and medially, and usually rests on the right psoas major muscle close to the brim of the true pelvis; whilst the opposite end is directed upwards and laterally and is continued into the ascending colon.

Fig. 546.—Cæcum and Vermiform Appendix from Front.

Its asymmetrical form is due to the fact that the lateral and medial portions of the organ undergo an unequal development in the child. The medial (or medial and posterior) section lags behind, while the lateral (or lateral and anterior) division grows much more rapidly, and, extending downwards, soon comes to form the lower end of the

cæcum. As a result the original extremity of the gut, with the vermiform appendix springing from it, is hidden on the back of the cæcum.

In *length* the distended cæcum usually measures about 2½ inches (60 mm.); whilst its *breadth* is usually more and averages about 3 inches (75 mm.).

Position.—It is usually situated in the right iliac fossa immediately above the lateral half or third of the inguinal ligament, but its lower end bulges medially to overlap the psoas major (Fig. 546). On the other hand, it is sometimes found high up near the liver (owing to the persistence of the fœtal position), or hanging over the pelvic brim and dipping into the pelvic cavity to a varying extent.

In most bodies the cæcum is completely covered with peritoneum on all aspects and lies quite free in the abdominal cavity; but in 6 or 7 per cent. of bodies, the posterior surface (probably as a result of adhesions) is not completely covered and over a greater or less portion of its extent is bound down to the posterior abdominal wall by fibro-areolar tissue.

Relations.—*Posteriorly*, the cæcum rests on the ilio-psoas muscle and the femoral nerve; generally, too, on the vermiform appendix. *Anteriorly*, it usually lies in contact with the greater omentum and anterior abdominal wall; but when the cæcum is empty the small intestine intervenes. Its *lateral side* is placed immediately above the lateral half or third of the inguinal ligament (Fig. 546), whilst the *medial side* has the terminal part of the ileum lying in contact with it. On the medial and posterior aspects, but more on the former than the latter, the small intestine joins the cæcum. On the same aspect, and usually from 1 to 1½ inches (25 to 35 mm.) lower down, the vermiform appendix springs from the cæcum.

Types of Cæcum.—Three chief types of cæcum may be distinguished—the *fœtal type*, conical in shape and nearly symmetrical, with the inferior end gradually passing into the vermiform appendix; the *infantile*, in which the passage from the cæcum to the vermiform appendix becomes more abrupt, the lateral wall more prominent, and the whole sac more asymmetrical; and the lop-sided *adult form*, which is the condition found in 93 or 94 per cent of adults.

Structure.—Nothing in the arrangement of the mucous and submucous coats calls for special notice. The tæniæ all spring from the root of the vermiform appendix (Fig. 549); the anterior runs up on the front, medial to the main prominence of the cæcum; the postero-lateral runs up behind this prominence; whilst the postero-medial passes directly upwards behind the ileum (Fig. 549). The longitudinal fibres on the superior aspect of the ileum partly join the postero-medial tænia; those on the anterior and posterior aspects join the circular fibres of the large gut.

The *interior* of the cæcum corresponds in general appearance to that of the large intestine; but it presents two special features on the posterior part of its medial wall, namely, the **ileo-colic orifice**, guarded by the **ileo-colic valve**, and below that a smaller orifice—the opening of the **vermiform appendix**.

The **position of the ileo-colic valve**, in the average condition, may be indicated on the surface of the body by the point of intersection of the intertubercular and right vertical planes. A point 1 to 1½ inches (2·5 to 3·8 cm.) lower down would correspond to the **orifice of the vermiform appendix**.

Ileo-Colic Valve.—Where the ileum enters the large intestine, the end of the small gut is, as it were, thrust through the wall of the large bowel carrying with it certain layers of that wall; these layers project into the cæcum in the form of two folds which lie one above and one below its orifice and constitute the two segments of the valve (Fig. 548). The peritoneum and longitudinal muscular fibres of the bowel take no part in this infolding; on the contrary, they are stretched tightly across the crease produced on the exterior by the inversion, and thus serve to preserve the folds and the formation of the valve.

As seen from the interior, in specimens which have been distended and dried (Fig. 548), the valve is made up of two crescentic segments—a superior, in a more or less horizontal plane, and an inferior, which is larger, placed in an oblique plane, and sloping upwards and inwards (*i.e.*, towards the cavity of the cæcum). Between the two segments is situated the slit-shaped opening, which runs in an almost antero-posterior direction, with a rounded anterior and a pointed posterior extremity. At each end of the orifice the two segments of the valve unite and are then prolonged around the wall of the cavity as a prominent fold—the **frenulum**. It is thought that when the cæcum is distended, and its

circumference thereby increased, the frenula are put on the stretch, and, pulling upon the two segments of the valve, they bring them into apposition and effect the closure of the orifice.

In bodies hardened with formalin the ileo-colic valve and orifice present a different appearance (see Fig. 547), suggesting, much more closely than in the dried state, the appearance of telescoping or inversion. The two segments of the valve are much thicker and shorter, but they can always be distinguished and have the same relation to each other as in the dried condition, although this may be obscured by foldings or rugæ. The aperture may be slit-like or may be rounded with sloping or funnel-shaped edges; the frenula are not so prominent in some; but the whole valve projects much more abruptly into the cavity of the cæcum than in the distended and dried specimen.

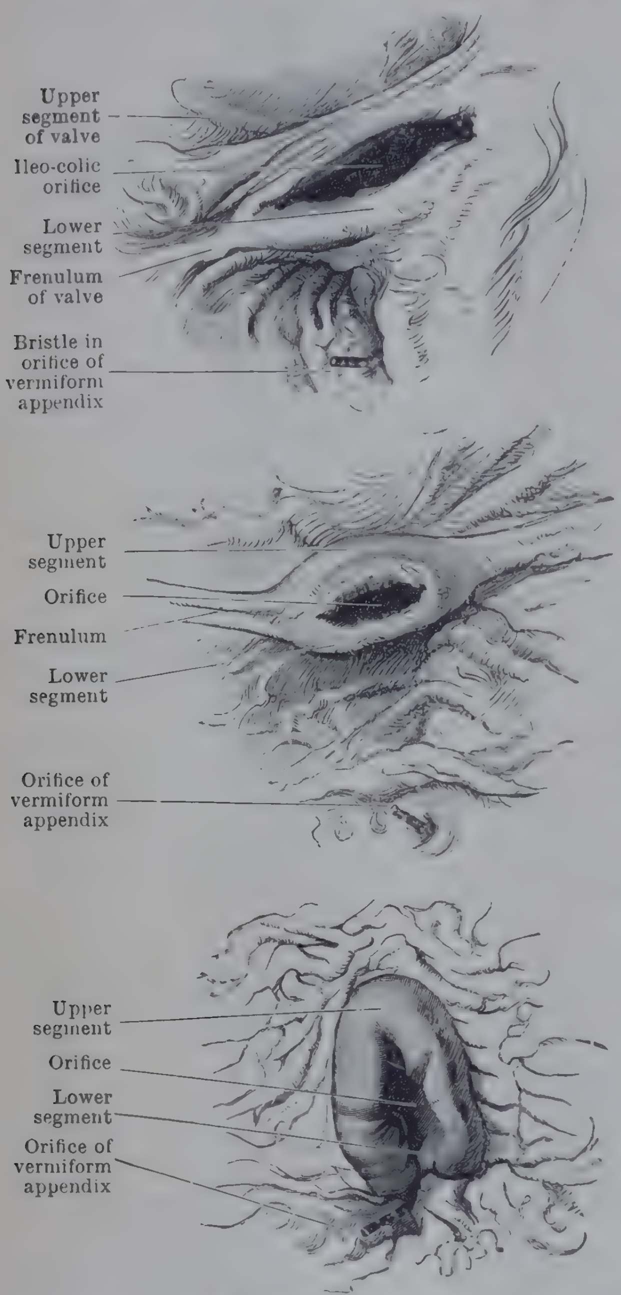

FIG. 547.—THREE FORMS OF ILEO-COLIC VALVE FROM BODIES HARDENED BY FORMALIN.

The hardening was not so complete in the highest of the three valves represented.

Form in the Living Body.—The ileo-colic valve has been observed, in the course of surgical operations, during life. It appears as a "hemispherical mamillary eminence, about 1·8 cm. in diameter, scarlet in appearance, smooth and glistening" (Rutherford, 1914). The summit is truncated, and the orifice is stellate, with lobulated elevations between the rays of the star. It is said also that no frenula are to be seen during life.

Structure of Ileo-Colic Valve.—Each segment of the valve consists of two layers of mucous membrane, with the submucosa and the circular muscular fibres between, all of which are continuous with those of the ileum on the one hand and of the large intestine on the other. The surface of each segment turned towards the small intestine is covered with villi and conforms in the structure of its mucous coat to that of the ileum; whilst the mucous coat of the opposite surface resembles the mucous coat of the large bowel.

The efficiency of the valve is partly due to the oblique manner in which the ileum enters or invaginates the large intestine and partly to muscular contraction.

Vermiform Appendix (Fig. 549).—The vermiform appendix is a worm-like tubular structure which springs from the postero-medial aspect of the cæcum about 1 to $1\frac{1}{2}$ inches (2·5 to 3·5 cm.) below the ileo-colic orifice. From that relatively fixed point the appendix may radiate in almost any direction. This it usually does with the degree of freedom permitted by its mesentery (p. 604), but this mobility may be more or less restricted by adhesions. In a considerable number of cases, however, the appendix is found in a fixed, somewhat buried position due to a retardation of its developmental migration in association with the cæcum (see p. 677). The most reliable guide to the vermiform appendix in all cases of difficulty is provided by the anterior tænia of the cæcum. When this band is traced to the back of the cæcum its fibres continue on to the root of the appendix, which is thus located with a good deal of certainty.

Wakeley (1933), from an analysis of 10,000 cases, has found that the relative frequency of the different positions of the appendix is approximately as follows:—

(1) Behind the cæcum and colon (65%). In this situation the appendix may either (*a*) lie free in a recess, (*b*) have a short mesentery which holds it in contact with the posterior surface of the cæcum or colon, (*c*) be adherent to the cæcum or colon, (*d*) lie extra-peritoneally, the peritoneal recess having been obliterated, or (*e*) be adherent to the posterior abdominal wall.

(2) Directed downwards (33%). In this variety the appendix may be long enough to curve below the level of the cæcum, and it is frequently of sufficient length to reach over the brim into the true pelvis.

(3) In a small percentage ($1\frac{1}{2}$%) of cases the appendix may be found directed upwards and medially in front of and more rarely behind the terminal part of the ileum.

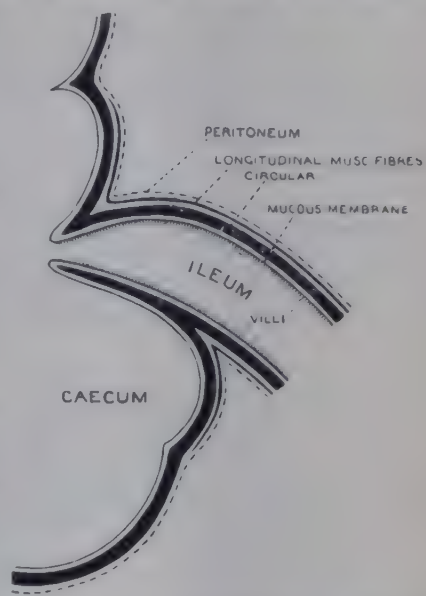

Fig. 548.—Diagrammatic Section through Junction of Ileum with Cæcum, to show Formation of Ileo-Colic Valve.

In addition to the positions mentioned above, the appendix has been found in almost every possible position consistent with its developmental history (see p. 677). In the rare condition of complete transposition of the abdominal viscera, the appendix lies naturally on the left side of the body.

Its *size* is almost as variable as its position. Its length, according to Berry (1895), may be given as about $3\frac{1}{2}$ inches (92 mm.), and its breadth as $\frac{1}{4}$ inch (6 mm.). On the other hand, it has been found as long as 9 inches (230 mm.), and as short as $\frac{3}{4}$ inch (18 mm.). Congenital absence has been recorded, but this must be looked upon as an extremely rare occurrence.

Its *lumen* or *cavity* is variable in size, and is found to be totally or partially occluded in at least one-fourth of all adult and old bodies examined. It opens on

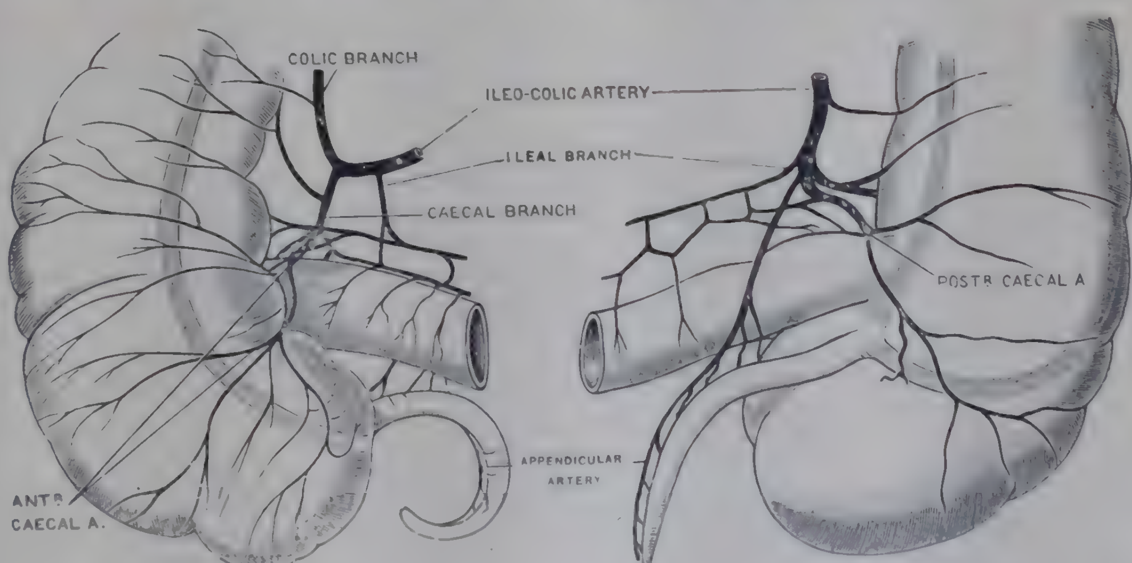

Fig. 549.—Blood-Supply of Cæcum and Vermiform Appendix. (Modified from Jonnesco, 1895.)
The left illustration is from the front, the right from behind. In the latter the appendicular artery and the three tæniæ coli springing from the root of the appendix should be specially noted.

the postero-medial wall of the cavity of the cæcum (Fig. 547), at a point 1 to $1\frac{1}{2}$ inches below the ileo-colic orifice and slightly farther back. These are the relative positions of the two orifices as seen from the interior of the cæcum; viewed from the exterior, the root of the vermiform process is within $\frac{3}{4}$ inch of the lower border of the ileum. The apparent difference is due to the fact that the ileum adheres to the medial side of the cæcum for a distance of nearly an inch before it opens into it. The *orifice* has a crescentic fold placed at its upper border; but the fold is probably of very little functional importance.

The vermiform appendix is completely covered with peritoneum and has a

considerable **mesentery**, which extends to its tip, as a rule, and connects the appendix to the inferior surface of that part of the mesentery proper which goes to the distal end of the ileum.

The vermiform appendix is longer, relative to the rest of the large intestine, in the child at birth than in the adult, the proportion being about 1 to 16 or 17 at birth and 1 to 19 or 20 in the adult. It attains its greatest length and diameter during adult and middle age, and it atrophies slowly after that time. It is said to be slightly longer in the male than in the female.

Total occlusion of its cavity is found in 3 or 4 per cent of bodies; it is then converted into a fibrous cord. Partial occlusion is present in 25 per cent of adults and in more than 50 per cent of those over 60 years old, but it is unknown in the child. The frequency of occlusion, the physiological atrophy which takes place after middle life, the great variations in length, and other signs of instability, have been considered to point to the retrogressive character of the appendix.

A vermiform appendix is found only in Man, the higher apes, and the wombat, although in certain rodents a similar arrangement exists. In carnivorous animals the cæcum is very

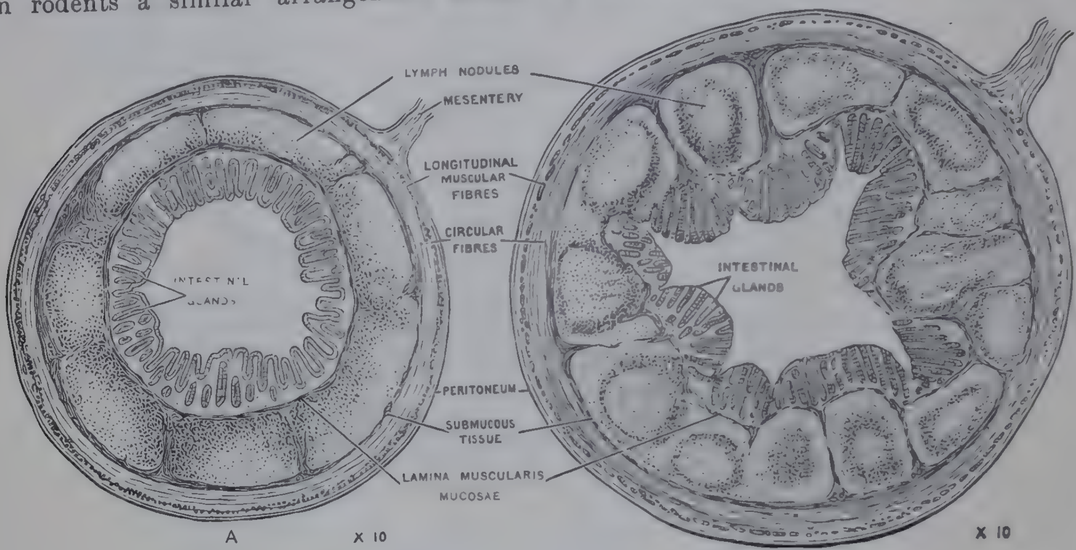

Fig. 550.—Structure of Vermiform Appendix.

A. From a child two years old. B. From a male, aged 56.

It will be observed that the submucous coat is almost entirely occupied by lymphatic nodules. The lamina muscularis mucosæ is very faint, and lies quite close to the bases of the intestinal glands. The longitudinal layer of muscular fibres forms a continuous sheet.

slightly developed; in herbivorous animals (with a simple stomach) it is, as a rule, extremely large. It has been suggested that the vermiform appendix in Man is the degenerated remains of the herbivorous cæcum, which has been replaced by the carnivorous form. Another and perhaps more probable view regards the appendix as a lymph-organ, having the same functions as lymphatic nodules, and, like these, undergoing degeneration after middle life (Berry, 1895).

In the fœtus and child, as well as in the adult with the infantile type of cæcum, the vermiform appendix springs from the apex, not from the postero-medial wall of the cæcum.

Foreign bodies, although reputed to find their way very easily into the appendix, are rarely found there after death. On the other hand, concretions or calculi, formed of mucus, fæces, and various salts, are often present (Berry, 1895).

Structure (Fig 550).—The **serous coat** forms a perfect investment for the appendix. The **muscular coat**, unlike that of the rest of the large intestine, has a continuous and thick layer of longitudinal fibres which passes at the root of the appendix into the three tæniæ coli (Fig. 549). The layer of circular fibres is well developed. The **submucous coat** is almost entirely occupied by large masses of lymphoid tissue surrounded by sinus-like lymph-spaces. Owing to the large size of the lymphatic nodules, the areolar tissue of the submucosa is compressed against the inner surface of the muscular coat and forms a well-marked fibrous tube which sends processes at intervals between the lymphoid masses towards the mucous membrane. The lymphatic nodules correspond to solitary lymphatic nodules, which, owing to their great number, have been almost completely crushed out of the mucous coat (in which they chiefly lie in the intestine) into the submucosa.

The **mucous coat** corresponds to that of the large intestine in its general characters, but the intestinal glands are fewer and are irregular in their direction; the lamina muscularis mucosæ is thin and ill-defined; it lies immediately internal to the lymphatic nodules of the submucosa and immediately outside the base of the intestinal glands. Some few lymphatic nodules lie in the mucous coat also.

Peritoneal Folds and Recesses.—In the neighbourhood of the cæcum there are several peritoneal recesses, of which the most important are the superior and the inferior ileo-cæcal recesses and the retrocæcal recess (Berry, 1897).

If the vermiform appendix is drawn down and the finger passed towards the cæcum along the inferior border of the terminal part of the ileum, it will enter a recess between the ileum and the cæcum known as the **inferior ileo-cæcal recess**. A peritoneal fold which bounds it in front is the **ileo-cæcal fold.** It extends between the terminal part of the ileum and the front of the mesentery of the vermiform appendix. The fold contains some plain muscle-fibres continuous with the longitudinal muscle coat of the cæcum, and some fat, especially at its free margin. The inferior ileo-cæcal recess is bounded above by the lower end of the ileum, laterally by the cæcum, in front by the ileo-cæcal fold, behind by the root of the mesentery of the vermiform appendix; and it is open medially.

Similarly, if the finger is run along the superior border of the ileum towards the cæcum, it will usually lodge in a smaller recess—the **superior ileo-cæcal recess**—which is bounded in front by a small peritoneal fold, called the **vascular fold of the cæcum**

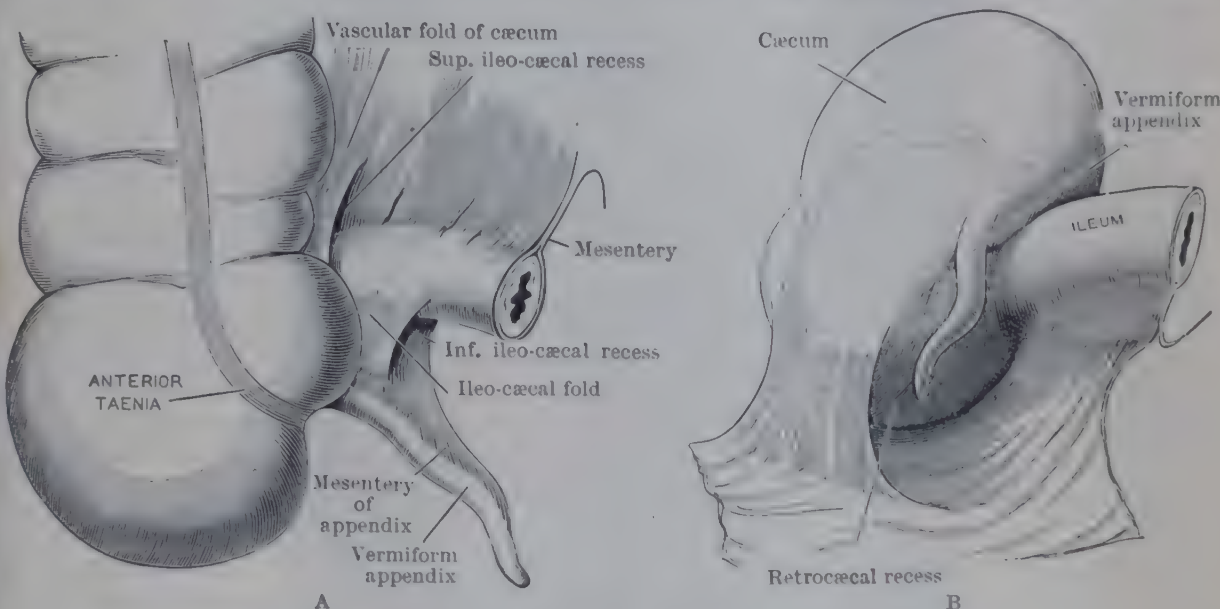

FIG. 551.—FOLDS AND RECESSES IN THE ILEO-CÆCAL REGION.

In A, the cæcum is viewed from the front; the mesentery of the vermiform appendix is distinct. In B, the cæcum is turned upwards to show a retrocæcal recess which lies behind it and behind the beginning of the ascending colon.

(Fig. 551, A), which contains the anterior cæcal artery. The superior ileo-cæcal recess lies at the upper margin of the junction of the ileum with the colon; it is bounded behind by the ileum and laterally by the cæcum.

The **retrocæcal recess** is an occasional pouch which passes upwards between the cæcum and the posterior abdominal wall. Its orifice looks downwards or medially, and it is bounded on each side by peritoneal folds termed the **cæcal folds**. It often contains the appendix.

COLON

Ascending Colon.—The ascending colon begins about the level of the intertubercular plane, opposite the ileo-colic orifice, where it is continuous with the cæcum. From there it runs upwards and slightly backwards, with a slight medial concavity, until it reaches the inferior surface of the liver, where it bends forwards and medially and passes into the right flexure of the colon (Fig. 552). In its course it lies in the angle between the quadratus lumborum and the psoas major.

Its *length* is extremely variable, depending upon the extent to which the cæcum has descended from the position it occupied during development, viz., in contact with the under surface of the liver. It is from 5 to 8 inches long, and it is wider and more prominent than the descending colon. It generally presents several minor curves or flexures, and it often has the appearance of being pushed into a space which is too short to accommodate it.

Relations.—*Anteriorly* it is usually in contact with the abdominal wall, but the small intestine frequently intervenes, particularly above. To its *medial side* lie the coils of the small bowel and the psoas major; to the *lateral side* is the side-wall of

the abdomen. Its *posterior surface*, which is free from peritoneum as a rule, is connected by areolar tissue to the iliacus muscle as far up as the iliac crest, to the quadratus lumborum and psoas major above that, and, finally, to the lower part of the right kidney.

In a small proportion of bodies the ascending colon is provided with a complete peritoneal coat and a mesentery, but the mesentery is so short that it allows only a slight amount of movement of the gut. Lateral to the cæcum and colon the peritoneum forms a gutter, termed the *paracolic groove*, which is usually divided by peritoneal folds into small recesses.

Like the cæcum, the ascending colon is frequently found distended with gas or fæces after death—hence, in part, its large size and prominence as compared with the descending colon, which is generally empty.

Right Flexure of Colon.—When the ascending colon reaches the inferior surface of the liver, it bends—usually acutely, sometimes obtusely—forwards and to the left on the anterior surface of the right kidney to form the flexure, and, on reaching the front of the second part of the duodenum, it passes into the transverse colon.

The flexure is placed between the duodenum medially and the anterior margin of the liver or the side-wall of the abdomen, laterally; above, it corresponds to the colic impression on the liver, and posteriorly it rests on the kidney. Its peritoneal relations are similar to those of the ascending colon.

Transverse Colon.—The transverse colon is the long and looped portion of the large intestine which lies between the right and left flexures. It begins at the right flexure, and, for the first few inches, it runs transversely and is comparatively fixed, being united to the front of the second part of the duodenum and the head of the pancreas either by a very short part of the mesocolon or by areolar tissue. Immediately to the left of the head of the pancreas, the mesocolon lengthens and allows the colon to hang down in front of the small intestine at a considerable distance from the posterior abdominal wall. The portion of the colon so suspended is therefore very movable; its position is consequently very variable and is influenced by posture and by the condition of the other viscera. Towards its left extremity the mesocolon shortens again, thus bringing the gut towards the body of the pancreas (Fig. 538), along which it runs towards the left and upwards under cover of the stomach, as far as the lateral end of the spleen, where it passes into the left flexure (Fig. 538). Its two ends lie in or above the transpyloric plane whilst its middle portion reaches down to the level of the umbilicus or even lower.

Its average *length* is about 19 or 20 inches (47·5 to 50·0 cm.), that is, more than twice the distance, in a direct line, between its two extremities. This great length is accounted for by the curved and somewhat irregular course which the bowel pursues.

Relations.—The greater part of the transverse colon lies behind the greater omentum, which must consequently be turned upwards in order to expose it. *Above*, it is in contact, from right to left (Fig. 552), with the liver and gall-bladder (which are also in front of it), the stomach, and near its left end, with the body of the pancreas and the spleen (Fig. 537). *Anteriorly* are placed the omentum and the anterior abdominal wall; towards its termination the stomach also is anterior. *Posteriorly* it first lies in contact with the second part of the duodenum and head of the pancreas; farther to the left, where it hangs down, the small intestine is placed below and behind it, and it is connected to the posterior abdominal wall by the transverse mesocolon. The transverse mesocolon is described with the peritoneum, p. 604.

The transverse colon is completely covered with peritoneum, with the exception of the first few inches of its posterior surface, which are often, if not usually, uncovered.

The state of the peritoneal covering on the posterior surface of the first part of the transverse colon would seem to depend, in some degree, on the extent to which the liver passes downwards on the right side. With a small, high liver no mesentery is present, and the posterior surface is devoid of peritoneum. On the other hand, when the liver is enlarged in the vertical direction, it pushes the colon downwards before it, and the peritoneum attached to the colon is drawn out to form a mesentery. In the fœtus of three or four months every part of the colon is supplied with a long mesentery.

Left Flexure of Colon.—The terminal portion of the transverse colon runs upwards (also backwards and to the left) until the spleen is reached; there it

bends sharply, forming the left flexure, and becomes the descending colon. The flexure is placed deeply behind the stomach, and in contact with the lower part of the spleen. It lies at a slightly higher level than the right colic flexure, and is connected to the abdominal parietes by the phrenico-colic ligament, which helps to maintain it in this position on the posterior abdominal wall.

The **phrenico-colic ligament** (Fig. 538) is a triangular fold of peritoneum, with

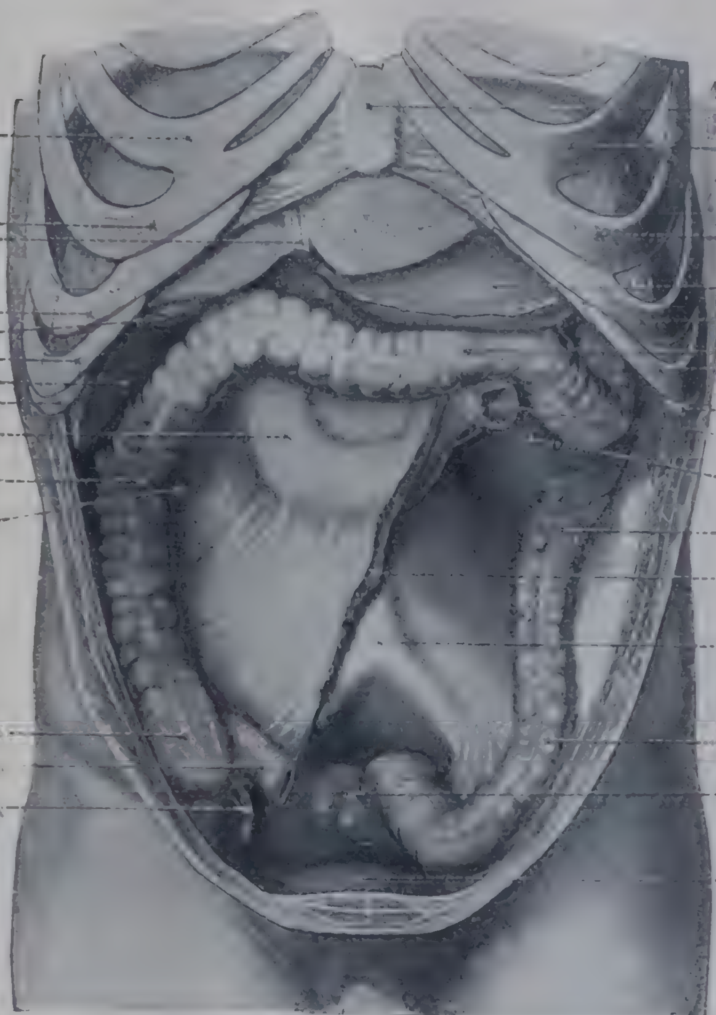

FIG. 552.—ABDOMINAL VISCERA AFTER REMOVAL OF JEJUNUM AND ILEUM. (From a photograph of the same body as depicted in Fig. 532.) The transverse colon is much more regular than usual.

a free anterior border, which is attached medially to the left flexure and laterally to the diaphragm opposite the eleventh rib.

The phrenico-colic ligament is formed in the fœtus from the left margin of the greater omentum (Jonnesco, 1895).

Descending Colon.—The descending colon is much narrower and less obtrusive than the ascending colon: indeed, in a large number of cases it is found firmly contracted. It begins at the left flexure, passes down on the left side of the abdomen, and terminates by passing into the pelvic colon at the inlet of the pelvis on the medial side of the left psoas muscle. Its course is not quite straight, for it first curves downwards and medially along the lateral border of the left kidney and then descends almost vertically to the iliac crest (Fig. 552). It then passes downwards and slightly medially in the iliac fossa, lying in front of the iliacus muscle. A little way above the inguinal ligament it turns medially over the psoas major and ends at its medial border by dipping into the true pelvis and becoming the pelvic colon (Fig. 552).

Its *length* is usually from 9 to 12 inches (22 to 30 cm.), and its *width*, which is less than that of the ascending colon, about 1½ inches.

The portion of the colon formerly described as a special segment, termed the *iliac colon*, is in structure and function a part of the descending colon and is here included with it.

Relations.—The upper part of the descending colon first lies in contact with the lateral border of the left kidney; below that it is placed, like the ascending colon, in the angle between the psoas major and quadratus lumborum muscles. Posteriorly it rests upon the lower part of the diaphragm above, and on the quadratus lumborum below. Anteriorly (and somewhat laterally also, except when the bowel is distended) are placed numerous coils of small intestine, which hide the colon completely from view, and compress it against the posterior abdominal wall. The lower part of the descending colon lies on the front of the ilio-psoas muscle. It also crosses the femoral and genito-femoral nerves, the left testicular (or ovarian) vessels, and the left external iliac vessels. Anteriorly it is usually covered by coils of small intestine, which hide it from view; but when distended, or when it occupies a lower position than usual, it comes into direct contact with the anterior abdominal wall.

In the great majority of bodies only the front and sides of the descending colon are covered with peritoneum; the posterior surface is connected to the posterior wall of the

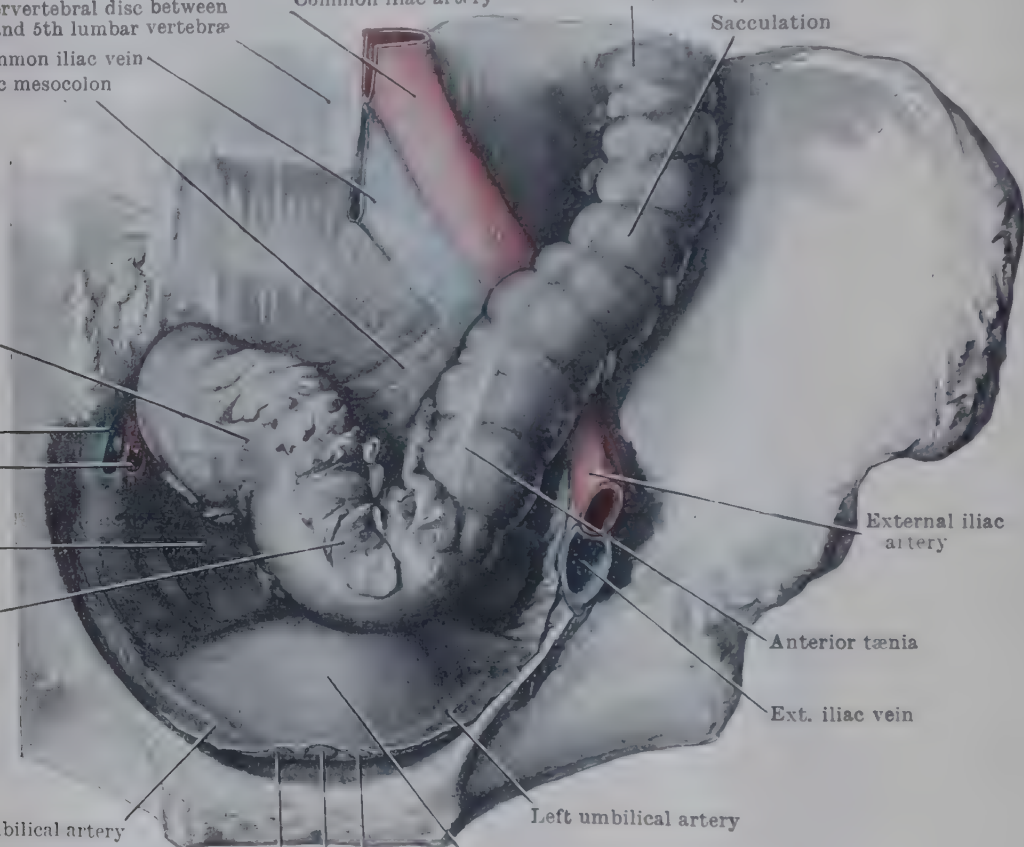

Fig. 553.—Pelvic Colon *in situ*.

abdomen by areolar tissue. In a small proportion of cases, on the other hand, the serous coat is complete, and the colon is furnished with a short mesentery.

Up to the fourth or fifth month of fœtal life the descending colon has a complete investment of peritoneum and a long mesentery. After the fifth month the mesentery adheres to, and soon blends with, the parietal peritoneum on the posterior abdominal wall, and is completely lost as a rule. The persistence of the mesentery, in a greater or less degree, explains the occasional presence of a *descending mesocolon* in the adult.

Pelvic Colon.—The pelvic colon begins at the medial border of the left psoas major muscle, where it is continuous with the descending colon, and it ends at the level of the third sacral vertebra by passing into the rectum. It is covered with peritoneum and has a well-developed mesentery which permits considerable movement. It forms a large and variously shaped coil which usually lies in the cavity of the true pelvis (93 per cent).

Whilst the loop of the pelvic colon is very irregular in form, the following may be given as perhaps its most common arrangement. Beginning at the medial margin of the left psoas major, it first descends into the true pelvis, and crosses that

cavity from left to right; it next bends backwards and then returns along the posterior wall of the pelvis towards the median plane, where it turns down and passes into the rectum (Figs. 552 and 553).

In *length* the pelvic colon generally measures about 16 inches (40 to 42·5 cm.), but it may be as short as 5 inches (12 cm.), or as long as 35 inches (84 cm.).

Relations.—As it passes from left to right across the cavity of the pelvis, it rests on the bladder or the uterus, according to the sex, and the coils of the small intestine lie above it.

When the pelvic colon is unusually long, in returning from the right side of the true pelvis it crosses the median plane, going even as far as the left wall, and then turns back a second time towards the middle of the sacrum, where it joins the rectum at the usual level, thus making an S-shaped curve within the pelvis. On the other hand, when the loop is short (a not infrequent occurrence), all its curves are abridged, and it fails to pass over to the right side, but runs more or less directly backwards after entering the pelvis.

From what has been said it will be seen that the loop of the pelvic colon is subject to considerable variations, which are dependent chiefly upon its length and that of its mesentery, and also upon the state of emptiness or distension of itself and of the other pelvic viscera. When the intestine is long the loop is more complex; when short, more simple. When the bladder and rectum are distended, or when the pelvic colon itself is much distended, it is unable to find accommodation in the pelvis and consequently it passes up into the abdomen proper, almost any part of the lower half of which it may occupy. But, as already stated, in the great majority of cases (92 per cent, according to Jonnesco, 1895) it is found after death lying entirely within the pelvis.

The **pelvic mesocolon** is a fan-shaped fold, short at each extremity and long in its middle portion (Figs. 552 and 553). Its root is attached along an inverted V-shaped line, one limb of which runs up close to the medial border of the left psoas major as high as the bifurcation of the common iliac artery (or often higher); there, it bends at an acute angle, and the second limb descends over the front of the sacrum to the middle of its third piece, where the mesentery ceases and the pelvic colon passes into the rectum. When the pelvic colon ascends into the abdomen proper, this mesentery is doubled up on itself, the side which was naturally posterior becoming anterior.

Recess of pelvic mesocolon.—When the pelvic colon with its mesentery is raised upwards, a small orifice will usually be found beneath the mesocolon, corresponding to the apex of the Λ-shaped attachment of its root to the posterior abdominal wall. This orifice leads into a recess which is directed upwards and will often admit the little finger. It is known as the recess of the pelvic mesocolon, and is due to the imperfect blending of the mesentery of the descending colon of the fœtus with the parietal peritoneum. The ureter is found lying behind the apex of the recess. In the fœtus the mesentery of the descending colon is well developed and extends from the region of the vertebral column towards the descending colon. After a time it begins to unite with the underlying parietal peritoneum; but in the line of the ureter the union is rarely perfect—hence the presence of the recess. The recess may occasionally be the seat of an internal hernia (p. 1505).

In the **child at birth** only the terminal part of the pelvic colon lies in the pelvis. That is chiefly owing to the small size of the pelvic cavity in the infant. Beginning at the end of the descending colon, the pelvic colon generally arches upwards and to the right across the abdomen towards the right iliac fossa, where it forms one or two coils, and then passes down over the right side of the pelvic brim into the pelvis.

Structure of Pelvic Colon.—Only the arrangement of the muscular coat need be referred to. As the tæniæ of the descending colon are followed down, it will be found that the postero-lateral band gradually passes on to the front and unites with the anterior tænia to form a broad band which occupies nearly the whole width of this bowel in its lower portion. The postero-medial tænia spreads out in a similar manner on the back; so that, in the lower half of the pelvic colon, the longitudinal layer of the muscular coat is complete, with the exception of a narrow part on each side; there the circular fibres come to the surface, and the intestine presents a series of small sacculations. As the rectum is approached, the sacculations disappear, and the longitudinal fibres, although thicker in front and behind, form a continuous layer all round.

Radiographic Examination of Large Intestine.—The large intestine may be examined by X-rays after a "barium meal" or after an opaque enema.

About three hours after a "meal" has been taken, the barium begins to pass through the ileo-colic valve and to fill the cæcum and ascending colon. The general progress of the barium in the **colon**, apart from sudden mass-movements of the contents, is so slow that it is difficult to detect by screen-examination. It reaches the pelvic colon from 18 to 24 hours after the taking of the meal, but traces of the barium are often to be seen in the colon after 48 hours or longer. The shadow of the colon is distinguished easily from that of other parts of the intestine by the undulating outline due to the sacculations (Pl. XLVIII, p. 559).

The enema method, by which the whole of the large intestine may be filled (Pl. LVIII, p. 648), is preferable for the detection of disease and is therefore the one usually employed

clinically. The enema, however, not only distends the colon but also appears to produce some increase in its length. Accordingly, radiographs taken after an enema always suggest that the colon, and in particular the pelvic colon, is markedly redundant; and, in addition, the sacculations are much less evident than in radiographs taken after filling the colon by a "meal" (Cf. Pls. XLVIII, p. 559, and LVIII, p. 648).

The presence of gas in the colon makes it, like the fundus of the stomach, radio-translucent so that any part of it may appear as a dark area in a radiograph (Pl. LIV, p. 613); the left flexure, where gas tends to collect, is usually easily distinguished from the air-bubble in the fundus of the stomach. The radio-translucency of the gas-filled colon is taken advantage of in the "double contrast" method of examination. The bowel is evacuated after a barium enema and then air is injected with the result that the mucous coat is very clearly defined (Pl. LIX, p. 649). This method is of special value in the detection of disease.

The length, shape, and position of the different parts of the colon show a wide range of variation (Pls. XLVIII, LVII, and LVIII); but typically they approximate to those shown in Fig. 552, p. 645.

The form and position of the **cæcum** vary with its activity and the posture of the subject. Some of the barium may enter the **appendix** after a "meal", or it may be filled with the rest of the large intestine by an enema, so that its position and direction may be demonstrated (Pl. LVII, p. 648).

RECTUM

The **rectum** is the portion of the intestine between the pelvic colon and the anal canal.

Unlike the pelvic colon the rectum has but a partial covering of peritoneum, and has no mesentery; sacculations, too, such as are characteristic of the colon, cannot be said to be present.

The rectum begins about the level of the third sacral vertebra, and ends, in the male, opposite the apex of the prostate, or, in both sexes, at a point $1\frac{1}{2}$ inches (3·5 cm.) in front of and slightly below the tip of the coccyx. It first descends along the front of the sacrum and coccyx; it then rests for about $1\frac{1}{2}$ inches on the posterior part of the pelvic floor, formed by the union of the two levatores ani; and, finally, it bends abruptly backwards and downwards to become the anal canal (Fig. 620, p. 740).

Curvatures.—The rectum is curved in both the antero-posterior and the transverse planes. Viewed *from the side* it forms a gentle curve, convex backwards, from the beginning of the rectum to the back of the prostate, and fits into the hollow of the sacrum and coccyx. At the back of the prostate a second curve is formed where the rectum joins the anal canal. The convexity of the second curve is directed forwards, and its concavity embraces the **ano-coccygeal body**—the mass of muscular and fibrous tissue which lies between the tip of the coccyx and the anal canal.

When *viewed from the front* the rectum is seen to be folded from side to side in a zigzag fashion, the folding being slightly marked when the rectum is empty, but becoming much more distinct with distension (Figs. 554 and 555). There are three more or less distinct lateral flexures. Of these the upper and lower have their concavities directed to the left as a rule; the third flexure, which is the best-marked, lies between the other two, but on the right side. Not infrequently, however, two are found on the right and one on the left side. The flexures are marked on the exterior by creases which appear in the interior as three prominent crescentic shelves known as the **horizontal folds of the rectum** (Fig. 557).

The folds are produced by an infolding of the mucous and submucous coats and the greater part of the circular muscular coat, and their form is preserved by the relative shortness of the anterior and posterior bands of longitudinal muscular fibres. Three are usually present (there may be four, five, or, it is said, even more), but often the lowest of the three is small or absent; or all the folds may be ill-developed and indistinct. They are most evident in a distended rectum which has been

PLATE LVII

PLATE LVII.—RADIOGRAPH SHOWING ALL THE PARTS OF THE LARGE INTESTINE. MOST OF THE BARIUM HAS ACCUMULATED IN THE LOWER PART OF THE DESCENDING COLON, THE PELVIC COLON AND THE RECTUM.

Note the residue of radio-opaque material in the Cæcum and Appendix, and the contraction of the Descending Colon. Compare this radiograph with Plate XLVIII, p. 559, which shows an earlier stage in the filling of the Cæcum and Colon.

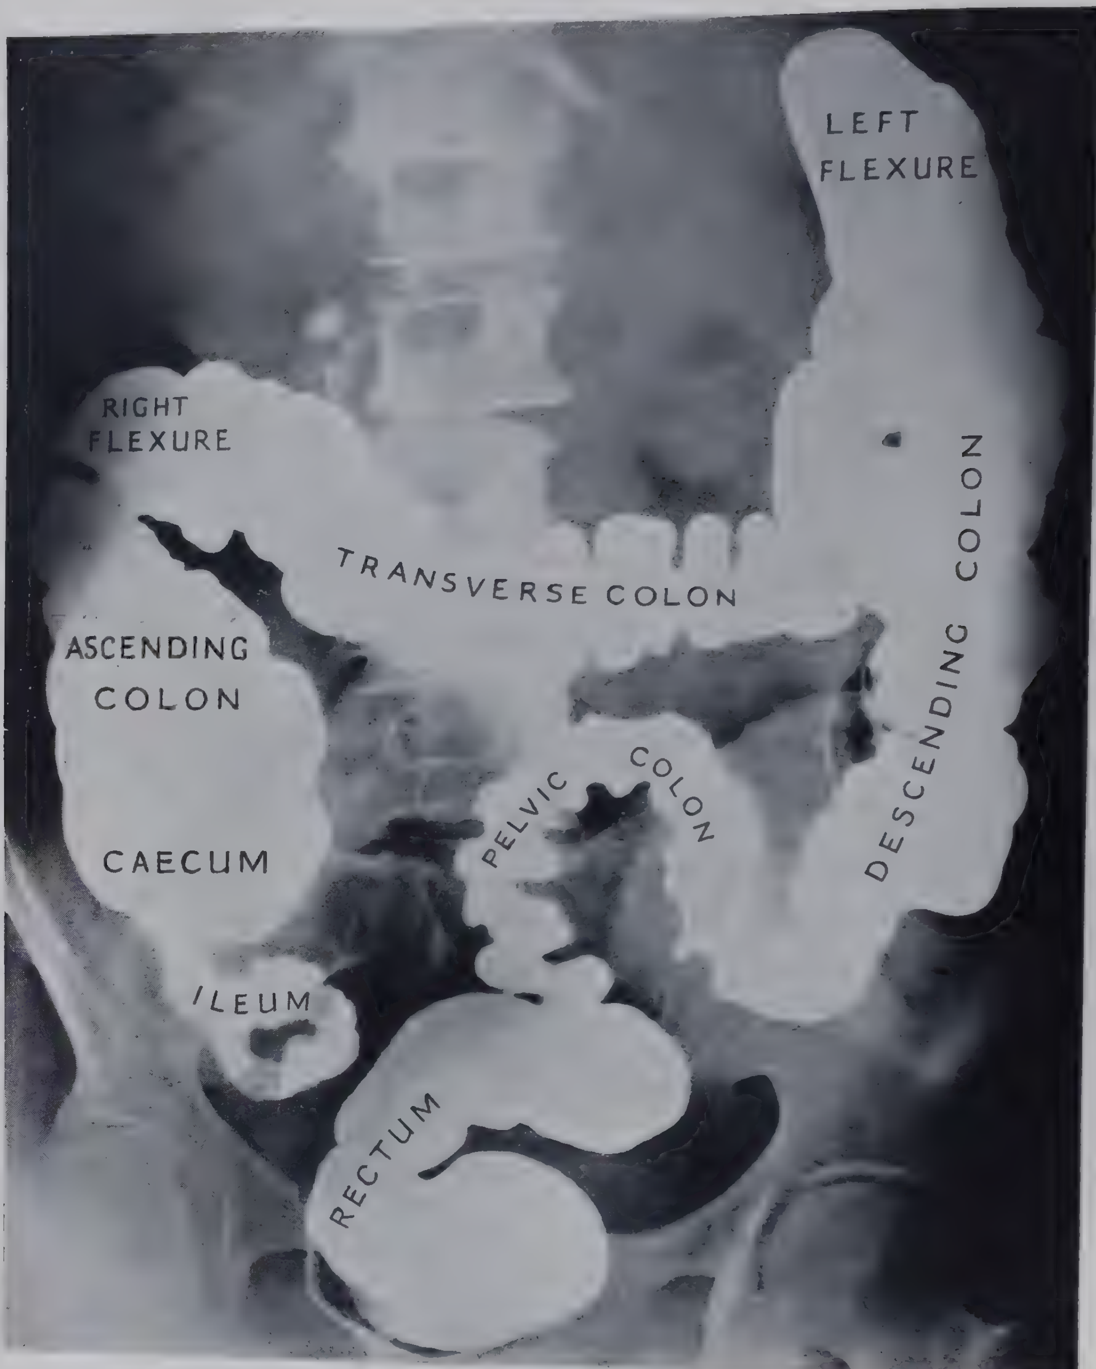

PLATE LVIII.—RADIOGRAPH OF LARGE INTESTINE FILLED ENTIRELY (WITH THE EXCEPTION OF VERMIFORM APPENDIX) BY BARIUM-ENEMA.

The position of the several parts of the Large Intestine is well shown. Note the loop of the Pelvic Colon, and that some of the barium injection has passed into the terminal part of the Ileum. Cf. Plate LVII, p. 648.

PLATE LIX

PLATE LIX.—RADIOGRAPH OF LARGE INTESTINE (MAN, AGED 26) SHOWN BY "DOUBLE-CONTRAST" ENEMA.

Note the definition of the sacculations (cf. Plate LVIII) and for details of the method employed see pp. 648 and 1555.

PLATE LX

FIG. 1.—SERIAL RADIOGRAPHS OF GALL-BLADDER (WOMAN, AGED 44) SHOWING PHYSIOLOGICAL CHANGES AFTER ADMINISTRATION OF SODIUM-TETRA-IODO-PHENOL-PHTHALEIN. (See pp. 667 and 1556.)

A. 16 hours after administration of S.T.I.P.P., showing concentration of bile; fatty meal given at this time.
B. $\frac{1}{2}$ hour after fatty meal, showing contraction of gall-bladder with discharge of bile.
C. $\frac{3}{4}$ hour after fatty meal, showing slight further contraction of gall-bladder.

Note that the colon is well shown by the radio-opaque S.T.I.P.P. taken by the mouth.

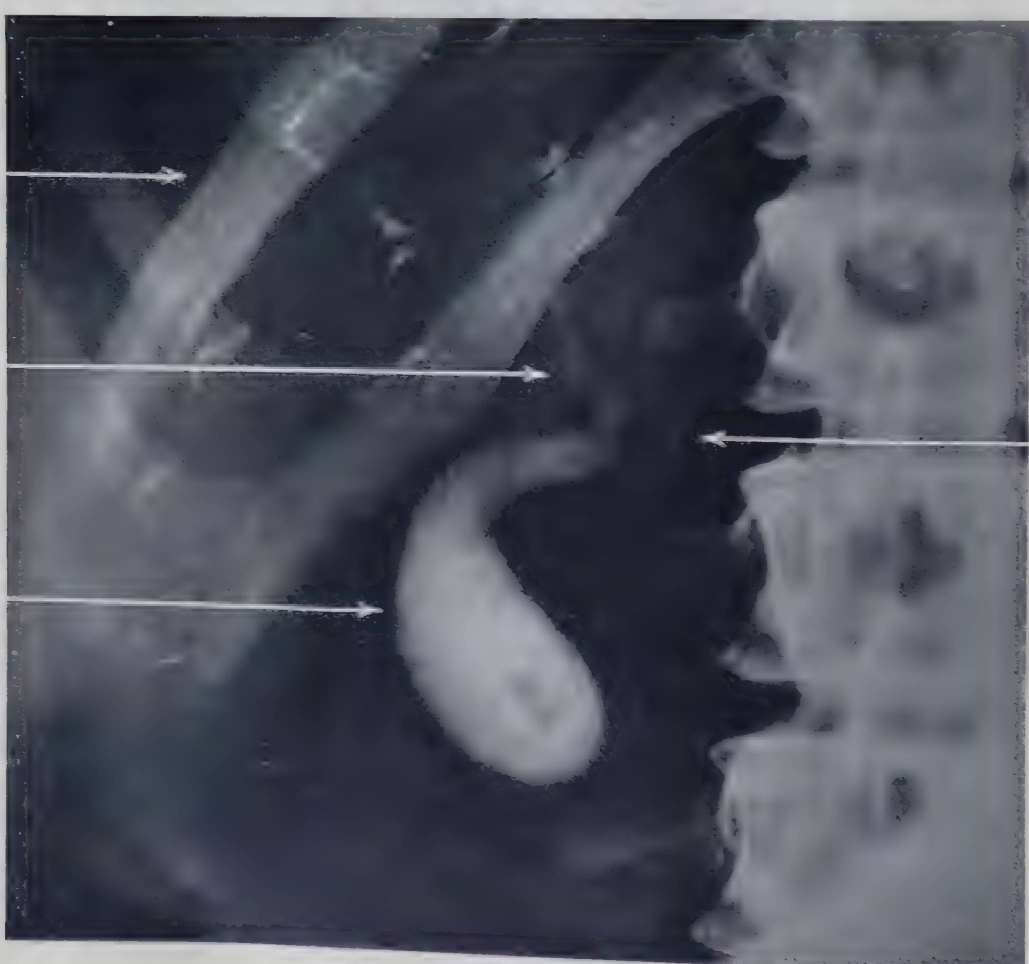

FIG. 2.—RADIOGRAPH (FEMALE ADULT), AFTER ADMINISTRATION OF S.T.I.P.P. (see pp. 667, 1556), SHOWING POSITION OF THE GALL-BLADDER AND THE CYSTIC DUCT THE BILE-DUCT ALSO IS FAINTLY SEEN.

hardened *in situ*; they can be seen also during life, *per anum*, with the aid of a rectal speculum; and they may interfere with the introduction of an enema-tube.

As a rule, two folds are found on the left and one on the right side; this latter is generally the largest, and is situated a little above the level of the peritoneal reflexion, viz., 3 or 3½ inches (7·5 to 8·5 cm.) above the anus; the other two folds are found about 1 to 1½ inches (2·5 to 3·5 cm.) higher up and lower down respectively. The folds are distinctly marked in the fœtus, and they seem to constitute an essential part of the

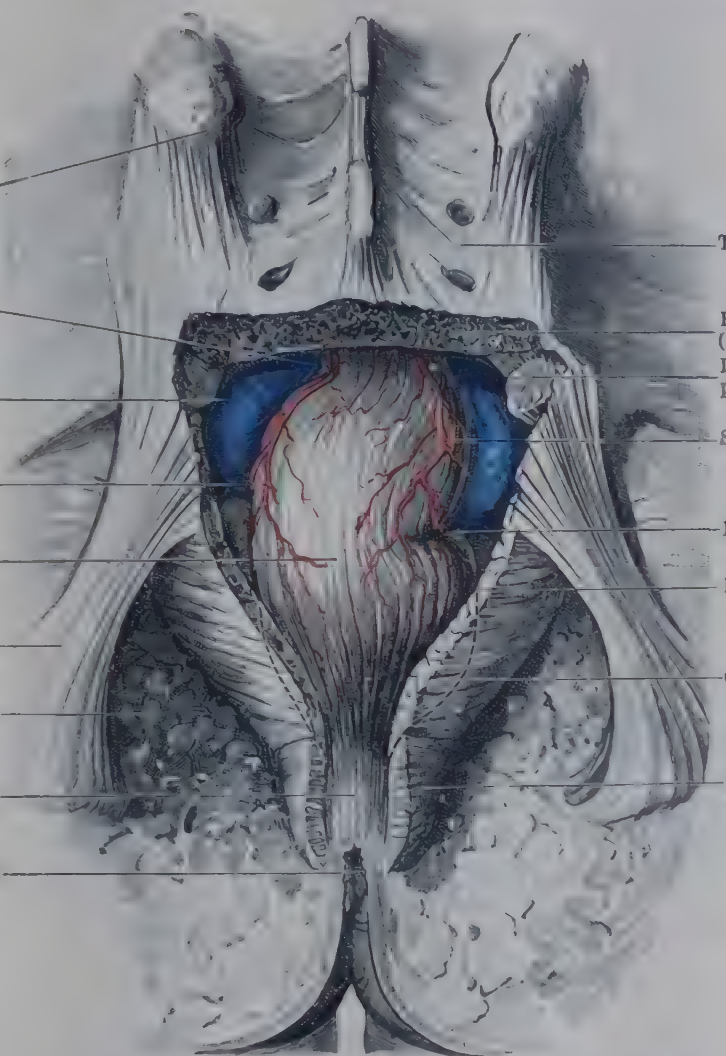

Fig. 554.—Rectum exposed by Dissection from Behind.

The sacrum has been sawn across through the 4th sacral vertebra, and its inferior part removed with the coccyx. The posterior portions of the coccygei, levatores ani, and of the external sphincter have been cut away. The "pinching in" of the lower end of the rectum by the medial edges of the levatores ani, resulting in the formation of the flattened anal canal, is suggested in the illustration, which has been made from a formalin-hardened male body, aged 30. The lateral flexures also are shown.

human rectum, their use being to support the contents of the rectum, which they break up into segments, each supported by a fold.

In *length* the rectum usually measures about 5 or 6 inches (12·5 to 15·0 cm.), but it may be much longer.

Its *diameter* is smallest above, near the junction with the pelvic colon, and is greatest below, near the anal canal, where there is an enlargement known as the **ampulla of the rectum.** When empty the rectum measures little over an inch (2·5 cm.) in diameter, but in a state of extreme distension it may be as much as 3 inches in width.

The folding is maintained by the arrangement of the longitudinal muscular fibres, the majority of which are accumulated in the form of two wide bands, one on the front of the bowel, the other on the back. The two bands, which are continuous with, and comparable in their functions to, the tæniæ of the colon, are shorter than the other coats of the rectum; hence they give rise, as in the case of the colon, to a folding or sacculation of the tube, which can be effective

only at the sides where the longitudinal fibres are fewest, for the front and back are occupied by the thickened longitudinal bands.

In addition to supporting the fæces, these foldings greatly increase the capacity of the rectum without unduly dilating the tube. When the rectum is empty (Fig. 556) its course is comparatively straight, its lateral flexures being but slightly marked, and its whole calibre very much reduced. In this condition it occupies only a small portion of the dorsal division of the true pelvis near the median plane, and at each side, between it and the side-wall of the pelvis, there is a large fossa of the peritoneum, which, when the bowel is empty, contains a mass of small intestine or pelvic colon (Figs. 556 and 558). When the rectum is distended the lateral flexures become

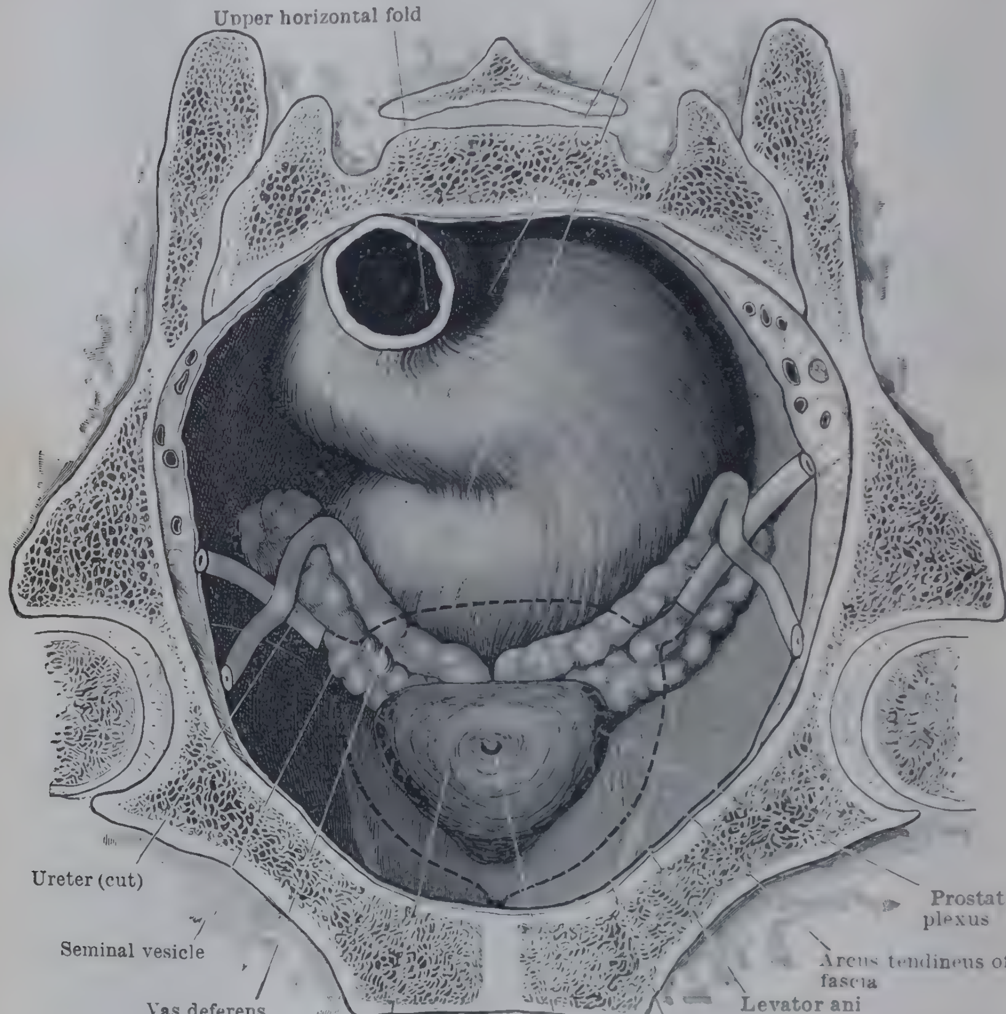

Fig. 555.—Distended Rectum *in situ*.

From a formalin-hardened male body, aged 56. The peritoneum and extraperitoneal tissue were removed, after the pelvis had been sawn along a plane passing through the upper part of the pubic symphysis in front and the lower part of the second sacral vertebra behind. The bladder, which was empty and contracted, has also been removed, but its form is shown by a dotted line. The rectum was very much distended, and almost completely occupied the pararectal fossæ.

much more marked, and the gut, bulging alternately to each side, passes laterally beneath the peritoneum, obliterating the pararectal fossæ (Fig. 555), and fills the greater part of the dorsal division of the pelvis.

Not uncommonly the abrupt curve at the junction of the rectum with the anal canal presents in front a knuckle-like projection (well seen on median section) immediately above the canal. It is most marked in females, and sometimes appears as if the bowel were doubled back upon itself at this point. The floor of the pouch thus formed may dip down in front even below the level of the upper aperture of the anal canal. That condition is most common in multiparæ and is evidently due to the relaxed condition of the pelvic structures, to the slight support afforded by the perineal body to this part of the gut in them, and to the great capacity and shallowness of the pelvis in the female (Fig. 657, p. 776).

Peritoneal Relations of Rectum (Figs. 554, 556).—Where the pelvic meso-colon ceases, its two layers separate and leave the posterior surface of the rectum destitute of peritoneum. Very soon the membrane quits its sides also and is then found on the front only; finally, it passes from the rectum on to the urinary

bladder in the male (Fig. 620, p. 740), and the vagina in the female (Fig. 627, p. 745); consequently the terminal part of the rectum is entirely devoid of peritoneum; the greater part of the rectum thus lies beneath the pelvic peritoneum and is capable of expanding and contracting without being in any way hampered by its partial peritoneal coat.

As the peritoneum is carried forwards to the base of the bladder in the male, it forms the floor of a recess called the **recto-vesical pouch** (Fig. 625, p. 744). In the female, as it passes to the upper part of the posterior wall of the vagina, it forms the floor of the **recto-uterine** or **recto-vaginal pouch**. In both sexes it passes from each side of the rectum on to the posterior wall of the pelvis, forming, when the rectum is empty, the bottom of a large fossa, known as the

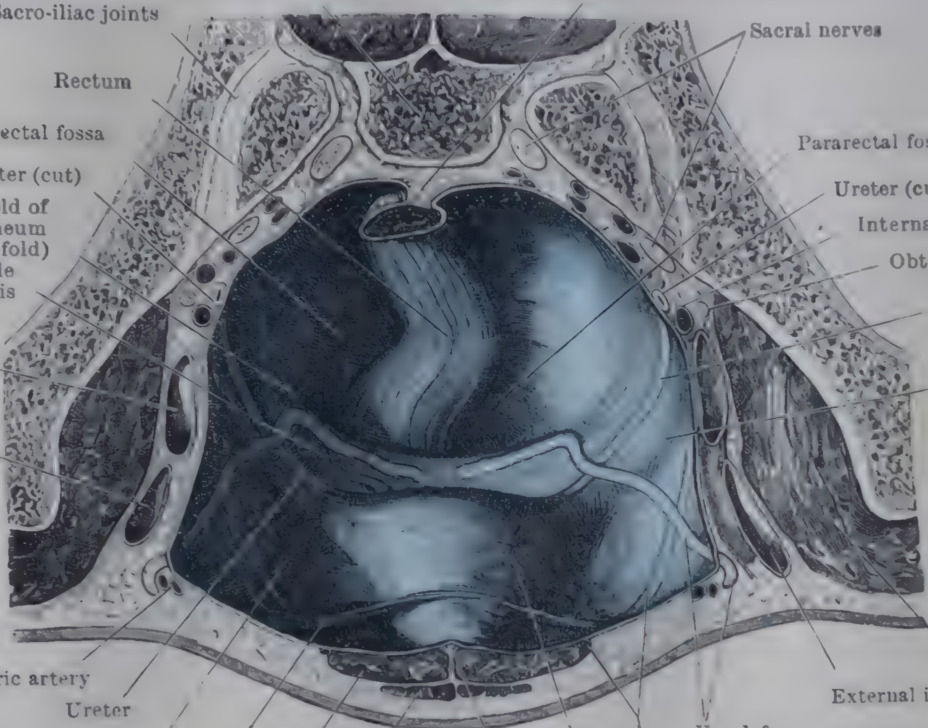

FIG. 556.—PERITONEUM OF PELVIC CAVITY SEEN FROM ABOVE.

The pelvis of a thin male subject, aged 60, was sawn across obliquely. Owing to the absence of fat the various pelvic organs were visible through the peritoneum, though not quite so distinctly as represented here. The urinary bladder and rectum are both empty and contracted; the paravesical and pararectal fossæ, as a result, are very well marked.

pararectal fossa. As the rectum becomes distended these fossæ are encroached upon by the enlarging bowel, and are soon obliterated.

The level at which the reflexion of the peritoneum takes place from the front of the rectum is of considerable practical importance in relation to operations in this region. As a general rule it is placed at a distance of 1 inch (2·5 cm.) above the base of the prostate, or about 3 inches above the anus, but the level is subject to considerable variation, being relatively much higher in well-developed muscular or fatty subjects, and lower in emaciated bodies owing to the thinness of the structures forming the pelvic floor. Further, the level is slightly raised by distension of the rectum and bladder, and lowered when they are empty. In the female the floor of the recto-uterine pouch is at a lower level and is relatively nearer the anus.

In the male infant at birth the peritoneum extends down to the base of the prostate (Symington, 1887), so that the rectum is not in direct relation to the bladder, which at that time is in a relatively higher position than in the adult.

As a rule it will be found that 2 inches (5·0 cm.) of the front of the adult rectum, exclusive of the anal canal, are entirely free from peritoneum, and this very distensible portion of the bowel forms

the ampulla of the rectum. The distance from the anal orifice to that part of the rectum which has a peritoneal covering in front is $3\frac{1}{2}$ inches (8·5 cm.). On the other hand, the back of the rectum is entirely free from peritoneum.

It is also of interest to notice that the connexion of the peritoneum to the rectum varies in its character at different parts: Above and in front it is closely adherent, and can be removed only with the greatest difficulty; at the sides and inferiorly the connexion is much looser. As a result the lower part of the peritoneum can be stripped off the rectum without much difficulty —an arrangement which admits of the free expansion of the rectal ampulla.

General Relations of Rectum (Figs. 554 and 556).—*Posteriorly* the rectum is related to the sacrum and coccyx, and below them to the posterior part of the pelvic floor—formed by the meeting of the two levatores ani in the ano-coccygeal body. When much distended it also comes into relation, on each side, with the lower part of the piriformis and the sacral plexus, but is separated from them by a very considerable amount of fibro-areolar tissue. In that tissue the two chief branches of the superior rectal vessels lie behind the rectum above, but lower down they are placed on its sides.

At its sides above are the pararectal fossæ and their contents (pelvic colon, or ileum); below the pararectal fossæ the rectum is in contact with the coccygei and levatores ani muscles.

Anteriorly in the male the rectum is separated from the bladder to within an inch of the prostate by the recto-vesical pouch of peritoneum, which usually contains some coils of small intestine. Below the reflexion of the peritoneum the front of the rectum is related to the posterior surface of the bladder, the vasa deferentia, seminal vesicles, and the posterior surface of the prostate gland (Fig. 555), from all of which it is separated by the recto-vesical septum.

The recto-vesical septum alone separates the rectum from a triangular area of the base of the bladder below the reflexion of the peritoneum and between the vasa deferentia. Through the triangle the operation of tapping the bladder from the rectum used to be performed.

The seminal vesicles, except when small, slope laterally and backwards round the front and sides of the distended rectum (Fig. 555), and, as it were, embrace it.

The ureters, as they run medially towards the base of the bladder, lie close below and in front of the vasa deferentia, and are not far separated from the distended rectum.

In the female the rectum is separated from the posterior surface of the uterus and the upper end of the vagina by the recto-uterine (recto-vaginal) pouch and the intestine which it usually contains. Below the peritoneal reflexion it is in direct contact with the posterior vaginal wall, to which it is loosely attached above, but more closely below.

The portion of the rectum below the level of the peritoneal reflexion is surrounded by a layer of fascia.

In the **child** the rectum, or at least its upper part, is relatively larger, and it pursues a much straighter course than in the adult. As pointed out above, its peritoneal covering is at a lower level at birth—reaching as far as the base of the prostate.

ANAL CANAL

In order to reach the exterior, it is necessary for the lower end of the bowel to pierce the floor of the true pelvis. This it does by passing through the narrow interval between the medial borders of the levatores ani muscles (Fig. 554); and the part of the large intestine through which the rectum communicates with the exterior is the anal canal. As it passes between the two muscles they pinch in the sides of the tube, and reduce its cavity to a mere slit-like passage.

The **anal canal** *begins* where the rectum proper terminates, namely, at the level of the levatores ani muscles, behind the apex of the prostate; and it *ends* at the anus. Its *length* is usually from 1 to $1\frac{1}{2}$ inches (2·5 to 3·5 cm.), and its antero-posterior diameter is from $\frac{1}{2}$ to $\frac{3}{4}$ inch (12 to 19 mm.) when the canal is closed. Its *direction* is downwards and backwards.

Relations.—It is *surrounded* by the external and internal sphincters, and above also by the borders of the levatores ani, these muscles forming a muscular cylinder around it (Fig. 558). *On each side* is situated the ischio-rectal fossa with its contained fat, which allows of the distension of the canal during the passage of fæces. *Posteriorly*, a mass of mixed fibrous and muscular tissue known as the **ano-coccygeal body** (Symington, 1888, 1912) intervenes between it and the coccyx. *Anteriorly*, it lies close behind the

perineal body and the bulb of the penis in the male, and a sound in the urethra can be easily felt by the finger introduced into the anal canal, particularly in thin bodies. In the female it is separated from the vagina by the perineal body.

Structure of Rectum and Anal Canal.—The wall of the rectum is made up of four coats. The **outer coat** is formed in part of peritoneum (already described), and, where the peritoneum is absent, of fibrous tissue which can be dissected off in several layers. In this fibrous tissue the rectal vessels run until they enter the muscular wall of the tube. In it also, at the back and sides of the rectum, a number of rectal lymph-glands are embedded.

The **muscular coat**, which is much thicker than in any other portion of the intestine, is composed of two thick layers of plain muscle—an outer longitudinal and an inner circular—like that of the intestine generally. The *longitudinal fibres*, although present all round, are accumulated chiefly on the front and back of the tube, where they form two broad bands; at the sides they are reduced to a thin layer, the deepest fibres of which are folded in and take part in the formation of the horizontal folds.

Where the rectum pierces the floor of the pelvis, the outer layer of longitudinal fibres is united to the deeper portion of the levator ani, partly by tendinous fibres and partly by an interchange of muscular fibres between the levatores and the muscular coat of the rectum. Below, the longitudinal fibres pass between the external and internal sphincter muscles, or through the latter to join the skin around the anus.

In sagittal sections of the pelvis near the median plane there can generally be seen a distinct band of red, longitudinally arranged, muscular fibres which descends on each side from the front of the coccyx to blend with the longitudinal fibres on the back of the rectum. That band is the *recto-coccygeus muscle.* It is composed of striated fibres above, but becomes plain muscle below.

Some plain muscular fibres which descend in the subcutaneous tissue of the lower part of the anal canal to join the skin around the anus were first described by Ellis (1867) as the *corrugator cutis ani.* The front of the rectum at the perineal flexure is, in the male, connected to the back of the membranous urethra by one or two slips of muscle termed the *recto-urethralis* (Fig. 402, p. 472).

The *circular fibres* form, along the whole length of the tube, a continuous layer, which is doubled inwards to assist in the formation of each horizontal fold and is thickened below to form the **internal sphincter** of the anal canal. The internal sphincter, as just pointed out, is formed by a great, and rather sudden, increase of the circular muscular fibres, which begins at the upper end of the anal canal. It surrounds the canal for about an inch (2·5 to 3·0 cm.), and may reach almost down to the anal orifice (Fig. 557).

The **submucous coat** is composed of loose areolar tissue, which allows of a free movement of the mucous layer on the muscular coat. The rectal plexus of veins is contained in this layer.

The **mucous coat** of the rectum is redder in colour than that of the colon. It is also thicker, and owing to the looseness of the underlying submucosa is thrown into numerous irregular rugæ when the rectum is empty; these disappear when the bowel is distended. Lymphatic nodules and intestinal glands are present; but the glands are not so numerous as in the colon, although their calibre is greater. The mucous coat of the rectum presents a characteristic punctated appearance which is due to the presence of a considerable number of rounded depressions, such as might be made by firmly pressing a finely pointed pencil against the membrane. These *rectal pits* are tubular in form, and have an accumulation of lymphoid tissue at the bottom of each, the whole appearance being such as might be produced if a small solitary nodule were drawn down from the surface into the intestinal wall.

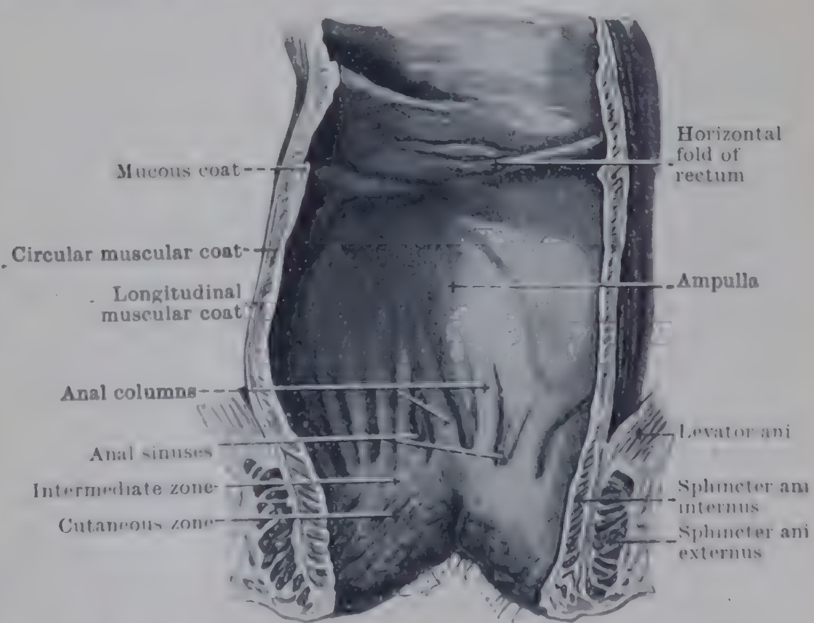

Fig. 557.—Interior of Lower Rectum and Anal Canal.

Anal Columns and Anal Valves.—The mucous coat of the anal canal presents a number (5 to 10) of *permanent* vertical folds, separated by grooves and known as the **anal columns** (Fig. 557). They are usually $\frac{1}{3}$ to $\frac{1}{2}$ inch in length, $\frac{1}{8}$ to $\frac{1}{4}$ inch in width, and they extend down to within $\frac{1}{2}$ or $\frac{2}{3}$ inch of the anal aperture. They are formed by infoldings of the mucous coat, containing in their interior some bundles of longitudinal muscle, and also, as a rule, an artery and a vein.

Very often the contained vein presents an enlargement, or a knob-like tortuous plexus in the lower part of the column; below this the plexus is continued down *external* to the mucous membrane of the lower zone of the anal canal into the anal veins. Dilated portions of the veins may form rounded nodular projections, known as hæmorrhoids or "piles", and this portion is therefore frequently termed the hæmorrhoidal zone of the anal canal. Sometimes the columns are very indistinct; occasionally no trace of them can be found in the adult, although in the fœtus they are usually well marked.

If a probe is passed downwards along the groove which separates two adjacent anal columns (Fig. 557), its point will usually catch in a small crescentic fold which joins the lower ends of the two columns. These little folds are the **anal valves**. They project inwards and upwards, and behind each there is a little pocket-like **anal sinus**.

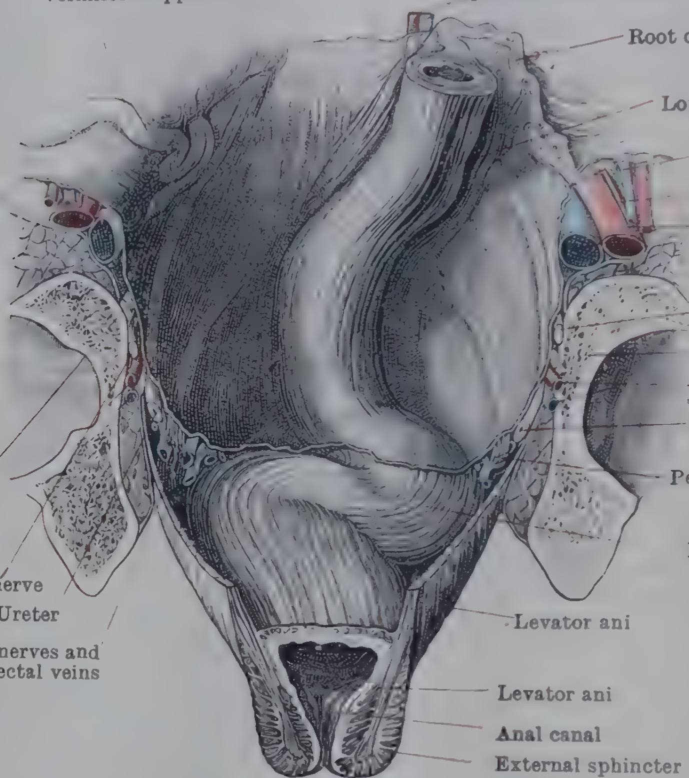

FIG. 558.—DISSECTION OF RECTUM AND ANAL CANAL FROM THE FRONT IN A SPECIMEN HARDENED BY FORMALIN INJECTION.

The front wall of the pelvis has been removed, and the bladder, prostate, and seminal vesicles taken away.

Anal Orifice.—At the inferior aperture of the anal canal, the modified skin of its lower zone passes into the ordinary skin.

The skin round the margin of the anus possesses hair-follicles and glands and forms a zone called the cutaneous zone. Above this zone there is a second zone, not sharply marked off, but its surface is smoother and no hairs arise from it. It is lined with a stratified squamous epithelium.

The region of the lowest part of the anal columns forms a third zone lined with columnar epithelium and clearly marked off from the second zone by a sinuous line which follows the level of the anal valves and crosses the bases of the columns between the valves; this sinuous line of union of mucous membrane and skin is known as the "white line" of Hilton (1863), and it corresponds to the junction of epithelium derived from the entoderm of the hind-gut with that derived from the ectoderm of the anal pit (pp. 62, 672).

Action of Anal Sphincters.—Three muscles act on the anal canal, namely, the paired levatores ani, the external sphincter, and the internal sphincter.

The fibres of the **levatores ani** which arise from the lateral part of the body of the pubis (pubo-rectalis) pass backwards on each side of the beginning of the anal canal, and meet behind the passage. The two muscular bands are closely approximated during contraction, like the limbs of a clamp, and, pressing on the sides of the anal canal, they assist in closing the upper part of that passage, whilst at the same time drawing it towards the pubes. There is little doubt that the *pubo-rectalis* in that way acts as one of the chief sphincters of the bowel; and it should be noticed that it is placed where its action would be most effective, namely, opposite the point at which the rectum is narrowed or "pinched in" to form the anal canal. In addition to its sphincter action the muscle supports the expanded bowel immediately above the

anal canal, and in that way sustains the weight of the fæces when the rectum is distended. It is probably relaxed during defæcation, except perhaps at the completion of the act. The muscle is under the control of the will and is closely associated with the deeper part of the external sphincter.

The **sphincter ani externus** forms a muscular cylinder around the lower two-thirds of the anal canal, with (except in the case of some of its inner fibres) an anterior and a posterior attachment. When the muscle contracts its fibres are tightly stretched between its two attachments, and the space between them is reduced to a narrow antero-posterior slit. By that action the anal canal is flattened from side to side and closed, so that, whilst the pubo-rectalis is the sphincter of the upper aperture of the anal canal, the external sphincter closes its inferior and greater part. It is under the control of the will, but under ordinary circumstances it is in a state of tonic contraction.

The **sphincter ani internus** is continuous with the circular fibres of the gut in structure and also in action, its chief use being to empty the anal canal completely after the passage of each fæcal mass.

Vessels and Nerves.—The **arteries** of the rectum and anal canal are the three rectal arteries; to these, another, less important though constant, source may be added—the median sacral artery.

1. The *superior rectal artery* is the principal artery of the rectum. It is the prolongation of the inferior mesenteric artery; and at first it descends in the root of the pelvic mesocolon until the rectum is reached. There, it divides into two chief branches which run downwards and forwards around the sides of the rectum—the right, usually the larger, lying more posteriorly, the left more anteriorly. From these two arteries secondary branches come off (about five to eight in all); they pierce the muscular coat about the middle of the rectum and then descend in the submucosa as a series of longitudinal "terminal branches" as far as the anal valves, above the level of which one is usually found beneath each of the anal columns. The terminal branches give off numerous twigs which form a plexus in the submucosa by anastomosing with one another and with branches of the middle rectal artery, and also, in the lower part of the bowel, with branches of the inferior rectal artery.

2. The *middle rectal arteries*, two in number—one on each side—are usually branches of the internal iliac but may arise from the internal pudendal; they run on the wall of the inferior part of the rectum, and each breaks up into four or five small branches, some of which supply the muscular wall of the lower part of the rectum, whilst the others pierce the muscular coat near the upper end of the anal canal and join in the submucosa with the plexus formed by the superior rectal artery already described.

3. The *inferior rectal arteries*, generally two or three in number on each side, arise at variable levels from the internal pudendal. They are distributed to the levatores ani and the sphincters. Some branches pierce the sphincters and break up in the submucosa into a close network which supplies the lower part of the anal canal and communicates above with the plexus formed by the superior and middle rectal arteries.

4. One or more small branches of the **median sacral artery** reach the posterior surface of the rectum, where they are distributed chiefly to the muscular coat.

The superior and middle rectal arteries anastomose freely in the plexus of the submucosa, and also by a few large branches on the exterior of the bowel: some perforating branches of the median sacral and inferior rectal arteries also join the plexus in the submucous layer at the lower part of the rectum. In addition, small branches of these several arteries unite with one another in the muscular coat. It should be remarked that the superior rectal artery supplies both the muscular and mucous coats in the superior part of the rectum, but that the muscular coats in the inferior part are supplied by the middle and inferior rectal vessels only. The inferior rectal artery is distributed chiefly on the posterior wall, and the middle rectal chiefly on the anterior wall.

The **veins** form two chief plexuses of large vessels devoid of valves, namely, an internal plexus situated in the submucous coat, and an external plexus in the outer coat. The internal plexus takes origin near the margin of the anus in a number of small (anal) veins, which are radially disposed beneath the skin of the anus and communicate below with the rootlets of the inferior rectal vein lying lateral to the external sphincter. The anal veins are joined by others from the surrounding parts to form larger and often tortuous vessels which ascend in the anal columns. Passing upwards, the veins are known as the "terminal veins"; they communicate freely with one another, and they unite into still larger vessels which pierce the muscular coat about the middle of the rectum and join to form the superior rectal vein.

From the inferior part of the internal plexus numerous vessels pass through the external sphincter to join a venous network on the outer surface of that muscle, from which the *inferior rectal veins* arise. The network also communicates with the internal plexus through the anal veins which descend from the latter beneath the skin of the anal canal to the exterior of the sphincter.

The various veins which pass out through the walls of the rectum unite freely on its exterior to form a rich venous plexus through which the three rectal vessels are brought into free communication with one another. Passing off from that plexus, the *superior rectal* joins the inferior left colic vein and forms with it the inferior mesenteric vein, which opens into the splenic; the middle rectal joins the internal iliac, from which the blood passes through the common iliac to the inferior vena cava; and the inferior rectal joins the internal pudendal—a tributary of the internal iliac vein. Thus, on the rectum, a free anastomosis is established between the veins of the portal and systemic circulations.

Most of the **lymph-vessels** of the rectum pass to the sacral lymph-glands.

The **nerves** are derived from various sources. The sympathetic fibres are derived from the *inferior mesenteric plexus* and from the branches of the *hypogastric plexus* that accompany the superior and middle rectal arteries to the rectum. The parasympathetic fibres arise from the *second* and *third* or *third and fourth sacral nerves* soon after these leave the sacral foramina. They run forward in the pelvic areolar tissue, join the pelvic plexuses, and reach the side of the rectum. Fibres of the *inferior hæmorrhoidal* branches of the pudendal nerve (third and fourth sacral) are distributed to the lower part of the anal canal as well as to the external sphincter.

Variations.—The best known anomalies of the rectum are those classed under the term **imperforate anus** or **atresia ani**. The atresia may be simply due to a partial or complete persistence of the anal membrane, which separates the anal pit from the hind-gut in the embryo; or the hind-gut may be deficient in its lower part when there is a considerable interval between the anal pit and the gut; or the rectum may open into the vagina, the uterus, the bladder, or the ureters, when usually no anus is evident; or finally the cloaca may persist. Other forms are also described, but the foregoing are those most commonly found.

LIVER

The **liver** (hepar) is a large glandular organ which lies immediately below the diaphragm, occupying the upper portion of the abdominal cavity mainly on the right side. It secretes a yellowish-green or brown fluid of bitter taste, called *bile* (fel). The bile is conveyed from it by two **hepatic ducts** which unite with each other to form a **common hepatic duct**. The common duct opens into the **bile-duct**, which conveys the bile to the duodenum. Connected with the bile-duct there is also a pear-shaped sac called the **gall-bladder** which is attached to the liver and serves as a temporary reservoir for the bile. The bile passes to and from it through a canal, called the **cystic duct**, which unites with the common hepatic duct to form the **bile-duct**.

In addition to secreting bile, the liver plays an important part in the metabolism of carbohydrate and nitrogenous materials which are absorbed from the food by the intestines and conveyed to the liver by the portal vein.

Physical Characters.—The liver is a large, mottled, reddish-brown mass, pliant to the touch, readily lacerated, and highly vascular. It is of uniform consistence, but the lacerated surface is granular. The granular appearance of the lacerated surface and the mottled colouring of the free surface are due to the lobules of which the liver is composed. Each lobule is polygonal or irregular in form and measures only 1 to 2 mm. in diameter; it is surrounded by a stroma of areolar tissue in which the vessels, nerves, and bile-capillaries lie.

Size and Weight.—The average dimensions of the adult liver are seven inches across (17·5 cm.), six and a half inches vertically (16 cm.), and six inches antero-posteriorly (15 cm.) where it is thickest. It is about $\frac{1}{50}$th of the body-weight, varying from 50 to 55 ounces in men, and from 43 to 48 ounces in women. The ratio to the body-weight is the same in both sexes, but it varies with age. In the fœtus and child it is relatively large and heavy. At birth it occupies the greater part of the abdominal cavity and is $\frac{1}{20}$th to $\frac{1}{18}$th of the body-weight; in a fœtus the ratio is still larger. The protuberance of an infant's abdomen is due chiefly to the liver.

Shape.—If the liver is not removed from the body until some time after death it becomes soft and flabby; it flattens out when placed on a table and appears to have only a superior and an inferior surface separated by a circumferential border. But if it is taken out shortly after death while still firm, or if it is hardened *in situ* and then removed, its form is fairly constant; and, although it is irregular and varies with the position of adjacent organs and with the degree of distension of the parts of the alimentary canal near it, nevertheless, for descriptive purposes, it may be looked upon as an irregular four-sided pyramid laid on one side. The pyramid has an edge-like apex, directed towards the left, a convex right surface, and four other surfaces—anterior, posterior, upper, and lower (or visceral)—the distinctive features of which are that the **anterior surface** is nearly flat, the **upper surface** is slightly convex on each side and slightly concave in the middle, the **posterior surface** is markedly concave from side to side, and the **lower surface** is uneven and oblique, looking to the left and backwards as

well as downwards. The anterior, upper, posterior, and right surfaces merge into one another over ill-defined, rounded borders; but the lower surface is marked off from the others by a definite, circumferential **lower border**. This lower border is indistinct between the posterior and the inferior surface, but forms a definite edge between the right lateral and the inferior surface. Between the anterior and inferior surfaces the lower border forms a characteristic sharp edge, and towards the left extremity of the liver it is the rounded edge of a sharp wedge between the stomach and the diaphragm (Figs. 559-562).

Porta Hepatis.—The porta hepatis, or hilum of the liver, is a deep, wide, transverse cleft, about two inches long, situated in the posterior part of the lower or visceral surface. Part of the upper border of the lesser omentum is attached to its lips (see p. 604). The hepatic artery, the portal vein, and the nerves of the liver enter through the porta, and the common hepatic duct and the lymph-vessels of the deeper parts pass out through it. These structures are

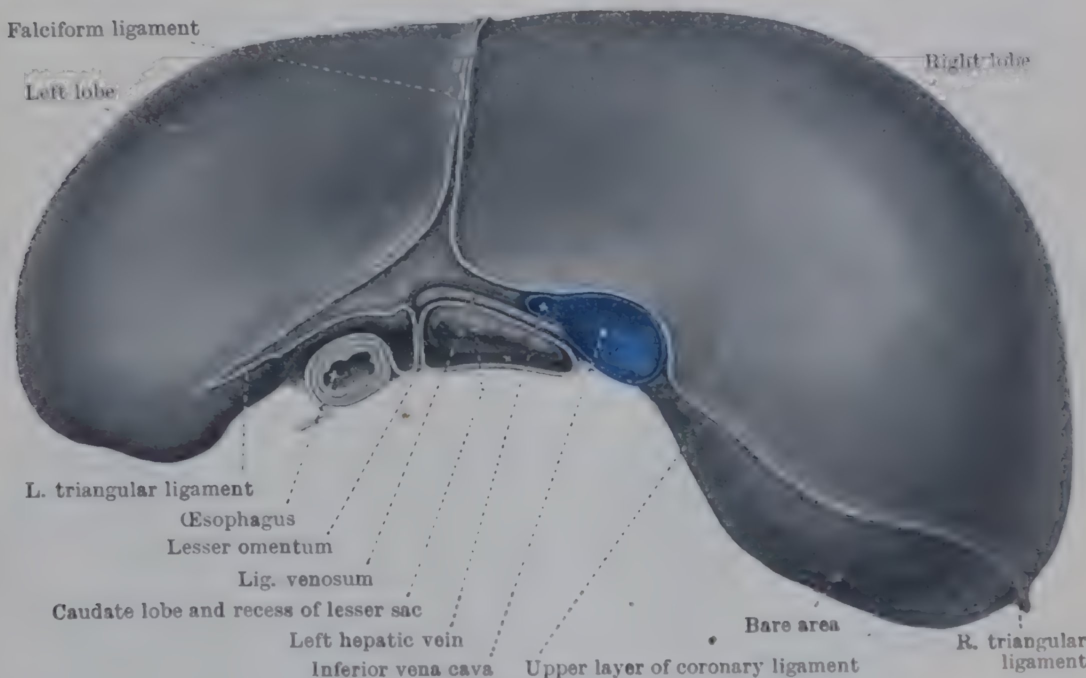

Fig. 559.—Liver viewed from Above.

surrounded by loose fibrous tissue which is continuous with the fibrous capsule of the liver.

The right and left hepatic ducts emerge from their lobes at the right and left ends of the porta, and unite near its right end to form the common hepatic duct, which unites, either inside or immediately outside the porta, with the cystic duct to form the bile-duct. The hepatic artery enters the porta to the left of the common hepatic duct, and its right and left branches run to their lobes behind the hepatic ducts. The portal vein divides similarly but at the right end of the porta, and its branches are behind those of the artery. Two or more lymph-glands are sometimes present in the porta, most commonly near its right end; if they become enlarged they may press upon the hepatic ducts and obstruct the flow of bile.

Surfaces.—The **right surface** of the liver is convex and roughly quadrilateral. It is closely related to the diaphragm, which separates it from the lower parts of the right lung and pleura and the lower six ribs and intervening intercostal spaces. Not uncommonly it descends below the ribs; its lowest part is then related to the fascia and muscles of the abdominal wall.

The **upper surface** is closely apposed to the diaphragm. On the right and left it is slightly convex and fits into the cupolæ of the diaphragm, which separate it from the pleuræ and lungs. Its middle part is slightly concave and lies below the pericardium and heart (Fig. 559).

The **anterior surface** is flat or slightly convex. In the infrasternal angle it is related to the xiphoid process, the linea alba, and the sheaths of the recti muscles,

and to the falciform ligàment, which lies between it and the abdominal wall with its left surface in contact with the left lobe of the liver and its right with the anterior abdominal wall. The smaller part of the anterior surface that lies to the left, and the larger part to the right, are under shelter of the ribs and costal cartilages in contact with the diaphragm.

The **lower or visceral surface** (Fig. 560) is in relation (*a*) with the right kidney posteriorly, (*b*) with the right flexure of the colon anteriorly, (*c*) with the second part of the duodenum to the left of the kidney, then (*d*) with the gall-bladder in its shallow fossa, and (*e*), near the apex, with the lesser omentum and the stomach.

The **posterior surface** (Fig. 562) is curved round the front of the vertebral column. On the right, a large convex part of it is in direct contact with the diaphragm, which separates it from the right pleura and lung and the lower

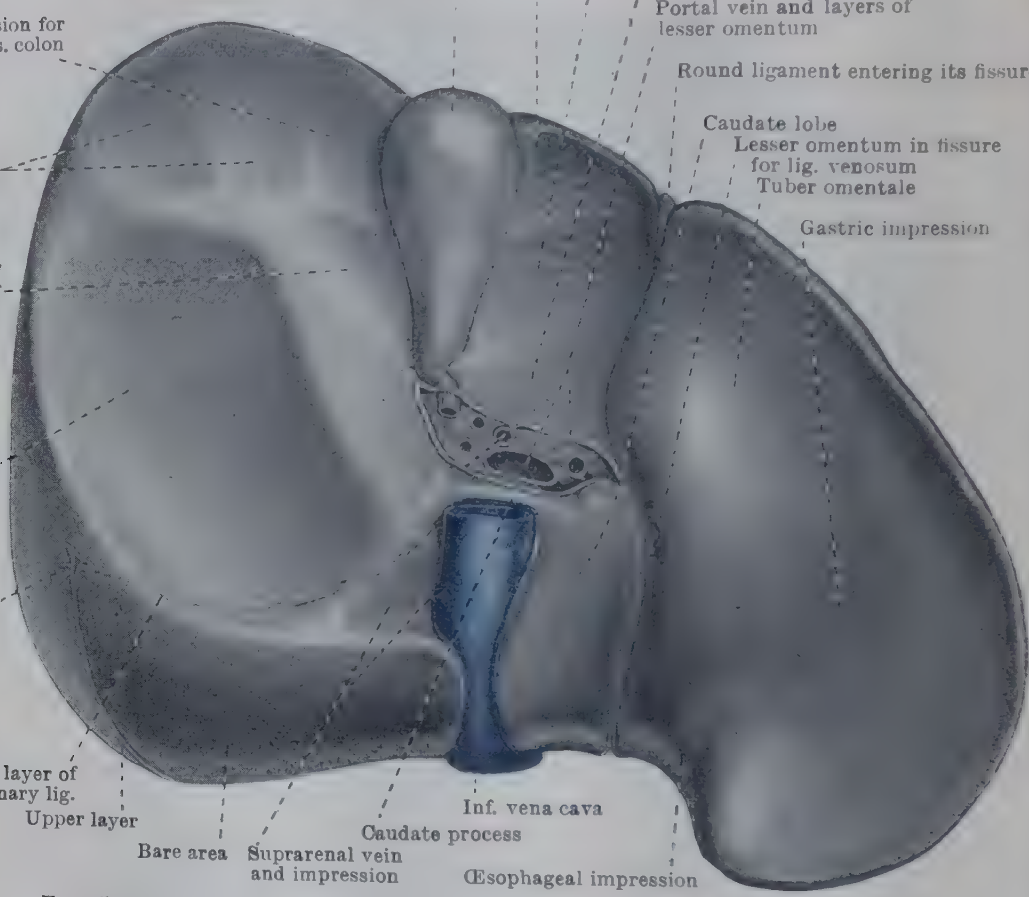

Fig. 560.—Lower (Visceral) and Posterior Surfaces of Liver.

ribs of the right side. Next, passing to the left, it is intimately attached to the upper part of the inferior vena cava, which is embedded in the liver in a deep **groove for the vena cava.** On the right of this groove there is an area which is in contact with the right suprarenal gland. To the left of the inferior vena cava, an oblong area of the surface lies on the front of the crura of the diaphragm, which separate it from the lower part of the descending thoracic aorta; that portion is called the **caudate lobe**; it is separated from the crura by the upper recess of the lesser sac (Figs. 515 and 559), and is bounded on the left by a deep, vertical cleft called the **fissure for the ligamentum venosum.** To the left of that, the surface is grooved vertically for the abdominal portion of the œsophagus, which produces the **œsophageal impression.**

Relation to Peritoneum.—The peritoneum covers the surfaces of the liver and adheres to its fibrous capsule, with the exception of (*a*) an area of the posterior surface, in contact with the vena cava and with the diaphragm, continued on to the posterior portion of the upper surface, and (*b*) a part of the inferior urface in contact with the gall-bladder. Also, along certain definite lines the

peritoneum passes from the liver to adjacent structures in the form of folds or reflexions which connect the liver with adjacent parts.

The largest of the folds is called the **falciform ligament**. It is a long, wide sheet, attached to the upper and anterior surfaces of the liver and to the lower surface of the diaphragm and the back of the linea alba—as far down as the umbilicus. Its line of attachment to the liver indicates the division of the liver into right and left lobes (see p. 661). Its lower border is free; it extends from the umbilicus to a notch in the lower border of the liver, and it encloses a fibrous cord called the ligamentum teres. At the lower border of the liver the **ligamentum teres** enters a deep cleft in the inferior surface called the **fissure for the ligamentum teres** (see p. 661), along which it passes to end by fusing with the left branch of the portal vein. The ligamentum teres (round ligament) is the remains of the umbilical vein of the fœtus and, during fœtal life, it conveyed purified, oxygenated,

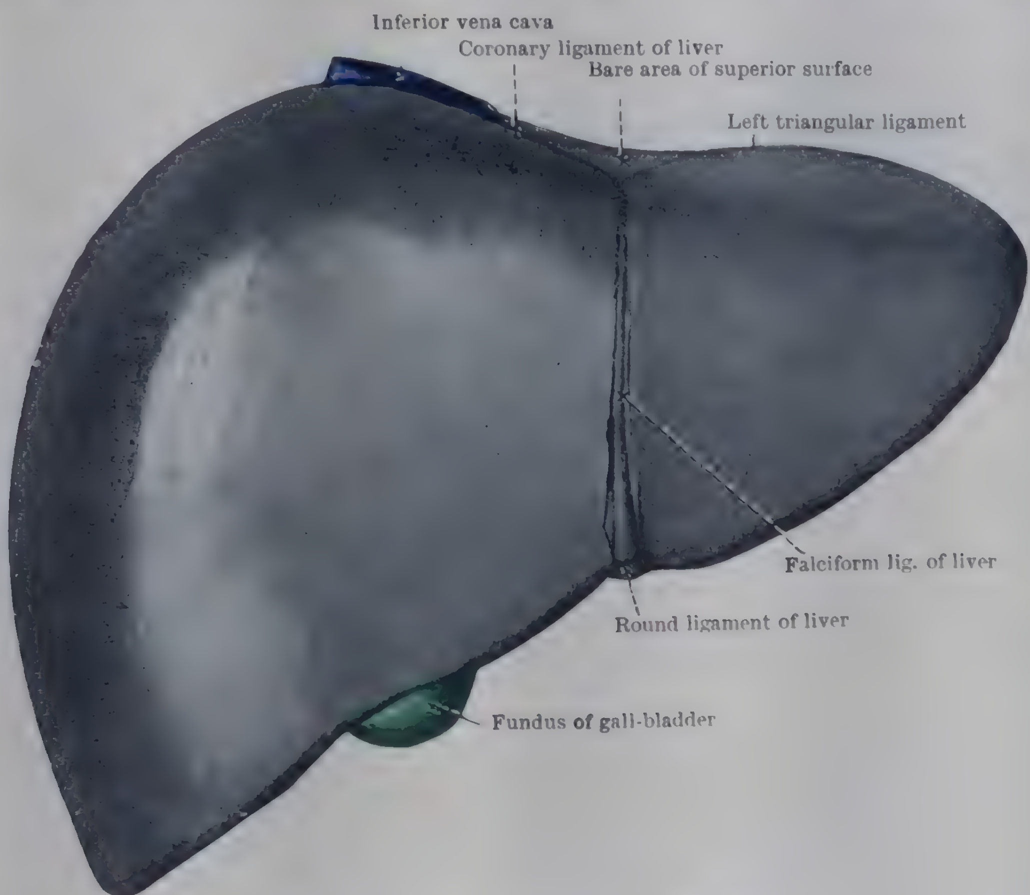

Fig. 561.—Liver viewed from the Front.

and food-laden blood from the placenta to the fœtus. Alongside it, in the adult, run some small venous channels which connect the left branch of the portal vein with the veins of the body-wall in the region of the umbilicus.

The falciform ligament consists of two layers of peritoneum. At the back part of the upper surface of the liver the left layer turns to the left and forms the anterior layer of a triangular fold called the **left triangular ligament**, which passes from the upper surface of the left lobe to the diaphragm (Fig. 559). At the left end of the left triangular ligament that layer turns to the right as the posterior layer of the left triangular ligament, and at the upper end of the fissure for the ligamentum venosum (see Fig. 559) it becomes continuous with the upper end of the lesser omentum.

At the point where the left layer of the falciform ligament turns to the left the right layer turns to the right in front of the inferior vena cava and along the posterior border of the upper surface, and then downwards along the posterior border of the right surface; along the whole of that line it is reflected to the diaphragm, and the reflected part is called the *upper layer* of the **coronary ligament**. At or near the meeting of the right and lower surfaces, towards the back, the line of reflexion makes an angular bend from which a fold called the **right triangular**

ligament passes to the diaphragm (Fig. 562). From the right triangular ligament to the lower end of the groove for the vena cava, the peritoneum is reflected to the diaphragm; that reflected portion is called the *lower layer* of the **coronary ligament** and it occasionally passes to the upper end of the right kidney instead of to the diaphragm. Continuing to the left, the line of reflexion passes in front of the inferior vena cava and behind a narrow bridge of liver, called the **caudate process**, which intervenes between the lower end of the groove for the inferior vena cava and the porta hepatis.

The part of the surface of the liver between the upper and lower layers of the coronary ligament, to the right of the inferior vena cava, is called the **bare area** of the liver, because it is devoid of peritoneum. It is closely attached to the diaphragm.

At the left border of the inferior vena cava the line of reflexion of the

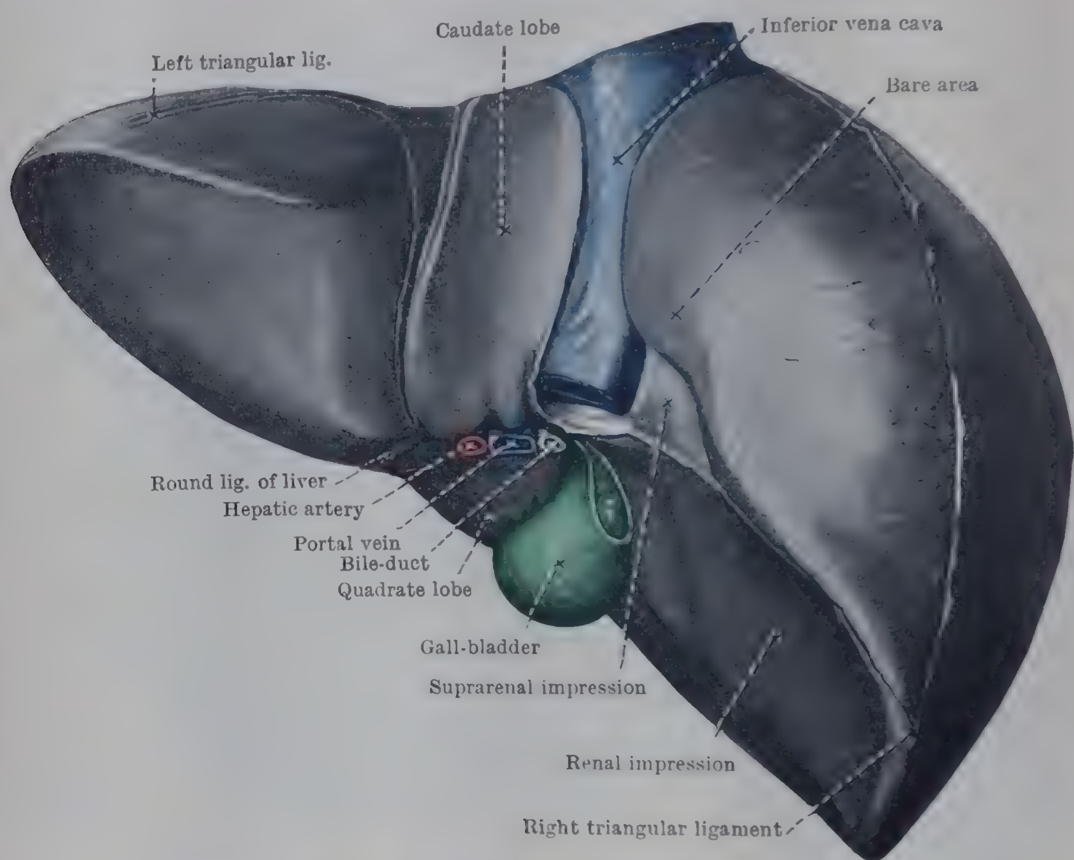

Fig. 562.—Liver viewed from Behind.

Comparison of the cut edges of peritoneum, as shown in this figure, with the cut edges of peritoneum in Fig. 538, p. 630, gives a very clear picture of the peritoneal reflexions from the surfaces of the liver. The upper and lower layers of the coronary ligament diverge from the right triangular ligament to enclose the bare area.

peritoneum ascends along the right border of the caudate lobe (Figs. 560, 562), and the reflected peritoneum, as it passes backwards to the diaphragm, forms the right boundary of the upper recess of the lesser sac; the line of reflexion then turns to the left above the caudate lobe from which it is reflected to the diaphragm as the roof of the recess. At the upper end of the fissure for the ligamentum venosum, the layer reflected from the right lobe comes into relation with the layer reflected from the left lobe, which is continuous with the posterior lamella of the left triangular ligament. The layers from the two lobes dip into the fissure for the ligamentum venosum, and line its walls. They return from the fissure together and extend from it to the stomach as the upper, left part of the lesser omentum.

From the lower end of the fissure for the ligamentum venosum the lines of attachment of the two layers of the lesser omentum pass to the inferior surface of the liver where they turn to the right along the margins of the porta hepatis, the left layer passing in front of the porta and the right layer behind it; and at

the right end of the porta the two layers join each other in the anterior margin of the opening into the lesser sac.

Lobes.—The liver is divided into two main lobes—a large right and a small left. The division is effected by the attachment of the falciform ligament on the upper and anterior surfaces (Figs. 559, 561), by the fissure for the ligamentum teres on the lower surface (Fig. 560), and by the fissure for the ligamentum venosum on the posterior surface (Fig. 562). But two subordinate lobes are cut off from the right lobe. They are the **quadrate** lobe on the lower surface to the left of the gall-bladder, and the **caudate** lobe on the posterior surface to the left of the inferior vena cava. The caudate lobe is connected by the caudate process with the main part of the right lobe.

In addition to the fissure for the ligamentum teres and the fissure for the ligamentum venosum, other surface depressions are the groove for the inferior vena cava and the fossa for the gall-bladder. The first two are deep, narrow clefts; the groove for the vena cava is a deep, wide furrow; the fossa for the gall-bladder is usually a mere shallow depression. They all represent, in Man, the much more definite fissures which, in many mammals, separate the liver into discrete or almost discrete segments.

The **fissure for the ligamentum teres** begins in a notch on the lower border of the anterior surface at the lower end of the attachment of the falciform ligament, and it extends to the left end of the porta hepatis. It contains the ligamentum teres (p. 659). Occasionally it is bridged over by liver-tissue.

The **fissure for the ligamentum venosum** is continuous with the fissure for the ligamentum teres at the left end of the porta hepatis; and it extends to the upper surface. The peritoneum which lines its sides is reflected from its floor as the upper, left part of the lesser omentum.

At the bottom of the fissure there is a fibrous cord, called the **ligamentum venosum,** which connects the left branch of the portal vein with the upper end of the abdominal part of the inferior vena cava. At the upper end of the fissure it turns to the right in front of the upper end of the caudate lobe and fuses with the left wall of the inferior vena cava. The ligamentum venosum is the remains of a fœtal blood-channel, called the *ductus venosus*, which during fœtal life transmitted blood directly from the umbilical vein to the inferior vena cava

Left Lobe.—The **left lobe** fits into the left cupola of the diaphragm, to which the posterior part of its *upper surface* is attached by the left triangular ligament. Its *lower surface* presents, in front and to the left, a deep concavity—the **gastric impression**—for the fundus and body of the stomach, whilst behind and to the right it bulges as a prominence called the **tuber omentale** because it rests against the front of the lesser omentum.

Parts of Right Lobe.—The **quadrate lobe** extends from the lower border to the porta hepatis, between the fissure for the ligamentum teres on the left and the fossa for the gall-bladder on the right. It is usually marked by impressions made by the pyloric end of the stomach and the first part of the duodenum.

The **fossa for the gall-bladder** extends from the lower border of the liver (at the level of the ninth right costal cartilage) to the right end of the porta hepatis. It is generally shallow, but sometimes it is so deep that the gall-bladder is almost entirely hidden in it. Its surface is devoid of peritoneum and is directly attached to the gall-bladder by areolar tissue through which small blood-vessels and lymph-vessels pass—and occasionally also minute **hepato-cystic ducts** which connect the bile-capillaries of the liver directly with the gall-bladder.

The **caudate lobe** is a relatively narrow, oblong lobe on the posterior surface of the right lobe. It forms the anterior boundary of the upper recess of the lesser sac and is related to the crura of the diaphragm opposite the lower part of the thoracic aorta and the lower thoracic vertebræ. The fissure for the ligamentum venosum bounds it on the left, and the groove for the inferior vena cava on the right. Its lower end is connected with the rest of the right lobe by the caudate process and is grooved antero-posteriorly by the cœliac artery. The part to the left of the groove is called the *papillary process*; and the part to the right is continuous with the caudate process.

The **caudate process** is a narrow band of liver-substance on the lower surface of the right lobe. It lies between the porta hepatis and the fossa for the inferior vena cava, and it forms the upper boundary of the opening into the lesser sac.

The **groove for the vena cava** is deep, rounded, and vertical—occasionally so deep that the vena cava is almost completely enveloped in it. Sometimes it is even bridged across posteriorly by liver-substance (*pons hepatis*). In it the walls of the inferior vena cava are closely attached to the fibrous capsule of the liver, through which the hepatic veins emerge from the liver-substance and join the vena cava on its anterior aspect—the main veins at the upper end of the groove and the smaller veins at varying levels.

The **remainder of the right lobe** forms the whole of the right surface and parts of the other four surfaces of the liver. Its *lower surface* is covered with peritoneum and is marked by three impressions (Fig. 560). The two to the right are (*a*) the smaller, below and in front, for the right flexure of the colon, and (*b*) the larger, above and behind, caused by the right kidney. The third is to the left of the renal impression and is caused by the commencement of the

FIG. 563.—LIVER OF A PIG INJECTED FROM THE HEPATIC VEIN.

second part of the duodenum. Its *upper*, *anterior*, and *right surfaces* are covered with peritoneum and lie in relation with the parietes (Figs. 559, 561). The *posterior surface* is the **bare area** of the liver. Through the areolar tissue of this area lymph-vessels from the liver pass to the diaphragm and so to the thorax, and also small veins which connect the portal circulation in the liver with the systemic veins in the diaphragm.

Fixation of Liver.—Adequate means of retaining the relatively heavy liver in its place is not provided by its connexions—which are the peritoneal folds, the attachment of its posterior surface to the diaphragm by areolar tissue, and its attachment to the vena cava by areolar tissue and the hepatic veins. The position is maintained partly by those connexions and partly by atmospheric pressure, but mainly by the **intra-abdominal pressure** caused by the tonic contraction of the muscles of the abdominal walls, which press the more movable contents of the abdomen against the less movable and keep them all in comparatively fixed positions. Atmospheric pressure, however, prevents sudden displacement of the liver, for the abdomen is a closed cavity: before the liver could move from its close contact with the diaphragm some viscus would have to be available to occupy the vacated space and prevent a vacuum, and none of the abdominal contents is sufficiently movable for that purpose.

Variations.—Few organs vary more in **size** than the normal, healthy liver; but increase or decrease is often pathological. The **position** varies normally with the size. The liver also moves down and up with every breath; and it descends slightly when the body is raised from

the reclining posture to the erect. Occasionally, without any evident cause, the liver and diaphragm are higher or lower than usual. In apparently healthy bodies the upper surface of the right lobe may be at the level of the fourth rib; or it may reach only the level of the sixth, and its lower border may be two or three inches below the costal margin—especially in women. Apart from pathological deformities, there may be congenital irregularities in **form** caused by additional fissures and lobes that resemble those in the higher apes and are commonly present in the fœtus (Thomson, 1899), or by division into several distinct lobes as in many other mammals. Grooving by the ribs and wrinkling on the surfaces opposed to the diaphragm are probably fixed by the hardening of the liver. In some cases a wide, tongue-like process (Riedel's lobe) projects downwards from the lower border on the right of the gall-bladder; it is more common in women than in men; it may be large enough to reach the iliac crest, and it has been mistaken for a tumour. **Correlated variations in form and position** normally result from the varying pressure of surrounding parts. Distension of the stomach or of the left part of the transverse colon pushes the liver to the right and increases its vertical diameter. Distension of the intestines flattens it from below upwards and increases its transverse diameter. But variations may be due to malformations of the thoracic framework, either congenital or acquired. When tight lacing was common, such malformations were frequent in women. When the chief constriction was low, the liver was forced up against the diaphragm and filled the whole left cupola as well as the right. More often, the constriction caught the liver; its upper part was forced upwards and to the left, and its lower part downwards.

Structure of Liver.—The liver is partially invested by an outer **serous coat**, which has been described with its peritoneal relations. Deep to that there is a thin **fibrous coat**—most evident where the serous coat is absent. In the neighbourhood of the porta hepatis it is more abundant, and there it surrounds the vessels entering the porta and accompanies them through the portal canals in the liver-substance. The fibrous coat is continuous with the fine areolar tissue which pervades the liver, surrounding its lobules and holding them together. The investment of fibrous tissue as a whole is known as the *hepato-biliary capsule* (Glisson's capsule).

The **liver-substance** proper is made up of an enormous number of small **lobules** $\frac{1}{25}$th to $\frac{1}{12}$th inch (1 to 2 mm.) in diameter, closely packed, and held together by a small amount of areolar tissue. In Man the lobules are not completely separated from one another all round their circumference but coalesce in places; the reverse is the case in certain animals such as the camel and the pig. Each lobule is composed of a large number of columns of liver-cells which radiate from the centre to the periphery.

Between the columns—which interlace freely—there is a sinusoidal, capillary-like network through which blood passes from interlobular veins at the margins to a central vein.

The endothelial wall of the network is incomplete, so that the liver-cells are in many places in contact with the blood. Some of the endothelial cells are modified into stellate cells which are a part of the reticulo-endothelial system and are known as the "star-cells" of Kupffer. The columns may be regarded as being composed of two layers of cells between which there is a minute channel—the intralobular bile-ductule—which passes from the centre to the periphery of the lobule.

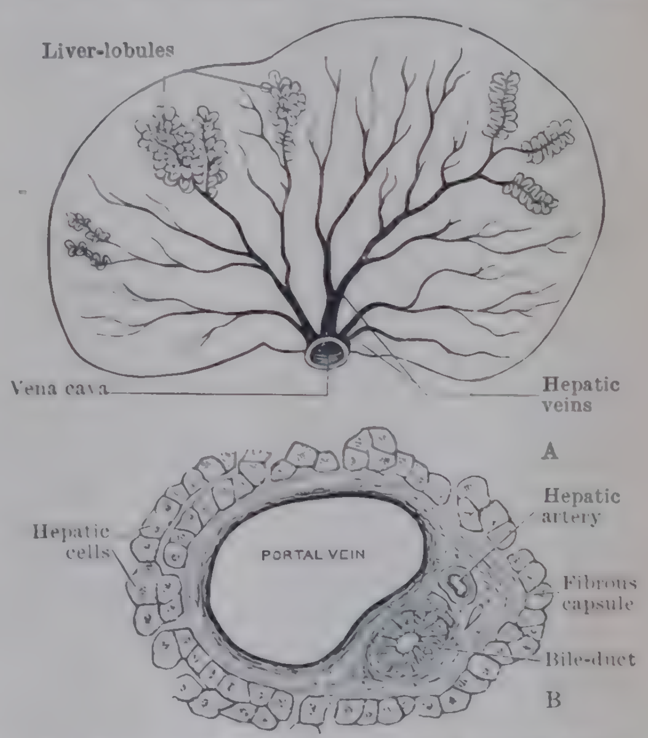

FIG. 564.—DIAGRAMS ILLUSTRATING STRUCTURE OF LIVER.

A. Arrangement of liver-lobules around the sublobular tributaries of the hepatic vein; B. Section of a portal canal, showing its contained branches of the portal vein, hepatic artery, and bile-duct, surrounded by a prolongation of the hepato-biliary capsule.

Vessels and Nerves.—Blood is conveyed to the liver by the hepatic artery and the portal vein, which enter the liver at the porta hepatis and break up into branches and finally into a sinusoidal network. The blood which has so entered is conveyed from the liver by the hepatic veins to the inferior vena cava.

The circulation within the liver is therefore arranged differently from that of other glands, and in order that the structure of the liver may be properly understood it is necessary to give some account of the relations which it presents to the blood-vessels which pass to and from it.

The **portal vein** and the **hepatic artery** pass to the liver between the two layers of the lesser omentum, accompanied by the bile-duct. Each breaks up into two chief branches—a right and a left—and several smaller ones, which enter the liver-substance, surrounded by a prolongation of the fibrous coat of the liver. Within the organ the three vessels run and divide together, so that every branch of the portal vein is accompanied by a corresponding (but much smaller) branch of the hepatic artery and of the hepatic duct; and the three, surrounded by

a prolongation of the hepato-biliary capsule, and accompanied by branches of the hepatic nerves and lymph-vessels, run in special tunnels of the liver-substance which are known as **portal canals** (Fig. 564, B).

The hepatic artery has but a small part to play in the hepatic circulation as its chief distribution appears to be to the fibrous tissue of the portal canals. The terminal branches of the artery end in the interlobular meshwork of veins through which some arterial blood is thus supplied to the liver-cells.

The portal vein within the liver divides, like an artery, into numerous branches, which eventually form an elaborate meshwork of *interlobular veins* around the periphery of the lobules. From this meshwork the small capillary-like channels described above pass into the interior of each lobule between columns of cells towards a channel in the centre of the lobule called the *central vein*. From the central veins the blood is carried into larger channels called *sublobular veins*, which pass to the hepatic veins.

The **hepatic veins** gradually unite with one another and run towards the inferior vena cava. Their mode of termination is variable but presents the following general arrangement: The left lobe is drained by a vessel which joins the upper part of the inferior vena cava. The right lobe is drained by one or two vessels which join the upper part of the inferior vena cava, and by a series of small vessels, 4 to 12 in number, which pass from the inferior portion of the right lobe to the inferior vena cava. The caudate lobe and the central portion of the liver are drained by vessels which pass to the inferior part of the hepatic portion of the inferior vena cava. The hepatic veins and their branches are not accompanied by branches of the bile ducts, and they are surrounded by a very small amount of areolar tissue.

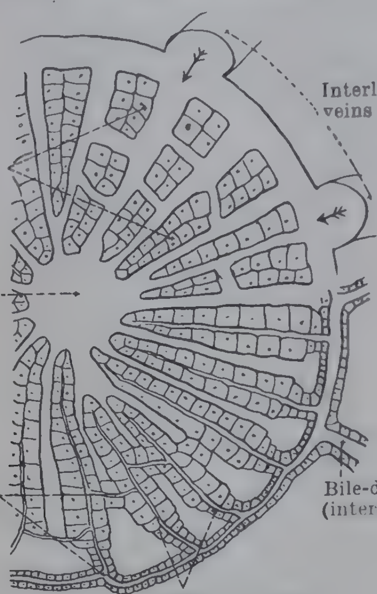

Fig. 565.—Diagram to illustrate Structure of Liver-Lobule.

The **lymph-vessels** of the liver pass either directly to the surface, where they appear beneath the peritoneum, or they accompany either (*a*) the portal or (*b*) the hepatic veins.

The **nerves** are both *sympathetic* and *parasympathetic*, being derived from both vagi and from the cœliac plexus. Branches of the anterior gastric nerve pass from the stomach between the layers of the lesser omentum to the hepatic plexus and are distributed to the liver, gall-bladder and ducts. Those from the cœliac plexus run along the hepatic artery—forming the hepatic plexus—to the porta hepatis, where they enter the liver with the blood-vessels. They are distributed chiefly to the walls of the vessels.

GALL-BLADDER AND BILE-PASSAGES

The excretory ducts of the liver begin within the hepatic cells as minute channels. Thence they run between the columns of hepatic cells (Fig. 565) and are known as the **bile-ductules**.

Hepatic Ducts.—Outside the lobules, the ductules join (Fig. 565) the **interlobular ducts**, which, by uniting, form larger and larger ducts, and finally end, as a rule, in two chief channels—a larger from the right lobe and a smaller from the left—called **the right** and **left hepatic ducts**, which unite in the porta immediately after leaving the liver-substance to form the **common hepatic duct**.

As a rule, five or six ducts leave the liver-substance at the bottom of the porta hepatis: they generally unite into right and left hepatic ducts; sometimes they all converge upon the common hepatic duct and unite at its beginning. The ducts from the caudate and quadrate lobes join the left hepatic duct.

The **common hepatic duct** is formed within the porta hepatis by the union of right and left hepatic ducts (Fig. 566). It passes downwards, and, just beyond the porta hepatis, it is joined by the **cystic duct** to form the **bile-duct**. Its length is usually about 1 or 1¼ inches (25 to 30 mm.), and in breadth, when flattened out, nearly ¼ inch, or about as much as a goose-quill.

Gall-Bladder and Cystic Duct.—The **gall-bladder** with the cystic duct may be looked upon as a diverticulum of the bile-duct, enlarged at its extremity to form a reservoir in which the bile is not merely stored but concentrated by the absorption of water from it by the mucous coat. It is pear-shaped,

and it lies obliquely on the inferior surface of the liver (Fig. 566). The wide end or **fundus** usually reaches the inferior border of the liver and comes into contact with the anterior abdominal wall behind the ninth costal cartilage opposite the lateral border of the rectus abdominis (Fig. 532). The **body** runs backwards, upwards, and to the left, lying in the fossa for the gall-bladder, and near the porta hepatis it passes rather abruptly into a narrow neck. The **neck** is curved medially towards the porta hepatis with an S-shaped kink in it and when distended it presents on its surface a spiral constriction which is

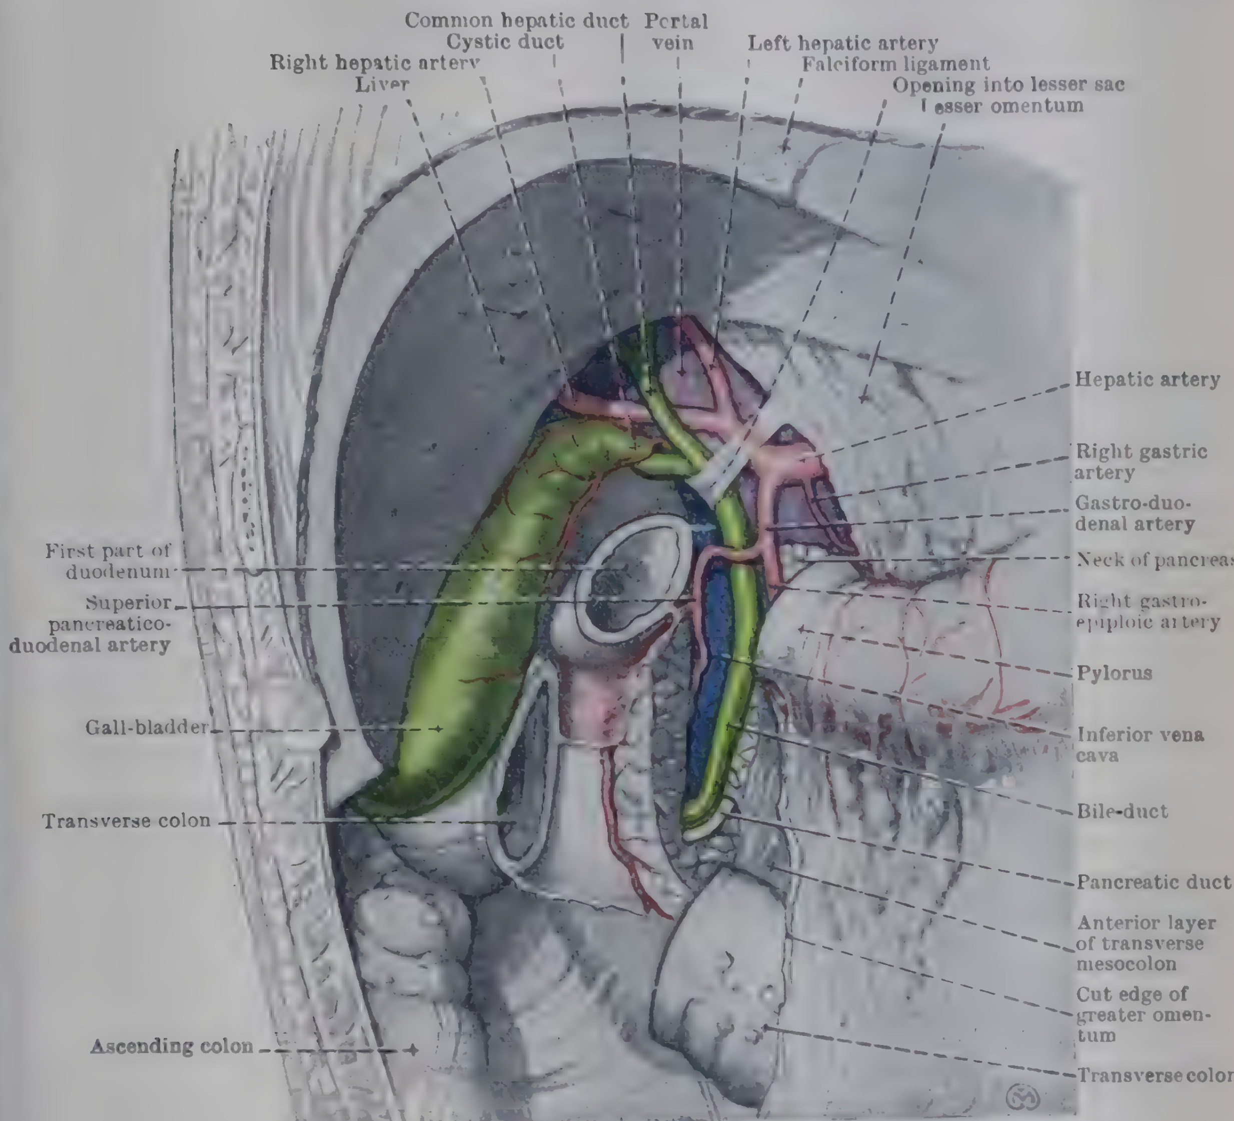

FIG. 566.—DISSECTION SHOWING RELATIONS OF GALL-BLADDER AND BILE-PASSAGES.

continued into the beginning of the cystic duct and is due to a series of crescentic folds placed more or less spirally round the interior of its cavity, forming the **spiral valve**. Having arrived near the porta hepatis, much reduced in size, it passes into the cystic duct.

As a rule the gall-bladder is covered with the peritoneum of the inferior surface of the liver, except on its antero-superior aspect, which is united to the walls of the fossa for the gall-bladder by areolar tissue. Sometimes, but rarely, the gall-bladder is suspended from the liver by a short peritoneal ligament. *Above*, the gall-bladder lies against the liver; and *below*, it rests on the transverse colon in front, and behind, near its neck, on the duodenum.

The fundus of the gall-bladder may not reach the inferior border of the liver or the abdominal wall. It may lie to the right of the right sagittal plane—possibly as a result of distension of the stomach and colon—or it may lie to the left, near the median plane and far below the ribs. Its total absence, as well as the presence of two distinct gall-bladders, and several other irregularities in form, have been recorded.

Its *size* is usually about 3 inches (75 mm.) in length, and 1 to 1¼ inches (25 to 30 mm.) in diameter. Its capacity varies between 1 and 1½ fluid ounces.

Vessels and Nerves.—The **artery** is the cystic, which comes from the right branch of the hepatic artery; it divides into two branches which diverge to descend over the upper and lower surfaces of the gall-bladder. The accompanying **veins** unite to form a single vein which enters the liver substance to the left of the neck of the gall-bladder. A variable number of accessory veins also enter the liver substance. These cystic veins communicate with the veins of the extrahepatic ducts, which also pass directly into the liver or join the intrahepatic branches of the portal vein. At the lower end of the bile-duct the veins anastomose with the veins of the duodenum and pancreas (Petrén & Karlmark, 1932). The **lymph-vessels** pass to glands that lie alongside the cystic duct and in the porta hepatis. The **nerves** come from the plexus on the hepatic artery and include sympathetic and parasympathetic (vagal) fibres.

The **cystic duct**, about half the diameter of the common hepatic duct (3 mm.), but usually slightly longer ($1\frac{1}{4}$ to $1\frac{1}{2}$ inches: 30 to 35 mm.), begins at the neck of the gall-bladder, pursues an irregular course backwards and medially, and joins the common hepatic duct at the mouth of the porta hepatis, to form the bile-duct. The spiral constriction found in the neck of the gall-bladder is continued into the beginning of this duct. Sometimes the cystic duct joins the right hepatic duct instead of the common hepatic duct.

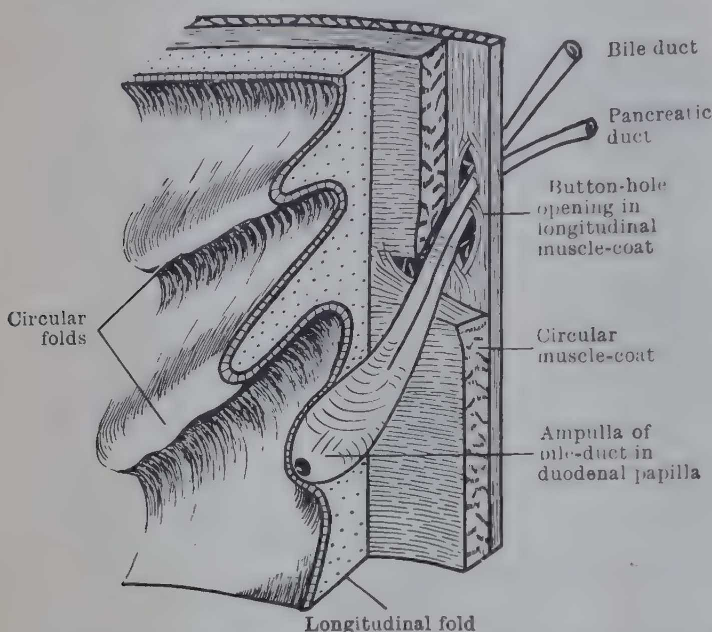

Fig. 567.—Diagrammatic Section of Wall of Duodenum to show Passage of Bile and Pancreatic Ducts and their Junction to form the Ampulla.

Bile-Duct (Ductus Choledochus).—The **bile-duct** is about 3 inches long (75 mm.) and of variable width—usually $\frac{1}{4}$ inch. It begins at the mouth of the porta hepatis, where it is formed by the union of the cystic and common hepatic ducts. (1) In the first part of its course it passes downwards in front of the opening into the lesser sac within the right free border of the lesser omentum, where it lies anterior to the portal vein and on the right side of the hepatic artery. (2) It then descends behind and to the left side of the first part of the duodenum, immediately to the right of the gastro-duodenal artery. (3) In this part of its course the bile-duct curves downwards and to the right, usually embedded in the head of the pancreas, but frequently in a groove on the posterior surface of the gland, where it comes into fairly intimate contact with the front of the inferior vena cava. (4) Finally it meets the pancreatic duct, and the two ducts, tapering abruptly, pierce the postero-medial wall of the second part of the duodenum in an oblique direction and open jointly into its interior through the constricted opening of the duodenal papilla (see p. 632).

In the first part of this oblique intramural passage or choledocho-duodenal junction, which averages from $\frac{1}{2}$ to $\frac{3}{4}$ of an inch (12 to 18 mm.) in length, the two ducts pass through a vertical 'button-hole' opening in the longitudinal layer of the intestinal muscle, and then through a similarly shaped but obliquely transverse opening in the circular layer. From the margins of this 'gridiron aperture' small bundles of muscle-fibres run to reinforce the angles of the two button-hole openings, whilst other fibres pass on to the walls of both the extramural and the intramural portions of the ducts, the whole arrangement constituting an extrinsic muscular mechanism for controlling the secretory flow (Fig. 567).

The greater part, however, of this oblique passage through the intestinal wall lies in the submucosa of the plica longitudinalis, in which the ducts unite to form the *ampulla of the bile-duct*, or in a considerable proportion of cases remain separate until they reach the opening of the duodenal papilla. The ampulla, when present, varies greatly in size, with an average diameter of $\frac{1}{8}$ of an inch (3 mm.), and a length which is usually slightly greater, and may be quite $\frac{1}{2}$ an inch (12 mm.) in extent. Its width is considerably greater than that of the lumen of either of the ducts, and is still more contrastingly greater than

that of the opening on the papilla, this being the narrowest part of the biliary passages. The presence of the ampulla is important in connection with the impaction of gall-stones, with resultant obstruction to the flow of bile and possible reflux of this secretion into the pancreatic duct.

The walls of the terminal part of the bile-duct and to a lesser extent of the pancreatic duct, are provided with a thin layer of paler circular muscle-fibres (*sphincter choledochus*), situated within the thicker and darker collar borrowed from the intestinal muscles. These circular fibres extend to a varying extent on to the ampulla (*sphincter ampullae*), but they do not reach the opening of the papilla. Opinion is still divided as to how far, if at all, these encircling fibres can be regarded as intrinsic sphincters, structurally and functionally independent of the intestinal muscles (Kreilkamp & Boyden, 1940; and Kirk, 1944).

The ampulla also contains a number of longitudinal muscle-fibres, which are extensions of two bundles in front of and behind the interval between the bile and pancreatic ducts. Some of these longitudinal fibres end in the connective tissue of the valvular folds of the mucous membrane with which the interior of the ampulla is richly lined.

The sphincteric arrangement of muscle-fibres round the termination of the bile-duct was first described by Francis Glisson in 1654. It was redescribed by Ruggero Oddi in 1887, since when the complex has become generally known to surgeons as the "*sphincter of Oddi*" (Boyden, 1936).

Structure of Gall-Bladder and Excretory Ducts.—The wall of the gall-bladder is composed of (1) an outer incomplete *serous coat* of peritoneum, (2) a *connective tissue coat* of fibro-elastic tissue, continuous in places with the connective tissue of the liver, (3) a *muscular coat* of plain muscle and elastic fibres arranged for the most part in a circular and oblique direction, and (4) a *mucous coat* consisting of tall columnar cells set on a lamina propria. The mucous membrane is raised into a number of small ridges which form a honeycomb pattern.

The walls of the excretory ducts present (1) an outer *adventitial coat* of fibrous tissue containing a few scattered outer circular and inner longitudinal plain muscle fibres, which increase in number as the duodenum is approached, (2) a thick *submucous coat* of connective tissue and elastic fibres, containing the alveoli of mucous glands, and (3) a *mucous coat*, lined by a single layer of columnar epithelium interspersed with goblet cells, with numerous folds and crypts.

Variations of Gall-Bladder and Ducts.—The gall-bladder may be attached to the liver by a peritoneal ligament. It may be deeply embedded in the liver, and its fundus may fall short of the lower border of the liver. It may be sacculated by constriction in its walls. It may be divided longitudinally into two gall-bladders, each with its own duct opening separately into a hepatic duct. It may be directly connected with the smaller bile-vessels by small channels, called **hepato-cystic ducts**, which pass from its upper wall into the liver. It may be absent, in which case one or other of the hepatic ducts is usually considerably dilated.

The hepatic ducts may be from two to five in number—accessory ducts coming usually from the right lobe of the liver. The right and left hepatic ducts may be so long that they descend into the lesser omentum before they unite; their increased length entails an elongated cystic duct and a shortened bile-duct. The cystic and hepatic ducts may open into the duodenum separately. The bile-duct itself may be double or septate, and it may have an inverted Y-shaped termination with one limb opening normally and the other into the duodenum more proximally or even into the stomach. The orifice of the bile-duct may be separate from that of the pancreatic duct. Any or all of the ducts may show different degrees of congenital dilatation or stenosis, and occasionally complete atresia.

A proper understanding of all these variations demands a knowledge of the development (see p. 681) and of the comparative anatomy of the biliary tracts (Zimmermann, 1935).

Radiographic Examination of Gall-Bladder.—Under normal conditions the gall-bladder and its contents do not throw a shadow on X-ray examination. By the use of artificial methods, however, especially by the administration of dyes (now usually by the mouth) which are excreted by the liver and concentrated with the bile in the gall-bladder, it is possible to demonstrate its position, form, and functional variations in size (Pl. LX, p. 649). Occasionally the wall of the gall-bladder becomes pathologically calcified and so appears in an ordinary radiograph (Pl. LII, p. 609).

PANCREAS

The **pancreas** is a long, soft, lobulated reddish or yellowish-grey gland which lies transversely on the posterior abdominal wall, its right end in the concavity of the duodenum (Fig. 568) and its left end touching the spleen.

It secretes a clear, watery, alkaline fluid—the *pancreatic juice*—which is conveyed to the duodenum by the **pancreatic duct** and constitutes one of the chief agents in intestinal digestion, for it contains ferments which transform starch into dextrin and sugar, split fats into glycerine and fatty acids, and reduce alkaline albuminous substances to peptone.

In **shape** the pancreas, when hardened *in situ* (Fig. 568), may be compared to the letter J placed thus ⊂.

The gland is divisible into a **head** with an **uncinate process**, a **neck**, a **body**, and a **tail**. The **head** corresponds to the hook of the ⊂. The stem of the ⊂ represents the **body** of the gland, and the left extremity of the body forms the **tail**. The narrow part that connects the head and body is the **neck** (Symington). An extension from the head to the left behind the superior mesenteric vessels forms the **uncinate process**. When removed from the body without previous hardening, the pancreas loses its true form, and becomes drawn out into a slender, tongue-shaped mass, with a wider end turned towards the duodenum, and a narrow end corresponding to the tail.

Its total *length*, when fixed *in situ*, is about 5 or 6 inches (12·5 to 15 cm.); after removal, if not previously hardened, it is easily extended to a length of 8 inches (20 cm.).

Its *weight* is usually about 3 ounces (87 grammes).

Relations.—The general position and relations of the pancreas may be briefly stated as follows: The head (Fig. 568) lies in the concavity of the duodenum, with the inferior vena cava behind it; the body crosses to the left in front of the aorta and the left kidney; and the tail touches the visceral surface of the spleen. The greater part of the organ lies behind the stomach.

In a description of the detailed relations, each part of the organ must be considered separately.

The **head of the pancreas**, flattened from before backwards, lies in the concavity of the duodenum. *Above*, in its right half, it is continuous with the neck; whilst to the left of the neck, a deep notch separates the upper and left part of the head from the neck, and contains the superior mesenteric vessels (Fig. 568). The margin of the head is moulded on the duodenum, which lies in a groove of the gland substance—the bile-duct being interposed as far down as the middle of the second part of the duodenum. The posterior surface of the head is applied to the front of the inferior vena cava, the right renal vessels and the left renal vein. Its anterior surface is in contact above and on the right with the beginning of the transverse colon (Fig. 538, p. 630), without the interposition of the peritoneum as a rule. Below that it is clothed with peritoneum and is covered by the small intestine.

The superior mesenteric vessels, after passing forwards through the notch between the head and the neck, descend in front of the uncinate process, which overlaps the aorta. The gastro-duodenal artery runs downwards behind the duodenum and divides into branches at the upper border of the head (Fig. 568).

The **neck of the pancreas** (Fig. 568) is a thin portion of the gland which lies in front of the portal vein and behind the pylorus, and it connects the head to the body. It is attached on the right to the upper portion of the head, and runs forwards, upwards, and to the left for about 1 inch (25 mm.), and passes into the body.

The neck is about ¾ inch (18 mm.) in width, and less than ½ inch (12·5 mm.) in thickness. *In front and to its right* lie the first part of the duodenum, the pylorus, and the lesser sac of the peritoneum; *behind and to the left* it rests upon the beginning of the portal vein, which is formed under cover of its lower border by the union of the splenic and superior mesenteric veins. It is generally marked off from the head by two grooves, of which the upper is occupied by the gastro-duodenal artery and its superior pancreatico-duodenal branch, and the lower by the superior mesenteric vessels.

As the transverse mesocolon is followed to the right it is found to end, as a rule, near the neck of the pancreas (Fig. 538). Beyond that, the posterior surface of the colon is connected by areolar tissue to the anterior surface of the head of the gland.

The **body of the pancreas** is of a prismatic form, and is largest where it lies in front of the left kidney (Fig. 568). From the neck it runs to the left and slightly backwards and upwards across the front of the aorta and left kidney, beyond which its extremity or tail comes in contact with the spleen. When hardened *in situ* it presents three surfaces

—anterior, inferior, and posterior—all of nearly equal width (namely, about 1¼ inches: 30 mm.).

The *anterior surface*, widest towards the left end, looks upwards and forwards (Fig. 568), and forms a considerable portion of the stomach-bed. It is completely

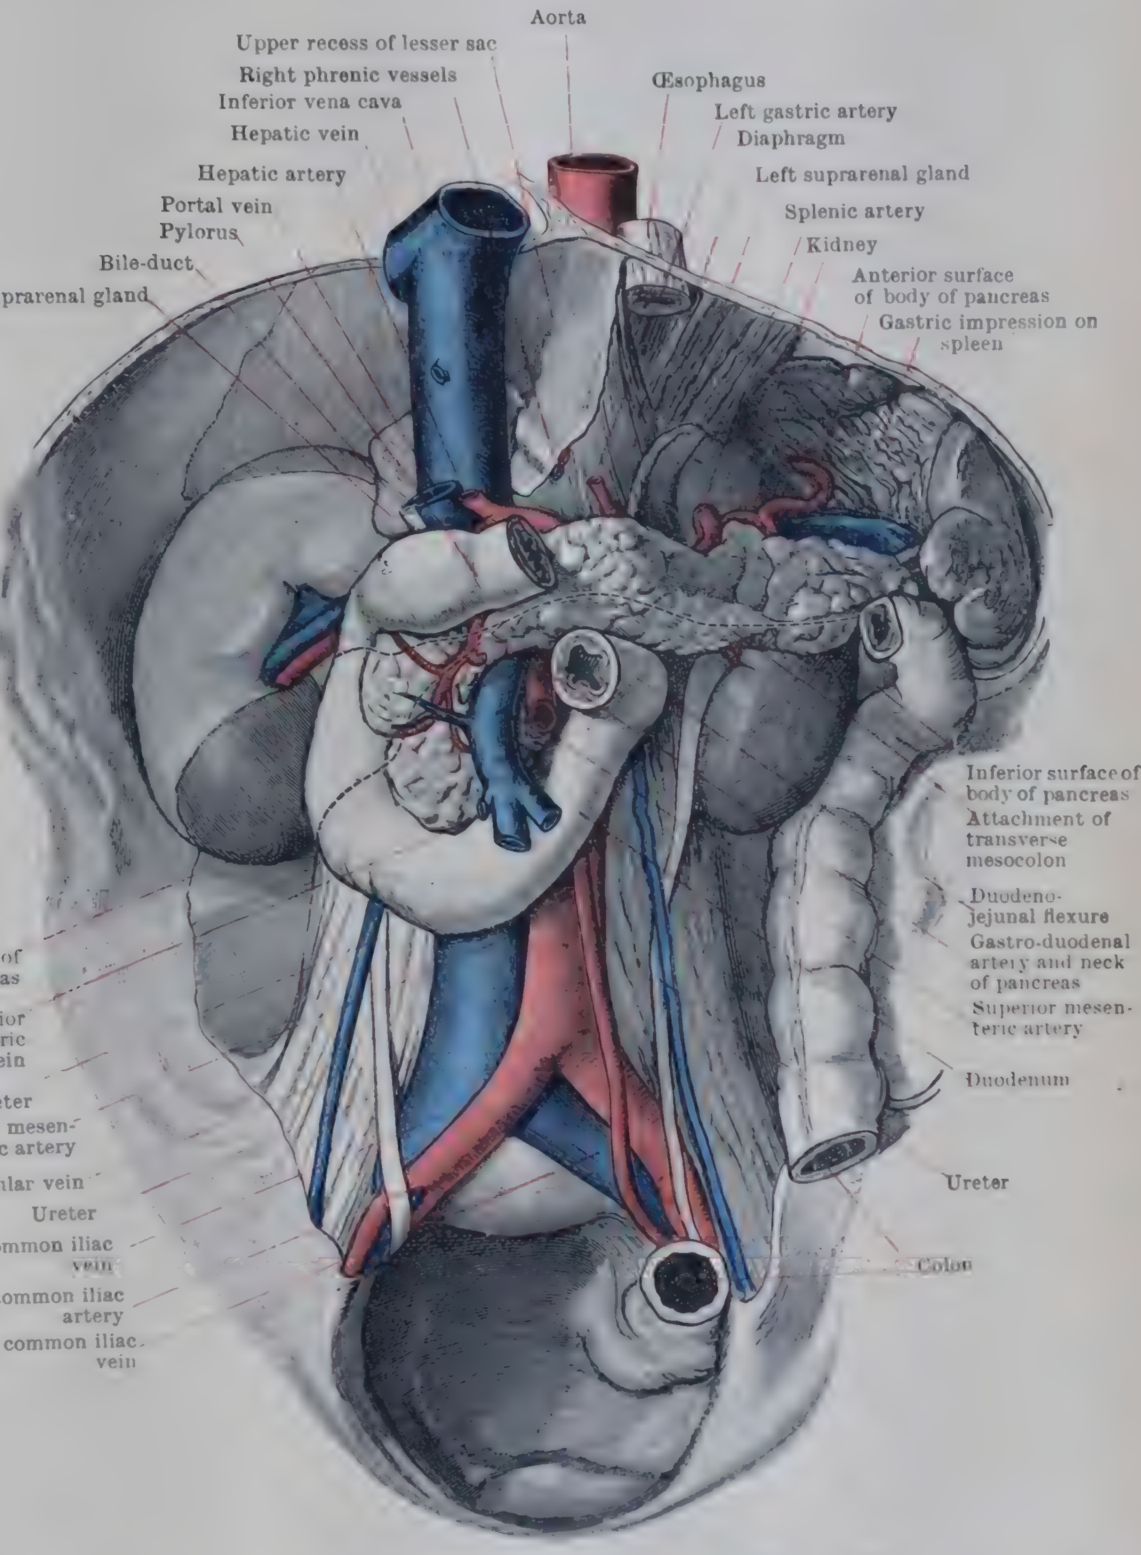

FIG. 568.—VISCERA AND VESSELS ON POSTERIOR ABDOMINAL WALL.

The stomach, liver, and most of the intestines have been removed. The peritoneum has been preserved on the right kidney and the recess behind the caudate lobe. When the liver was taken out, the inferior vena cava was left *in situ*. The stomach-bed is well shown. (From a body hardened by chromic acid injections.)

covered with the peritoneum of the posterior wall of the lesser sac, which separates the pancreas from the stomach (Fig. 569). Towards its right end where the body joins the neck it usually presents an elevation which, when the stomach is distended, projects against the back of the lesser omentum and is consequently known as the **tuber omentale**.

The *inferior surface* looks downwards and slightly forwards. It is completely covered with peritoneum which is continuous with the posterior layer of the transverse

mesocolon (Fig. 538). It is in contact with the duodeno-jejunal flexure towards its right end, with the left end of the transverse colon near its left end, and with a mass of small intestine (jejunum, which is always found packed in beneath it) in the rest of its extent.

The *posterior surface* looks directly backwards and is entirely destitute of peritoneum. It is connected by areolar tissue to organs that lie on the posterior abdominal wall. From right to left they are: the aorta with the origin of the superior mesenteric artery, the left renal vessels, the lower end of the left suprarenal gland, and the left kidney. In addition, the splenic artery runs its tortuous course to the left along the superior border of the pancreas, whilst the splenic vein runs behind the upper border of the gland.

The three surfaces of the body of the pancreas are separated by three borders.

The *lower border* is the most prominent, and gives attachment to the transverse

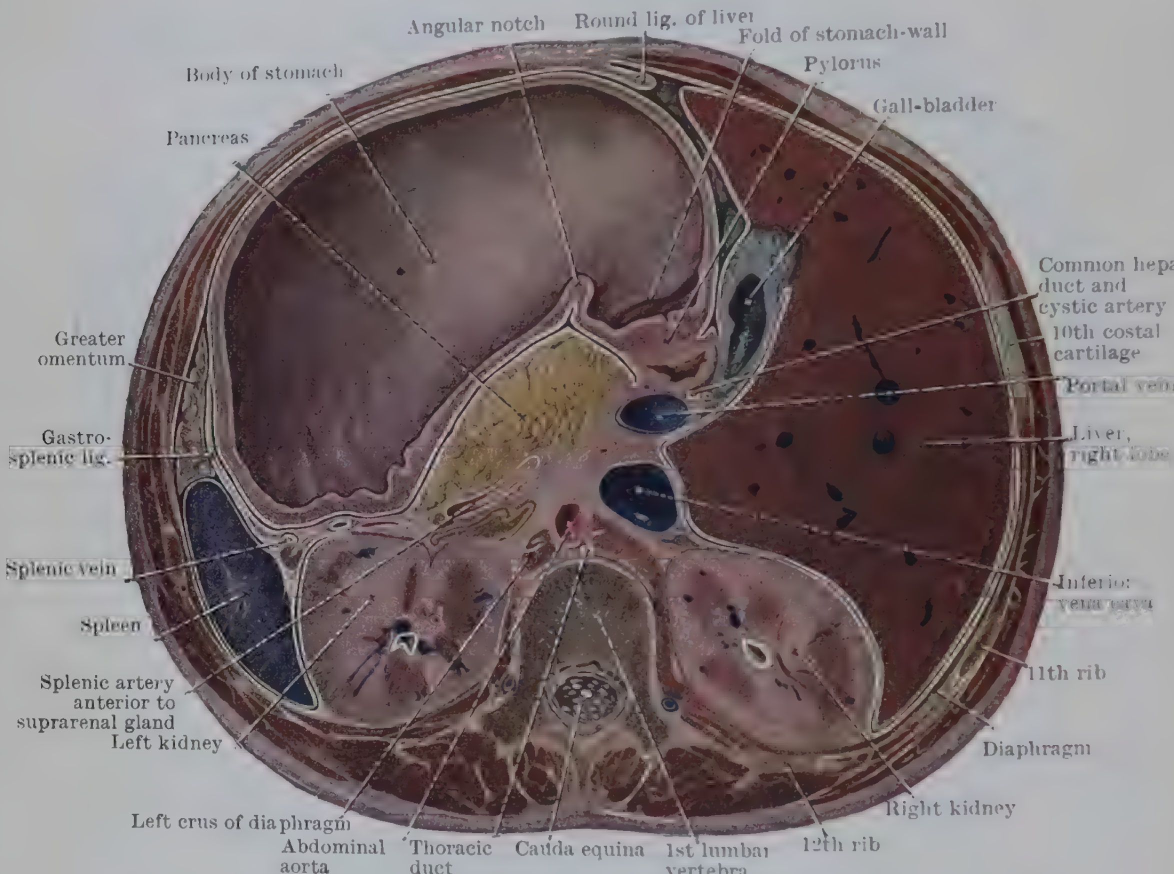

FIG. 569.—TRANSVERSE SECTION OF TRUNK AT LEVEL OF FIRST LUMBAR VERTEBRA.
Showing relations of stomach, pancreas, kidneys, etc. From a subject ten years old.

mesocolon (Fig. 568). It is, as it were, squeezed forward, by the pressure of the stomach above and the small intestine below, into the interval between these two sets of viscera, thus following the line of least resistance. Towards the neck that border is no longer prominent, but becomes rounded off, so that there the anterior and inferior surfaces are confluent.

The cœliac artery projects over the *upper border*, and sends its hepatic branch to the right, resting upon it, whilst the splenic artery runs to the left along it (Fig. 568).

The *posterior border* calls for no special description.

The **tail of the pancreas**, at the left end of the body, usually presents an abrupt, blunt ending, but it may be elongated and narrow. It is in near relation with the spleen to the left and with the left flexure of the colon below (Fig. 538, p. 630).

Ducts of Pancreas.—Almost invariably two ducts are found in the interior of the pancreas—the **pancreatic duct** and the **accessory pancreatic duct**.

The **pancreatic duct** begins at the tail by the union of small ducts that emerge from the lobules of that part of the organ. From there it pursues a rather sinuous or zigzag course (Fig. 570) in the axis of the gland; at first it runs nearly transversely to the right, until the neck is reached; it then bends downwards into the head,

approaches the second part of the duodenum and meets the bile-duct (see p. 666).

In its course through the gland the pancreatic duct receives numerous tributaries which join it, as a rule, at a right angle. The tributaries, as well as the main duct itself, are easily recognized by the whiteness of their walls, which contrasts with the darker colour of the gland-tissue. Beyond its point of junction with the accessory duct (see below), the main duct receives tributaries from the posterior part of the lower portion of the head and the uncinate process, and, towards its termination, it attains a considerable width ($\frac{1}{10}$ to $\frac{1}{6}$ of an inch: 2·5 to 4 mm.).

The **accessory pancreatic duct** is a small and variably developed duct (Fig. 570) which opens into the duodenum about $\frac{3}{4}$ of an inch above and slightly anterior to the pancreatic duct. From the duodenum it runs to the left and downwards and soon divides into two or more branches; one of these joins the pancreatic duct, and another, which descends vertically in front of the main duct, drains the anterior part of the lower portion of the head. Should the orifice of the main duct become obstructed, the communication with the accessory duct forms an outlet for the secretion into the duodenum.

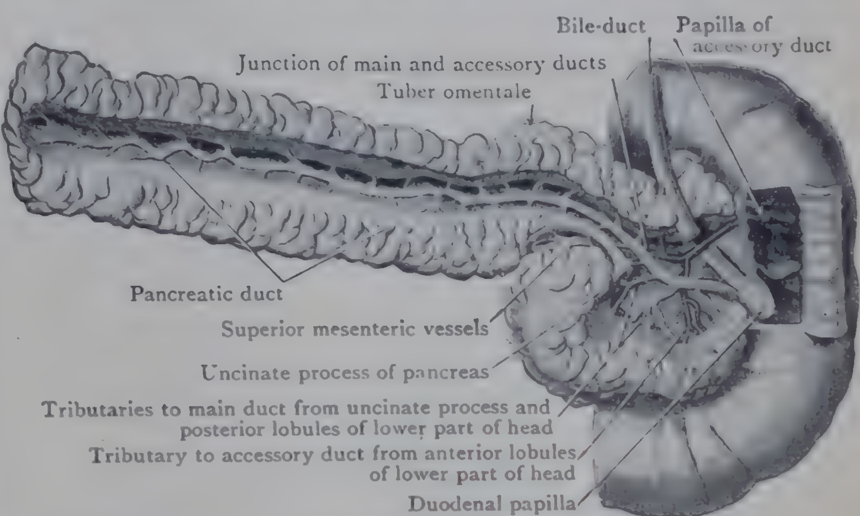

Fig. 570.—Dissection of Pancreas from Behind to show its Ducts.

Structure of Pancreas.—The lobules of the pancreas resemble closely in structure the lobules of the salivary glands and show a similar arrangement of secreting tubules and ducts. The tubules are lined with short cylindrical cells, with a deeply placed nucleus, and often showing granules in the free margin. The flattened spindle-shaped cells of the terminal ducts are continued into the commencement of the secreting tubules, where they are known as *centro-acinar cells.*

In addition, however, each lobule contains irregular groups of cells known as **islets of Langerhans.** These cells are not connected with the ducts, and they produce the internal secretion known as *insulin.*

Variations.—The chief variations found are: (1) A separation of the part of the head known as the uncinate process, which then forms a *lesser pancreas.* (2) A growth of the pancreas around the duodenum, which it may practically encircle for a short part of its course. And (3) an opening of its duct into the duodenum independently of the bile-duct. Accessory pancreatic tissue is also sometimes found in the wall of the stomach or of the jejunum, or even in the diverticulum ilei. Diverticula of the duodenum, already described (p. 633), ought perhaps to be mentioned in this connection.

Vessels and Nerves.—The **arteries** of the pancreas are: (1) The *superior pancreatico-duodenal*, a branch of the gastro-duodenal artery; its two terminal branches, anterior and posterior, run downwards, one in front of and the other behind the right margin of the head (Fig. 568), sending branches laterally to the duodenum, as well as numerous twigs into the substance of the pancreas. (2) The *inferior pancreatico-duodenal*, a branch of the upper part of the superior mesenteric artery or from the root of one of its jejunal branches; it runs upwards and to the right across the back of the head, and sends branches to it and to the duodenum, one of which runs between the head and the duodenum. The two pancreatico-duodenal arteries anastomose around the inferior border of the head. (3) *Pancreatic branches* of the *splenic artery* are several (3 to 5) fair-sized branches which come off from the splenic as it runs along the upper border of the gland; they enter the pancreas immediately and traverse its substance from above downwards, some sending branches in both directions along the course of the pancreatic duct.

The **veins** are: (1) The *pancreatico-duodenal veins* (Fig. 568), of which some pass downwards and to the left, on the front of the head, and join the superior mesenteric; while others cross the back of the head and open into the superior mesenteric or the portal vein; (2) several small *pancreatic veins* which join the splenic. The blood-vessels of the pancreas are described in detail, from the surgical point of view, by Pierson (1943) and by Falconer & Griffiths (1950).

The **lymph-vessels** pass mainly to the suprapancreatic glands.

The **nerves**, which are almost entirely non-medullated, are (1) sympathetic filaments which have passed through the hepatic and splenic plexuses, and (2) parasympathetic filaments from the vagi.

DEVELOPMENT OF DIGESTIVE SYSTEM

In the chapter on Embryology it has been pointed out that the alimentary canal is formed from three separate parts: (1) A middle, large entodermal portion, and (2) two smaller ectodermal parts, one at the cephalic end—the stomodæum or oral pit—and one at the caudal end—the proctodæum or anal pit. It has been shown further that the three portions are at first separated from one another by septa—the bucco-pharyngeal membrane and the anal membrane, respectively—but the septa disappear at an early date, and the three parts are thrown into continuity. There is thus formed a tube—the primitive alimentary canal—which extends through the body from the oral aperture to the anal orifice.

The entodermal segment of the primitive alimentary canal is derived from the dorsal portion of the entodermal sac and is divided into three portions as follows:—That portion which is enclosed within the head-fold and lies above the septum transversum is termed the fore-gut; the portion within the tail-fold is termed the hind-gut; and the middle portion is termed the mid-gut. The mid-gut at first is opposite the communication with the yolk-sac, and the other portions are cephalic to and caudal to this level. From the fore-gut are formed the posterior part of the mouth, the pharynx, œsophagus, stomach, and the greater part of the duodenum. The remainder of the small intestine and the large intestine as far as the left flexure of the colon are developed from the mid-gut. The hind-gut gives rise to the remainder of the large intestine as far as the "white line" of the anal canal. It should be noted that these three parts of the embryonic gut give rise to the abdominal parts of the adult alimentary tract which are supplied by the cœliac, superior mesenteric, and inferior mesenteric arteries respectively.

The primitive intestinal tube not only forms the basis of the alimentary canal and its associated organs, but it is also the source from which many other organs, not ultimately connected with digestion, are formed. Thus, the respiratory tract below the level of the orifice of the larynx is formed as an outgrowth from the ventral wall of the primitive fore-gut, and remains permanently connected with it at that point, though in structure and function it becomes very different from the tube from which it is derived. Other structures also, namely, the thyroid gland, the parathyroid glands, and the thymus, are formed as diverticula of the primitive pharynx, but they soon lose their connexion with the wall of the tube. Furthermore, the allantois, a diverticulum from the hind-gut, and the ventral part of the primitive hind-gut are cut off to form the urinary bladder and a portion of the urethra.

Development of Primitive Pharynx and Mouth

The blind, terminal part of the fore-gut in the head-region constitutes the primitive pharynx. Its roof is formed by the tissues that cover the ventral aspect of the mid- and fore-brain, and its floor by the tissues that overlie the heart and pericardium. Each side-wall is a lamina of tissue which extends from the floor to the roof, continuous, in front, with the bucco-pharyngeal membrane, which forms the oral wall of the pharynx and separates it from the oral pit. In the roof the tissues of the dorsal part of the base of the skull are formed. In the side-wall and in the floor extensive changes occur, connected with the appearance of structures known as the pharyngeal arches and pouches, and with the origin of numerous structures from them and the development of the tongue (see pp. 65-70, 810-812).

The cavity of the adult **mouth** is formed in part from the oral pit and in part from the cephalic end of the fore-gut or primitive pharynx. The line of division between the portions of the mouth derived from these two parts is difficult to trace on account of the very extensive changes which occur after the bucco-pharyngeal membrane has disappeared and are associated with the formation of the face and of the nose. The portion of the oral cavity derived from the fore-gut is lined with entoderm, and that derived from the oral pit with ectoderm. The position of the original bucco-pharyngeal membrane may be represented by an imaginary plane that extends from the anterior part of the body of the sphenoid to the floor of the mouth close to the mandible.

The enamel of the teeth and the secreting epithelium of the salivary glands are ectodermal structures, while the epithelium of the tongue is entodermal in origin.

The **upper lip** is formed from the tissues that cover the median nasal and maxillary processes (see development of face, p. 63). The **lower lip** similarly is formed from the tissues that cover the mandibular arches. By an ingrowth of epithelium from the surface into the subjacent mesoderm and by subsequent desquamation of the superficial layers, a groove is formed between the lips and cheeks on the one hand and the alveolar ridges on the other. That groove, when deepened, forms the vestibule of the mouth, and it is termed the *alveolo-labial sulcus*. The surface covered with mucous membrane becomes everted to form the red portion of the lips; and at birth it is divided into an outer, smooth portion and an inner portion whose surface is villous. The distinction between these two parts disappears shortly after birth. Several explanations of the formation of the **philtrum** or groove on the front of the upper lip have been put forward; most probably it is produced by the union of the margins of the two

globular processes with each other—the floor of the groove being formed along their line of union, and the ridges that bound the groove corresponding to the medial portions of the globular processes.

The **parotid glands** are formed as outgrowths of the epithelium in the outer wall of the alveolo-labial sulcus. The outgrowth on each side has been found in embryos 8 mm. long. It is at first a furrow. The posterior part of the furrow becomes closed off from the oral cavity and forms a tube which grows backwards for some distance on the surface of the first pharyngeal arch. The terminal portion of the tube gives rise to a number of buds which divide repeatedly and form the lobules of the gland. They are at first solid, and the alveoli do not become hollowed until about the twenty-second week. The epithelium of the terminal buds forms the secreting glandular epithelium, while that of the stalk forms the lining epithelium of the duct.

The **submandibular** and **sublingual glands** are formed in the alveolo-lingual groove, immediately behind the first arch, by outgrowths similar to those which form the parotid gland. The submandibular outgrowth occurs about the fifth week, and the sublingual outgrowths, several in number, on the outer side of it at the ninth week.

The **gums** are developed in two parts—labio-buccal and lingual (West, 1925). The labio-buccal part takes the larger share in the formation of the gums; its surface becomes villous, and it becomes divided into segments that correspond in number and size to the dental sacs of the deciduous teeth. The vessels of the developing gum furnish materials for the growth of the teeth, and they even pierce the reticulum of the enamel-organ.

Tongue.—Several elements in the floor of the primitive pharynx go to the formation of the tongue. One is a median elevation—the *tuberculum impar*—closely related to the ventral ends of the second pair of arches. Just in front of this there is a pair of swellings on the ventral ends of the mandibular arches, and behind it there are paired elevations called the *copula* that arise in relation to the fused ventral ends of the second and third arches. The anterior two-thirds of the tongue are formed by a fusion of the bilateral elements from the first arch incorporating the tuberculum impar to an extent that is still undetermined, and the posterior third is formed by the elements related to the copula (Fig. 84, p. 68). This dual formation of the tongue is reflected in the sensory nerve-supply to the **mucous membrane**, the anterior two-thirds of which are supplied by the lingual and the posterior third by the glossopharyngeal nerve. The foramen cæcum and the sulcus terminalis mark the junction of the two parts, the foramen cæcum representing the position where the outgrowth took place which forms the thyroid gland. The epithelial covering is derived from the entodermal lining of the pharynx, while the **muscle** substance is derived from mesoderm which is continuous with the occipital myotomes and derives its nerve-supply from the hypoglossal nerve.

The investing epithelium of the anterior two-thirds gives rise to the papillæ and the taste-buds, while that covering the posterior portion remains smooth. The papillæ appear about the third month as elevations of the corium covered with epithelium. The vallate papillæ are formed by ingrowths of the epithelium, in rings, around a central core. The superficial layers of the epithelium desquamate and form the trench around the papilla.

Tonsil.—The palato-glossal arch arises in the position occupied earlier by the second pharyngeal arch, behind which, in the embryo, lies the lower portion of the second pharyngeal pouch. Part of that pouch enlarges, and forms a recess termed the *sinus tonsillaris*. From the lower and greater part of the sinus tonsillaris the tonsil is developed; the upper part of the sinus persists, however, as the intratonsillar cleft. The tonsil at first is a smooth depression of the mucous membrane. About the fourth month of intra-uterine life downgrowths of the epithelium take place, which are afterwards converted into the tonsillar pits. Subsequently lymph-cells accumulate around the downgrowths and form the lymphoid tissue which constitutes the mass of the organ. The plica triangularis is formed from a tubercle which becomes flattened to form a fold on the anterior and medial aspect of the inferior part of the tonsil.

Development of Teeth

Teeth, like the skin, are formed from two sources; the enamel is derived from ectoderm and the dentine with its associated tissues—tooth-pulp and cement—from mesoderm. The stages of the formation and union of the two elements may be followed in the diagrams in Fig. 571.

The first stage is the formation, along the site of the future gum, of a thickened ridge of ectoderm which sinks to a deeper level by the active growth of the mesoderm on each side of it, and it becomes slightly furrowed along its surface. The ridge is termed the **primary dental lamina**; and its deep border widens out and soon divides into two secondary ridges, separated from one another by a process of mesoderm. The outer ridge is known as the **labio-gingival lamina**, as it marks the site of the formation of the groove between the lip and the gum; hollowed out by an extension of the primary furrow, it is converted into the *labio-gingival groove*. The inner ridge, now termed the **dental lamina**, alone is shown in Figs. III, IV, and V, for it is the source of the formation of the enamel of the teeth. The dental lamina is at first a continuous band of equal width throughout, but in each jaw on each side its deep surface comes to show five enlargements, one corresponding to each deciduous tooth, and for a time these enlargements remain connected together by a narrow strip of ectoderm. Each of these enlargements or **enamel-organs** is invaginated by a papilla of the mesoderm—the **dental papilla**—for which it forms a cap.

The connexion of the dental lamina with the surface ectoderm becomes drawn out into a thin stalk, and from the inner side of this stalk, superficial to each enamel-organ of a deciduous tooth, a small bud arises which is the source of the enamel-organ of the corresponding permanent tooth. Each enamel-organ is vesicular in shape: the cells in its interior form a loose *stellate reticulum* with fluid in its spaces; the row of long columnar cells (*ameloblasts*) in contact with the mesodermal papilla become the hexagonal enamel-prisms by the deposit on their free surface of successive droplets of calcareous enamel substance. This layer of cells caps not only the apex but also the upper part of the sides of the dental papilla. In the areas of this contact, dentine is formed by the superficial cells of the papilla, which are known as the *odontoblasts*. The peripheral margins of the cells become calcified around a central, minute, thread-like process from the cell-body, and thus they eventually form the hollow dentinal tubules. The dental papilla, which underlies the enamel-organ, assumes the shape of the crown of the future tooth; in the molars, for example, elevations are found in the position of the tubercles of the teeth. The cells in the interior of the papilla become the cells of the pulp of the tooth—vessels and nerves passing in among them from below.

Cement is formed, in the same manner as bone, around the deeper part of the papilla, up to and even beyond the level at which it is invested by the epithelial sheath formed by the prolongation of the enamel-organ already mentioned, which is in part perforated by the cells which form the cement.

The tissues immediately surrounding the enamel-organ and the dental papilla form a fibrous capsule termed the dental sac or follicle (Scott, 1948). The **dental sacs**, when fully developed, are large and distinct fibrous bags which lie in the tooth-sockets of the maxilla and mandible and are continuous above with the tissue of the gum. On the lingual side of the sacs of the deciduous teeth are found the germs of the permanent teeth, surrounded by their own sacs. The sacs are at first very small, and they are partly embedded in the wall of the deciduous dental sacs, but subsequently they come to lie in distinct but incomplete bony cavities of their own. The bone around the dental sacs, temporary and permanent, is always wanting over the summit of the sac, and the band of fibrous tissue which passes through that deficiency and connects the sac with the overlying gum-tissue is known as the **gubernaculum dentis**.

All the points mentioned are easily demonstrated on the mandible of a child at birth, particularly when the tissues have been allowed to soften a little. If, in such a specimen, the gum and periosteum are reflected upwards from the labial and lingual surfaces of the mandible and are freed as far as the upper border of the jaw, the gum, with the tooth-sacs depending from it like small bags, can be pulled out of the bony groove of the jaw; and, if the operation has been successfully performed, the tooth-sacs of the three front permanent teeth may be seen, in size from a small pin's head to a hemp-seed, hanging down behind the upper part of the corresponding deciduous sacs.

I. Shows the dental lamina D.L, the surface epithelium E and the enamel-germ E.G.

II. Shows the further growth of the enamel-germ and its invagination to form the enamel-organ.

III. The enamel-organ is more invaginated, and its inner layer of cells A becomes columnar. The dental lamina is thinner, but near its posterior or lingual edge there is an enlargement R.G which is the reserve germ for a permanent tooth. The superficial cells of the dental papilla P are becoming columnar.

IV. The inner columnar cells of the enamel-organ (ameloblasts) A have formed a cap of enamel En., inside which the superficial cells of the papilla, the odontoblasts O, have formed a layer of dentine D.

V. Shows a still more advanced stage. The deposit of dentine is extending downwards and enclosing the papilla to form the future pulp, in which a vessel V is seen.

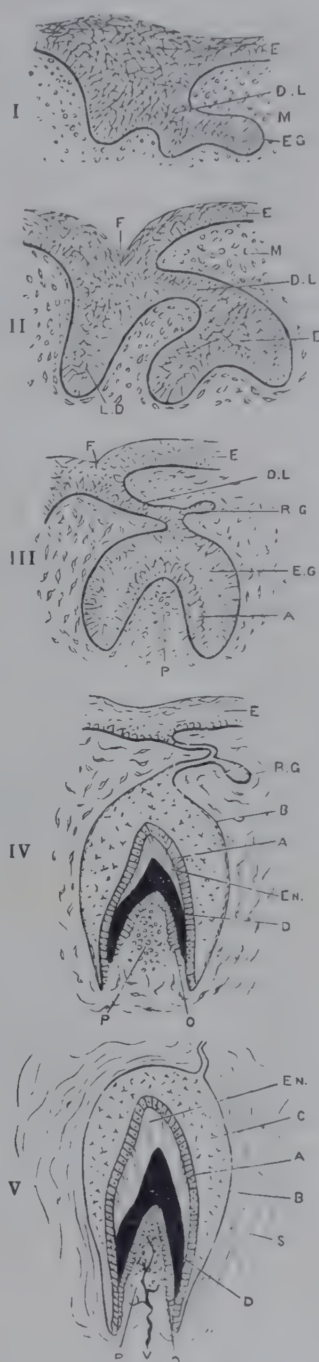

Fig. 571.—Diagrams to illustrate Development of a Tooth.

A, Ameloblasts; B, Outer layer of enamel-organs; C, Stellate reticulum; D, Dentine; D.L, Dental lamina; E, Epithelium; E.G, Enamel-germ or organ; En., Enamel; F, Primary dental lamina and furrow; L.D, Labio-gingival lamina; M, Mesoderm; O, Odontoblasts; P, Dental papilla; R.G, Reserve germ; V, Blood-vessel.

The *roots* of a tooth are formed by ingrowths from the base of the dental papilla, each papilla lying in a groove in the surface of the developing jaw. The groove is divided into compartments for the individual teeth by the formation of intervening septa of bone.

Permanent Teeth.—The anterior five permanent teeth (each of which replaces a deciduous tooth) are developed from the bud-like process on the connecting stalk of epithelium already mentioned and from a dental papilla which forms in relation to each of these buds on the lingual side of its predecessor. The hinder three permanent teeth in each jaw are formed in the same way as the deciduous teeth from an extension backwards of the original dental lamina behind the last deciduous tooth.

Eruption of Teeth, *i.e.*, the extrusion of the crown through the superficial investing tissues, is accompanied by an active absorption of these tissues and also by growth of the roots of the teeth. When the eruption of the deciduous teeth is about to take place, the labial wall and roof of the socket are absorbed; the tooth passes through the sac and appears above the gum, and the socket is re-formed closely around the tooth. The root, which is only partly formed at the time of the eruption, continues to elongate. When the permanent tooth is about to be erupted, it makes its way from its own bony cell through the lingual wall of the socket of its deciduous predecessor; the root of the deciduous tooth undergoes absorption at the same time, but quite independently of pressure from the permanent tooth. The socket, now occupied by both teeth, is again much enlarged by absorption, particularly on the labial side; what remains of the temporary tooth is shed; the permanent tooth passes onwards through the enlarged socket, and, making its way to the surface, appears above the gum. After some time, when the tooth has taken its final position, the socket is again re-formed, first around its neck, and, later on, as the root is built up, around it also, and thus the tooth is permanently fixed. All these processes occur while the alveolar parts of the jaws are themselves growing in height (Brash, 1926).

Morphology of Teeth

In most vertebrates below mammals all the teeth are alike in form; such a dentition is said to be **homodont**. In the majority of mammals, on the other hand, the teeth are arranged in groups of different size and form; such a dentition is **heterodont**.

Again, mammals have (neglecting exceptional cases) but two functional sets of teeth; they are consequently said to be **diphyodont**. Most vertebrates below mammals, on the other hand, have a continuous succession of teeth throughout life, and hence they are said to be **polyphyodont**.

The teeth of fishes and reptiles, and even of some of the mammals, such as dolphins and porpoises, are conical pegs set in the jaw, and none of them have flattened crowns or crowns furnished with tubercles like those of human premolar and molar teeth.

An intermediate form of teeth is shown in some carnivorous mammals in which, at the base of a conical tooth, a ring of enamel forming a cingulum is found. (See p. 569.)

The current view of the origin of the human teeth rests upon evidence that in each tooth three primary tubercles are represented. It is possible that this *tritubercular* origin may be accounted for by the fusion into one of three originally separate conical simple teeth.

The tubercles are found one on the lingual and two on the labial aspect. In the incisors and canine teeth the cingulum represents the lingual tubercle; and the cutting margin of the incisors and the conical apex of the canines represent the two labial tubercles fused together. In the premolars also the two labial tubercles are fused.

In the molar teeth, two labial tubercles and one lingual tubercle persist, but in these teeth additional secondary tubercles also are present. They are one or two in number and are added to the original tubercles at the back on the lingual side when four tubercles are present, and on both lingual and labial sides when there are five of them.

The complete or **typical mammalian dentition**, in its highest development, as in the horse, is represented by the following formula: I. $\frac{3}{3}$, C. $\frac{1}{1}$, PM. $\frac{4}{4}$, M. $\frac{3}{3}=44$. In the dentition of Man, therefore, one incisor and two premolars are wanting. Different views are held as to which teeth have been suppressed—most probably they are the second incisors and the first and second or first and last premolars.

In general it may be said that in the **dentition of the non-civilized races** the dental arches are squarer in front, the teeth larger and more regular, the canines stronger, the last molars better developed, and the tubercles on the molars more perfect than in the more civilized races. It may be mentioned that the teeth of a savage man, if seen in the mouth of a European, would be looked upon as an "exceedingly perfectly formed set of teeth" (Tomes).

For Flower's "dental index", which expresses the proportion in size of the crowns of the premolars and molars to the length of the cranio-facial axis in different races, see the works cited on p. 329.

Development of Œsophagus, Stomach, and Intestines

Development of Tissues of Œsophagus, Stomach, and Intestine.—The wall of these portions of the alimentary tube consists at first of an internal lining of epithelial entodermal cells, several layers thick, and of an external investment of mesenchyme. The intra-abdominal portion of the tube has also a partial external covering of the flattened cells which form the lining wall of the cœlom. The entodermal cells give rise to the epithelium of the adult œsophagus,

stomach, and intestine (whether it is stratified and squamous as in the œsophagus or columnar as in the stomach and intestine), to the secreting cells of the glands of the canal, including the liver and pancreas, and to the lining epithelium of the ducts of those and other glands. The epithelium may be ciliated for a time in the œsophagus, and in the duodenum it may be so thickened as to obliterate the lumen of the tube for a time.

The epithelium shows early very active proliferation, so that ridges and furrows are formed; and the glands arise from downgrowth of the epithelium. In both large and small intestine, the longitudinal ridges become broken up into isolated, finger-like stalks to form villi, which are present for some time in the large as well as in the small intestine. Additional villi are formed later on by a rapid growth of the epithelium in the intervals between the original villi. The circular folds of the intestine are formed much later, but are well formed at birth.

The **muscular coats** are formed from the mesenchyme by a gradual extension of its cells and their modification into the fibrils of plain muscle. The circular coat is the first to originate, and later the longitudinal coat. In the colon the longitudinal coat is formed first at the rectal end and thence spreads headwards; from the first it is in the form of three separate longitudinal bands, while in the small intestine it is a continuous sheet.

Vessels and Nerves.—The nerves and probably also the vessels grow into the wall of the intestine, the vessels being derived from the primitive vascular network connected with the yolk-sac. The cœliac artery and the superior and inferior mesenteric arteries represent splanchnic (vitelline) vessels which have persisted to supply the parts of the alimentary canal in the abdomen derived from the fore-gut, mid-gut, and hind-gut respectively.

Formation of Gastric and Intestinal Glands, etc.—The epithelial lining of the intestinal tube is composed, at first, of a single layer of cells, and the inner surface is smooth. In the second month the epithelium increases rapidly, and as a result its surface is thrown into folds and furrows, arranged irregularly. Mesenchymal tissue passes into the interior of the folds, and also blood-capillaries. The folds appear first in the stomach, especially in the regions of the curvatures, and later in the duodenum and small intestine, and then in the large intestine, where they are formed first in the rectum and last in the vermiform appendix. In the stomach the folds are arranged so as to surround small isolated depressions which afterwards become the gastric pits. In the small intestine isolated elevations are found, in place of continuous folds, and at a later stage new elevations are formed between the primary ones. Those papillary elevations form the villi. In the large intestine the arrangement resembles that in the stomach. The glands of the stomach and intestine are formed by an active proliferation of the epithelium at the bottom of the furrows; at first their cells are everywhere of a similar character, but they become differentiated later. In the stomach the formation of the glands begins about the end of the third month. The intestinal glands of the large intestine appear as depressions between adjacent elevations, and there is not so much active proliferation of cells as in the formation of the glands in the small intestine. The glandular epithelium of the gastric glands begins to assume its differentiated form in different parts, *i.e.*, cardiac and pyloric glands, towards the fifth month of development.

Organ Formation—Œsophagus.—The lengthening of the thoracic region of the trunk, which occurs with the growth and development of the heart and lungs, causes the œsophageal portion of the alimentary tube to become greatly lengthened. Vacuoles appear in the epithelial lining, and they coalesce to form the lumen.

Stomach.—As early as the fourth week, the fore-gut exhibits a fusiform enlargement in the region of the developing heart which is the first evidence of the differentiation of the stomach: this enlargement first takes the form of an outgrowth on the dorsal border to form the fundus. Soon, however, as the diaphragm is being formed, the stomach passes into the abdomen, and its dorsal wall—the future greater curvature—begins to grow more rapidly than the ventral wall. As a result the whole organ becomes slightly curved, and its inferior end is carried forwards from the posterior abdominal wall, giving rise to the curvature of the duodenum. The excessive growth of its posterior wall and the development of the liver on the right side cause the stomach to turn over on to its right side, which now becomes posterior or dorsal. As it rotates, the upper or cardiac portion moves to the left of the median plane, and the whole organ assumes an oblique direction across the abdomen. Already, at the fifth or sixth week, the adult form of the stomach is clearly indicated.

The rotation of the stomach around its long axis, which is accompanied by a rotation of the lower end of the œsophagus, explains why the gastric nerves are on the front and back of the lower end of the œsophagus instead of its right and left margins.

Intestines.—At first there is no separation into large and small intestines; the primitive canal is a simple, slender tube, with a convexity towards the umbilical orifice, through which the vitelline duct passes to the yolk-sac. Later, the tube increases in length, and in embryos of 8 or 9 mm. an outgrowth of the canal appears which represents the future cæcum, and indicates the separation into large and small intestines. Growing longer, the intestine forms a large loop with the vitelline duct springing from its apex (Fig. 572), and the superior mesenteric artery running down between the layers of its mesentery. That loop passes outside the body of the embryo and lies for some time in a part of the cœlom in the umbilical cord: but as the abdominal cavity increases in size the loop is retracted into the abdomen. The primary loop is known as the entero-colic loop, and from it are formed the intestine from the distal end of the duodenum to the left colic flexure. At the root of the loop, where the proximal and distal ends come to lie close to one another, lateral bendings of the intestine appear; the intestine head-

wards to the upper root bends over and forms a loop convex to the right—the gastro-duodenal loop, supplied by a branch of the cœliac artery, and giving origin to the duodenum. The caudal portion of the intestine, supplied by the inferior mesenteric artery, forms a loop convex to the left on the posterior abdominal wall (Fig. 572). There now takes place a change which entirely modifies the position of the parts—that is, a rotation of the entero-colic loop, with its mesentery, around the superior mesenteric artery as an axis (Fig. 572). The result of this rotation is that the original right side of the loop of gut and mesentery becomes the left side; and the beginning of the large intestine is carried across the duodenum (Fig. 572), thus explaining the passage of the transverse colon in front of the second part of the duodenum in the adult. At the same time the cæcum comes to lie near the middle of the abdomen below the liver—a position in which it is found during the third month. Subsequently, it passes farther to the right; and finally, descending, comes to occupy its adult position (Fig. 573).

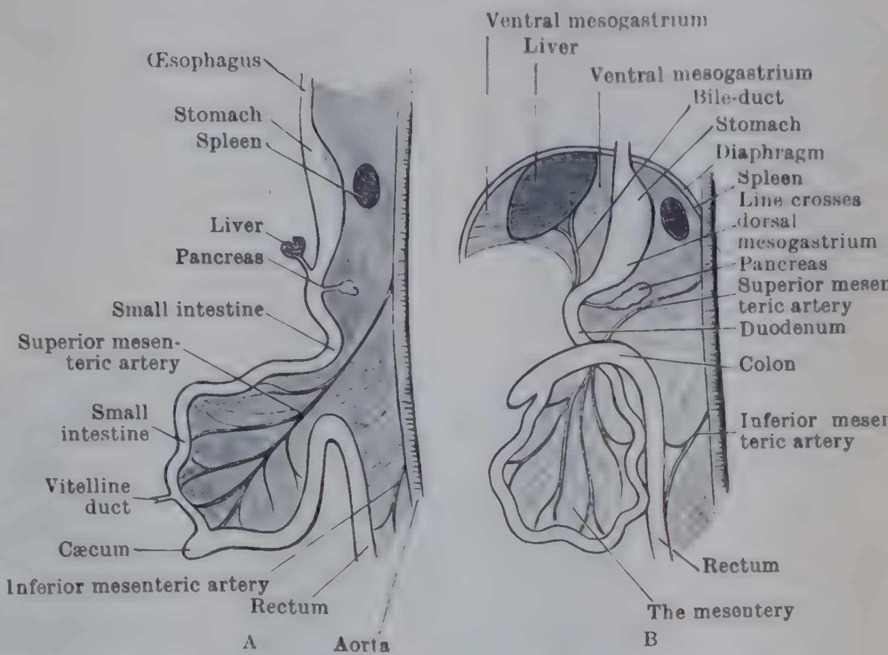

FIG. 572.—TWO DIAGRAMS TO ILLUSTRATE DEVELOPMENT OF INTESTINAL CANAL.

In both figures the parts are supposed to be viewed from the left side. The ventral mesogastrium is shown in Fig. B only, which shows also the rotation of the intestinal loop around the superior mesenteric artery.

The small intestine continues to grow in length, and, as a result, is thrown into coils, which become more and more complex as the length increases, until the adult condition is attained. The terminal portion of the large bowel retains its position on the left side and passes down to the anus.

Cæcum and Vermiform Appendix.—The cæcum appears in the sixth week of development as a small outgrowth of the wall of the primitive gut (mid-gut) not yet differentiated into small and large intestines. The outgrowth is of the same size throughout and is practically equal to the intestine in diameter. About the eleventh week it increases very considerably in length (its length being equal to about five times the diameter of the small intestine, and thus being relatively as long as in the adult); but even at that early date the basal portion, for about one-fifth of its length, is quite as wide as the intestine, whilst the remaining four-fifths of the outgrowth—the future vermiform appendix—is only about one-half or one-third the diameter of the gut. Thus, the distal portion of the outgrowth, which subsequently becomes the vermiform appendix, begins to lag behind even at this early period of its development.

The basal portion continues to expand with the gut; the distal part grows rapidly enough in length, but otherwise enlarges very slowly, so that, towards the end of fœtal life, the cæcum has attained a conical shape, the wider end joining the ascending colon, the narrow end tapering gradually and passing into the appendix. That form, known as the infantile type of cæcum, is retained for some time after birth, and it may (in 2 or 3 per cent of cases) persist even throughout life.

About the sixth or seventh month of intra-uterine life the wall of the terminal portion of the small intestine adheres to the medial side of the cæcum for some distance below the ileo-colic orifice. The connexion, which is made more intimate by the passage of two folds of peritoneum, one on the front, the other on the back, between the two parts, profoundly modifies the subsequent growth of the cæcum, and determines very largely its adult form. For, when the cæcum begins to expand, the medial aspect is prevented, by its connexion with the termination of the ileum, from enlarging as freely as the rest of the wall; in consequence of this the lateral part grows and expands much more rapidly, producing the lop-sided appearance already referred to, and soon comes to form the lowest part of the cæcum and the greater part of its sac; whilst the original apex, with the vermiform appendix springing from it, anchored, as it were, to the end of the ileum, is thrust to one side, and is finally on the medial and posterior aspect of the cæcum, a little way below the end of the ileum and usually behind it.

The position of the cæcum varies at different periods of intra-uterine life. About the eleventh or twelfth week it lies immediately beneath the liver and to the left of the median plane; it then gradually travels to the right, crossing the second part of the duodenum, and is found lying on the right side, just beneath the liver, at the fourth month. From there it descends slowly to its adult position, which it usually approaches towards the end of fœtal life, but it may not actually reach it until some time after birth.

Rectum.—The rectum and anal canal are formed from the tailward portion of the hind-gut and from the anal pit. The primitive closed, cloacal portion of the hind-gut becomes divided by a septum into ventral and dorsal portions. The ventral portion, with the allantois growing from it, forms the urogenital sinus; the dorsal portion forms the rectum and the upper part of the anal canal. The anal pit is separated from the primitive gut by the anal membrane, but that membrane disappears, and thus the anal canal comes to open on the surface.

A spindle-shaped enlargement of the terminal portion of the rectum is early formed; it persists until birth, and a smaller temporary enlargement is formed proximal to it. The wall of the distal swelling is thrown into numerous longitudinal ridges and folds from which the anal columns are formed.

The rectum and anal canal at first form a single, continuous, straight tube which passes downwards in front of the comparatively straight pelvic surface of the sacrum to the anal orifice. That is the condition which the parts present at birth. After birth, the bony pelvis undergoes great enlargement. The sacrum and coccyx become curved, and the antero-posterior diameter of the true pelvis increases very considerably. The urinary bladder and, in the female, the uterus—both of which are mainly in the abdomen at birth—descend into the true pelvis. The anal orifice appears to be moved farther forwards in the perineum owing to the bending

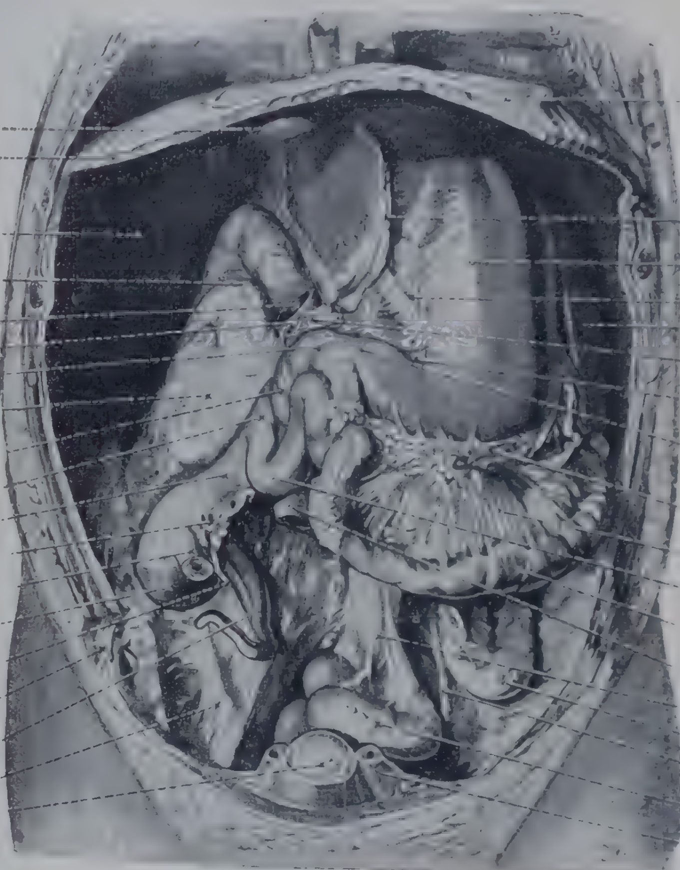

FIG. 573.—ABDOMINAL VISCERA IN THE NEW-BORN CHILD. The liver and the jejunum and ileum have been removed. The vertical stomach, the large suprarenal gland, the high position of the cæcum, and the whole arrangement of the large intestine are typical of the condition found at birth, and differ, as can be seen, largely from the adult condition.

of the sacrum and coccyx, and the rectum is pushed back into the hollow of the sacrum, whose curvature it follows. Another curvature is formed by the junction of the curved rectum with the straight anal canal as it passes downwards and backwards through the tissues of the pelvic floor. The increase in the thickness of the pelvic floor gives to the anal canal the length which it attains in the adult.

DEVELOPMENT OF PERITONEUM

At first the primitive alimentary canal is suspended from the dorsal wall of the embryo, along the median plane, by a simple **dorsal mesentery** which extends along the whole length of the tube and is common to all its divisions—a condition found in the adult stage of many reptiles. In the upper part of the cavity, after the stomach and liver descend into the abdomen, there is also a **ventral mesogastrium** (Fig. 572) which connects the stomach and duodenum to the liver and passes on over the liver to connect it to the anterior abdominal wall and septum transversum. The portion of the ventral mesogastrium between the stomach and liver

becomes the lesser omentum; its anterior portion, between the liver and the parietes, forms the falciform ligament (Fig. 572); and, in its inferior margin, the umbilical vein runs from the umbilicus to the liver.

The portion of the dorsal mesentery connected with the stomach is known as the **dorsal mesogastrium.** At first it is relatively short; but with the growth of the posterior border of the stomach, and the turning of that organ over on its right side, the dorsal mesogastrium becomes elongated and is folded on itself, forming more or less of a pouch directed downwards and to the left. The wall of this pouch becomes in part the greater omentum, and the cavity enclosed by it forms the greater part of the lesser sac. In the rotation of the stomach and the accompanying passage of the lesser omentum from an antero-posterior to a more or less transverse direction, a portion of the cavity of the abdomen is, as it were, caught in behind the stomach and lesser omentum. That portion of the cavity becomes the upper part of the lesser sac, and at first it communicates with the general cavity by a wide opening to the right of the lesser omentum; but the growth of the liver and other factors reduce it to a relatively small size, and it forms the opening into the lesser sac in the adult.

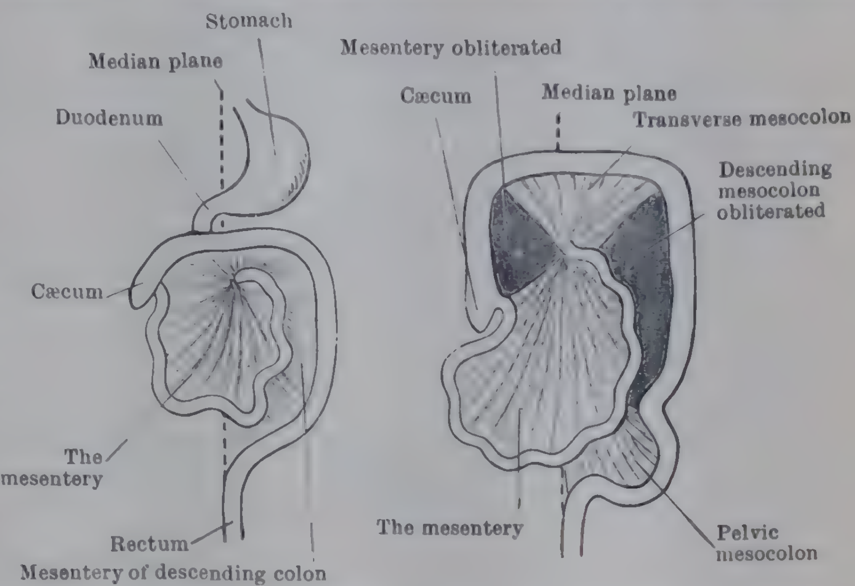

FIG. 574.—TWO DIAGRAMS TO ILLUSTRATE DEVELOPMENT OF THE MESENTERIES.

In the first figure the rotation of the intestinal loop and the continuous primitive mesentery are shown. In the second figure, which shows a more advanced stage, the portions of the primitive mesentery (going to the ascending and descending colons) which disappear, through their adhesion to the posterior abdominal wall, are shaded dark; the portions which persist are lightly shaded.

The upper recess of the lesser sac has a complicated origin. It represents the right of two pocket-like recesses, a right and a left, which are formed very early in the dorsal wall of the cœlom. The two recesses are narrow and horizontal slits which burrow into the dorsal wall and turn upwards by the side of the œsophagus. They are termed the "pneumato-enteric recesses". The left one disappears entirely. The apex of the right one remains occasionally as the "bursa infracardiaca" of the right lung, and is cut off by the diaphragm from the lower portion, which is the rudiment of the upper recess.

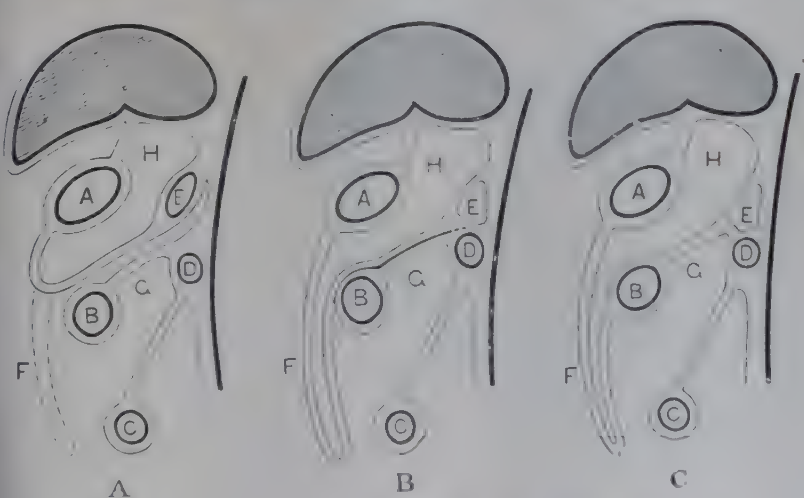

FIG. 575.—DIAGRAMS TO ILLUSTRATE DEVELOPMENT OF GREATER OMENTUM. (After Hertwig, 1892.)

A shows the beginning of the greater omentum and its independence of the transverse mesocolon; in B, the two come in contact; and in C, they have fused along the line of contact. (According to Lockwood, 1884, the two layers of the fold shown in A, instead of fusing, as shown in B, are drawn out—unfolded—producing the condition shown in C.) A, stomach; B, transverse colon; C, small intestine; D, duodenum; E, pancreas; F, greater omentum; G, placed in greater sac; H, in lesser sac.

The **greater omentum** is, as pointed out above, a bag-like growth of the lower part of the dorsal mesogastrium which passes downwards and to the left in front of the transverse colon. As shown in Fig. 575, A and B, it is first entirely unconnected with the transverse colon and mesocolon; but about the third or fourth month it becomes united to both, and the adult condition is established (Fig. 575, C). It would appear that the growth of the inferior part of the lesser sac, and of the greater omentum, is primarily due to a proliferation of the cells over a limited area of the dorsal mesogastrium and a resulting folding of this layer downwards and to the left.

In the upper part of the dorsal mesogastrium the **spleen** is developed, and the portion of that

fold which intervenes between the stomach and spleen forms the gastro-splenic ligament, whilst the part behind the spleen becomes the lieno-renal ligament.

Of the primitive mesentery, the portion connected with the stomach—the mesogastrium—becomes modified in the manner just described. The next division—the mesoduodenum—disappears completely, owing to the turning over of the duodenal loop on to its right side and its subsequent adhesion to the posterior abdominal wall, accompanied by the absorption of the right side of its mesentery. The mesenteries of the small and large intestine are continuous at first (Fig. 572, A). When the rotation of the intestinal loop takes place around the superior mesenteric artery (Fig. 572, B), the beginning of the large intestine, with its mesentery is carried to the right across the duodenum, and a fan-shaped portion of the general mesentery, lying within the concavity of the loop, is partially cut off; that, later on, forms the mesentery proper in the adult. At first it is continuous by its right border with the mesentery of the ascending colon (a part of the primitive mesentery), which itself is continued into the mesentery of the transverse, descending, and pelvic colons. Subsequently, as shown by the darkly shaded parts in Fig. 574, the backs of the mesenteries of the ascending and descending portions of the colon adhere to the posterior abdominal wall, and these mesenteries become lost; whilst the mesenteries of the transverse and pelvic portions of the colon remain free, and they persist in the adult.

At the same time, the mesentery proper (which was at first attached only at its narrow neck between the duodenum and transverse colon, and, below that, was continuous on the right with the ascending mesocolon) now acquires a new attachment to the posterior abdominal wall through the absorption of the ascending mesocolon (Fig. 574), and the adult condition is attained.

Development of Liver and Pancreas

The glandular tissue of the liver and pancreas and the epithelial linings of the ducts of those organs, including the gall-bladder and cystic duct, are formed from protrusions of the

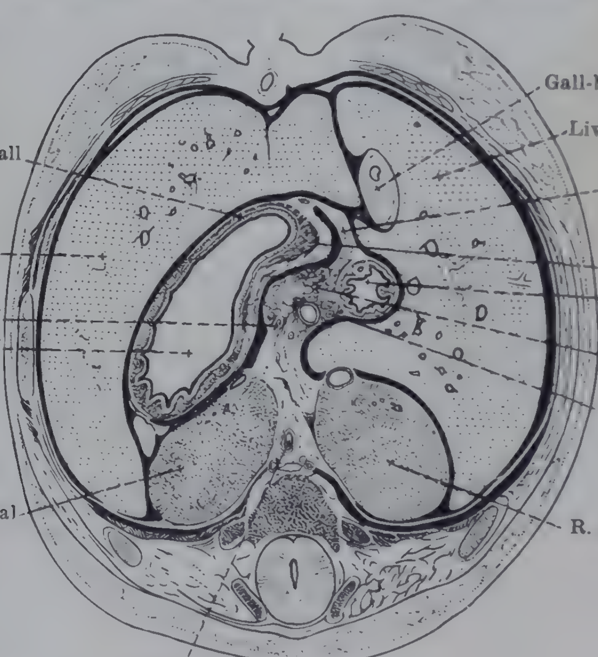

Fig. 576.—Transverse Section of 26 mm. Human Embryo, at Level of Upper Part of Umbilicus. (Embryo E 1. St. Andrews University Collection.)

The liver at this stage is of large size, and its left lobe extends into the left half of the abdominal cavity. The suprarenal glands are also relatively very large. The lesser omentum (ventral mesogastrium) is attached to the duodenum as well as to the lesser curvature of the stomach. Buds of developing pancreatic tissue are shown lying to the left side of the duodenum, while, dorsal to them, other buds surround the bile-duct, on the left side of which lies the portal vein. The cavity of the lesser sac is shown in black, behind and to the right side of the stomach.

epithelial wall of the fore-gut below the stomach. The areolar tissue framework of the glands is formed from the mesodermic tissue into which the protrusions grow.

Liver.—A longitudinal groove appears on the interior of the ventral wall of the fore-gut, close to its union with the mid-gut, at about the third week. The groove appears on the external surface of the gut as a projection which rapidly increases in size and grows forwards and upwards towards the lower part of the septum transversum. The septum transversum is a mass of mesodermic tissue which lies in front of the fore-gut, just caudal to the heart, and is attached to the ventral wall and side-walls of the trunk. The umbilical and vitelline veins pass through it on their way to the sinus venosus.

The liver-bud grows into the lower (caudal) portion of the septum transversum, and divides into two, from each of which strands of cells, termed *trabeculæ*, grow out, make contact with the vessels in the septum, and enclose them. By the growth of capillary vessels from the vitelline and umbilical veins and the growth of the trabeculæ, a spongy network is produced, the framework of which is formed by branching and anastomosing trabeculæ, while the spaces of the network represent portions of the lumen of the vessels and are filled with blood. This form of vascular network is known as a "sinusoidal tissue". The trabeculæ become hollowed out and are reduced in size, so that eventually a minute channel is formed in the centre of each of them, and is surrounded by a single layer of cells. The lumen of the channel becomes the lumen of a bile-ductule, and the cells surrounding it form the secreting cells of the liver-lobule. The bile-ductules of adjacent trabeculæ converge and unite to constitute the interlobular ducts. Adjacent trabeculæ become arranged into the form of a lobule, each with a vascular channel in its interior which communicates with the vascular network in the surface of the lobule by capillary intervals between adjacent trabeculæ. The central vein becomes a tributary of a hepatic vein, and the capillary network becomes the terminal distribution of branches of the portal vein.

The proximal portion of the original hollow diverticulum becomes the bile-duct, and the gall-bladder and cystic duct are formed by an evagination from it. For an account of the development of the choledocho-duodenal junction see Schwegler & Boyden (1936, 1937).

As the liver increases in size, it begins to bulge down from the lower part of the septum transversum into the ventral mesogastrium, so that now, instead of being situated within the septum, it looks like an appendage of its inferior surface. In other words, the septum begins to differentiate into two parts—an inferior, the liver, and a superior, which constitutes the greater portion of the diaphragm, both of these having been at first one continuous mass. In the course of development the separation of the two becomes more marked, and finally is complete everywhere except at the coronary and triangular ligaments behind, and at the falciform ligament in front, where they are still connected. As the liver separates off from the future diaphragm and descends into the abdomen, it lies between the layers of the **ventral mesogastrium** and divides it into two parts—the falciform ligament and the lesser omentum (*vide ante*).

Pancreas.—The pancreas is developed at a very early period (being present in embryos of less than 5 mm.) from two outgrowths from the alimentary canal—a dorsal and a ventral (Fig. 577).

The dorsal rudiment is an outgrowth from the dorsal wall of the intestine proximal to the origin of the hepatic outgrowth. The ventral rudiment grows at a later stage from the root of the hepatic bud in the form of two offshoots, one on each side. That on the left side, however, soon disappears.

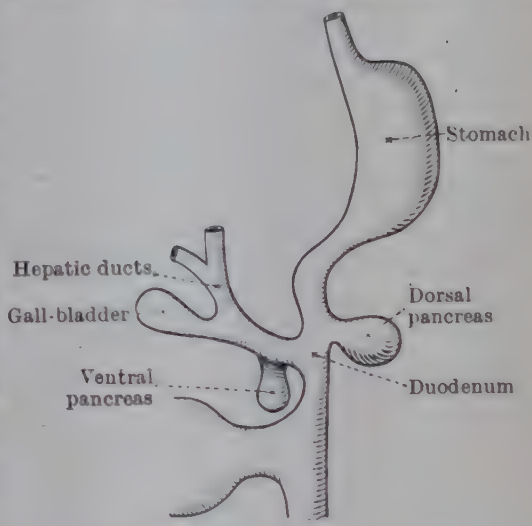

FIG. 577.—DIAGRAM OF DEVELOPMENTAL ORIGIN OF LIVER AND PANCREAS.

Through the rotation of the duodenum around its long axis, the dorsal and ventral rudiments approach one another and become fused, and their ducts open on the left side of the duodenum. The connecting stalk between the ventral rudiment and the hepatic bud becomes the main duct of the pancreas, while the connexion of the dorsal outgrowth with the duodenum remains as the accessory pancreatic duct. In embryos of the fifth week, a large dorsal pancreatic rudiment is present, and also a smaller ventral rudiment, which opens into the duodenum in common with the bile-duct and lies on the right of the portal vein. In the sixth week, the two rudiments meet and unite with one another, forming a long slender glandular mass which passes backwards within the dorsal mesentery (mesoduodenum) between the vertebral column and the greater curvature of the stomach. As the duodenum comes to lie on the posterior abdominal wall the dorsal extremity of the pancreas is displaced over to the left side, and the body of the gland and the head (included within the curve of the duodenum) also come to lie on the posterior abdominal wall.

The dorsal (proximal) outgrowth, which passes in front of the portal vein, gives rise to the main mass of the gland, including the upper and anterior parts of the head, the body, and the tail; the ventral outgrowth, which lies dorsal to the vein, becomes the uncinate process and the posterior portion of the lower part of the head.

Each developmental portion of the pancreas has at first its own duct, but a connecting channel is formed between the ducts of the dorsal and ventral rudiments, so that the **pancreatic duct** is a composite structure. The **accessory duct** (see Fig. 570, p. 671) is the terminal part of the duct of the dorsal outgrowth.

The primary diverticula give off buds which are lined with cylindrical epithelium, and these in turn give off other buds, and the process goes on until the mass of the gland is formed.

The **islets of Langerhans** are formed at a very early stage from the entodermal lining cells of some of the branching diverticula which lose their connexion with the system of

RESPIRATORY SYSTEM

by J. C. B. GRANT, M.C., M.B., Ch.B., F.R.C.S.Ed.,
Professor of Anatomy, University of Toronto

THE **Respiratory System** (Fig. 578) comprises the *larynx*, *trachea*, *bronchi*, and *lungs*. The larynx and trachea are the successive parts of a median air-passage. The trachea bifurcates below into two smaller air-passages, called the right and the left bronchus, which conduct air to the right and the left lung respectively. A serous membrane, called the *pleura*, envelops each lung and lines the portion of the thoracic cavity which contains that lung.

The larynx opens into the inferior part of the pharynx, and the air that passes into and out of the air-passages traverses the pharynx and the nasal cavities, and also the oral cavity if the mouth is open. The connexion between the digestive and respiratory systems is explained by the fact that the respiratory system develops as an outgrowth from the ventral wall of the primitive fore-gut of the embryo.

LARYNX

The larynx is a mechanism specially adapted to protect the opening of the air-passage, to close it against the entrance of solids, liquids, and even air if necessary, and to control the expiration of air from the lungs, thus providing an organ of voice in Man. Above, it opens into the pharynx; below, its cavity is continuous with the lumen of the trachea or windpipe.

Position and Relations of Larynx.—In the natural position of the neck the larynx is situated anterior to the bodies of the fourth, fifth, and sixth cervical vertebræ. Its highest point, represented by the tip of the epiglottis, extends to the upper border of the body of the third cervical vertebra, whilst its lowest limit (the lower border of the cricoid cartilage) usually extends to the lower border of the body of the sixth cervical vertebra. From the vertebral column the larynx is separated not only by the prevertebral muscles and the prevertebral fascia but also by the posterior wall of the pharynx—indeed, the posterior surface of the larynx forms the inferior part of the anterior wall of the pharynx, and it is covered with the pharyngeal mucosa.

The larynx lies below the hyoid bone and the tongue, in the interval between the great vessels of the neck, and it forms a more or less marked projection on the front of the neck. In the median plane it is separated from the surface merely by skin and two layers of fascia; laterally it is overlapped by the the sterno-mastoid muscle, and is covered with the two strata of thin ribbon-like muscles that are attached to the thyroid cartilage and the hyoid bone. It is clasped by the upper parts of the lobes of the thyroid gland.

The position of the larynx is influenced by movements of the head and neck. Thus, it is elevated when the head moves backwards and is depressed when the chin is carried downwards towards the chest, but its relation to the vertebræ is scarcely changed. During deglutition the larynx moves upwards. The pharyngeal muscles attached to it, and more especially the palato-pharyngeus muscles, are responsible for bringing about these movements. In the production of vowel-sounds the pharynx undergoes marked alterations in outline, and the larynx accommodates itself to these in position and

in the relation of its thyroid to its cricoid portions. In singing, there are no changes of position other than those essential to vowel-production. In untrained singers the pharyngeal and laryngeal movements are erratic and lacking in orderly control.

In the fœtus, shortly before birth, the larynx lies nearer the head. The tip of the epiglottis then corresponds in level to the atlas, and the lower border of the larynx to the

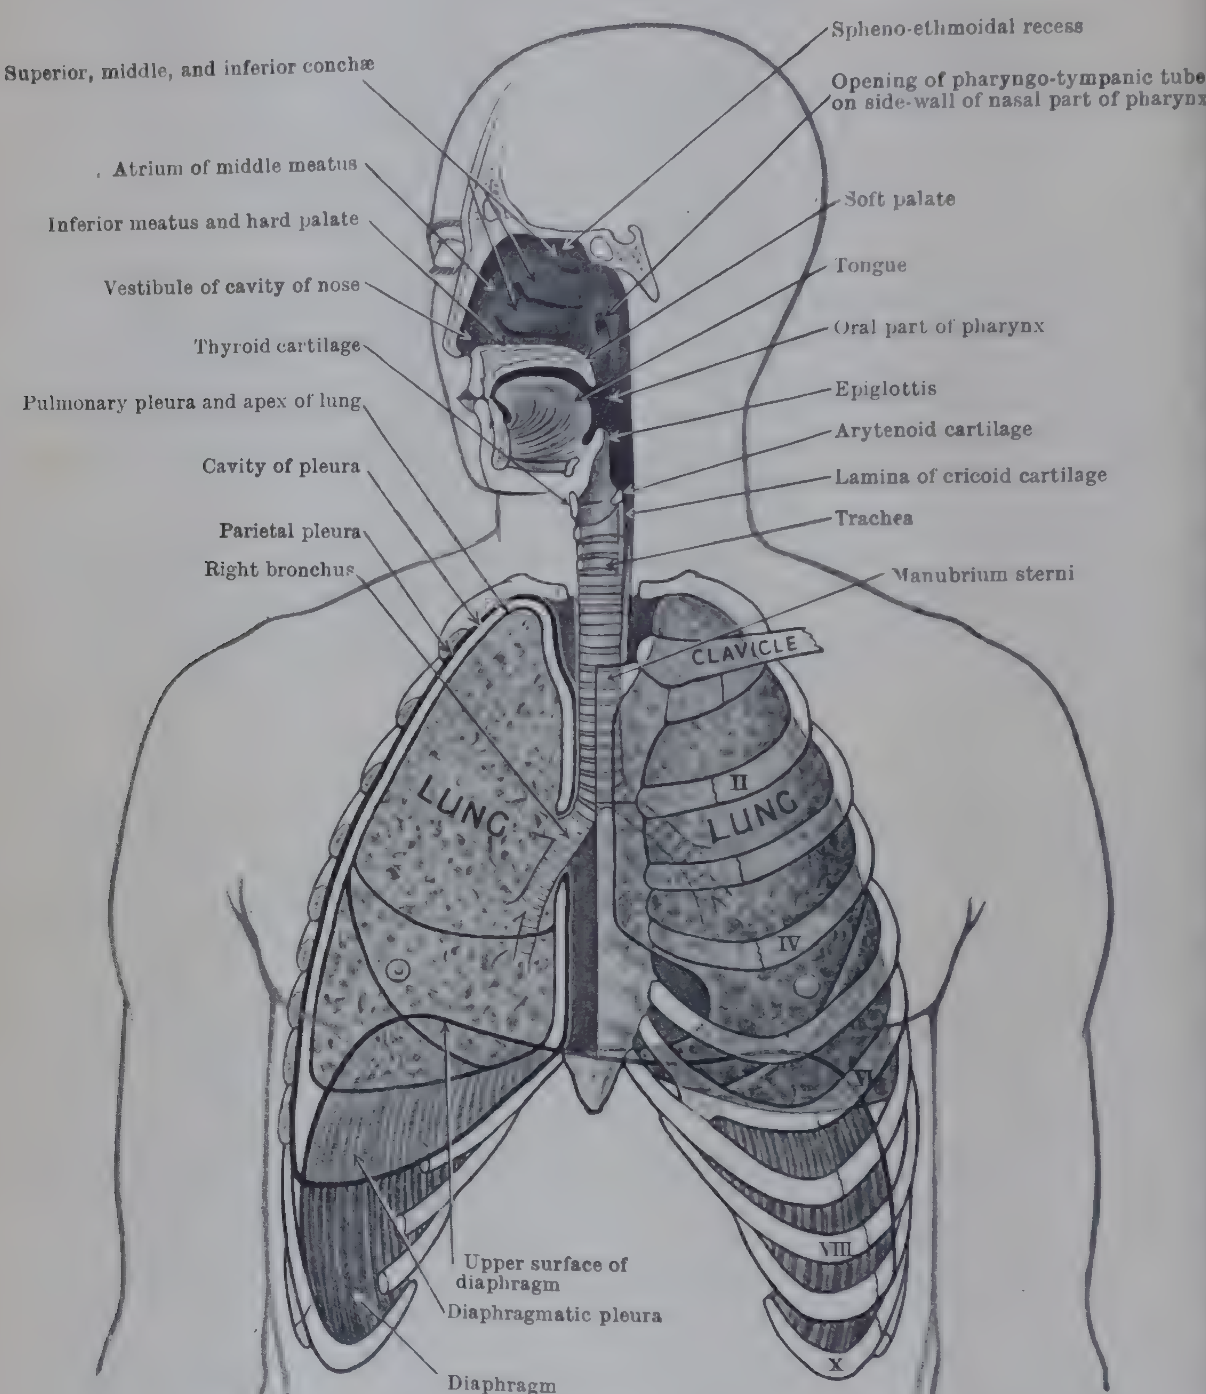

FIG. 578.—DIAGRAM OF GENERAL ARRANGEMENT OF RESPIRATORY SYSTEM.
The lung, pleura, and ribs of the right side are represented as cut.

lower border of the body of the fourth cervical vertebra. From four years onwards, in both sexes, the larynx maintains a fairly constant position in the neck—namely, the adult position given on the previous page. The elasticity of the trachea ensures practical uniformity of laryngeal relations in all positions of the head and neck.

General Construction of Larynx.—The framework is composed of several cartilages which are connected by synovial joints and also by extensive elastic membranes. Two elastic cords, which stretch from the anterior to the posterior wall of the larynx, form the groundwork of the vocal folds. Many muscles operate upon

the cartilages of the larynx, bringing about changes in the relative positions of the vocal folds, and producing different degrees of tension in those folds. The cavity of the larynx is lined with mucous membrane, under which, in certain localities, are collected masses of mucous glands.

CARTILAGES OF LARYNX

There are three single cartilages and three pairs of cartilages in the laryngeal wall. They are named as follows:—

Single cartilages	Thyroid. Cricoid. Epiglottic.	Paired cartilages	Arytenoid. Corniculate. Cuneiform.

The **thyroid cartilage**, the largest of the laryngeal cartilages, is formed of two quadrilateral plates, called the **laminæ**, which are fused together in front in the median plane. The laminæ diverge posteriorly to enclose a wide angular space open behind. The *anterior borders* of the laminæ are fused only in their inferior parts. Above they diverge to produce a deep, narrow, V-shaped, median notch called the **thyroid notch**. The median prominence just below the notch is known as the **laryngeal prominence** (Adam's apple).

The angle formed by the meeting of the two laminæ of the thyroid cartilage presents considerable individual variation and shows marked differences in the two sexes and at different periods of life. In the adult male the average angle is about 90°; in the adult female about 120°. In the fœtus the larynx is relatively large compared with the trachea and is flattened antero-posteriorly. In the infant the laminæ meet in a gentle curve, convex forwards.

The *posterior border* of each lamina of the thyroid cartilage is thick and rounded and is prolonged beyond the superior and inferior borders in the form of two slender cylindrical processes, termed horns or cornua. The **superior horn** is the longer. It is directed upwards, with a slight dorso-medial inclination, and its end or tip, which is rounded, is joined to the tip of the greater horn of the hyoid bone by the lateral thyro-hyoid ligament. The **inferior horn** is shorter and stouter. It curves downwards with a slight inclination towards the median plane. On the medial face of its extremity there is a circular, flat facet which articulates with a similar facet on the lateral surface of the cricoid cartilage.

The *superior border* of each lamina is, for the most part, slightly convex. In front it dips suddenly to become continuous with the margin of the thyroid notch, and, behind, as it joins the superior horn, it exhibits a shallow concavity. The *inferior border* is divided by a rudimentary **inferior tubercle** into a short, concave, posterior part and a longer anterior part, also concave, but to a lesser degree.

The *lateral surface* of each lamina is divided into two unequal areas by the **oblique line** which runs from a prominence (the **superior tubercle**) situated immediately antero-inferior to the root of the superior horn, forwards and downwards to end in the inferior tubercle. The area behind the oblique line is much smaller than that in front and is covered by the inferior constrictor muscle of the pharynx. The anterior area is, for the most part, covered by the thyro-hyoid muscle. To the oblique line are attached the sterno-thyroid, thyro-hyoid, and inferior constrictor muscles.

The *medial surface* of the lamina is smooth and slightly concave.

The **cricoid cartilage** is shaped like a signet-ring. Its posterior part or *lamina* is a broad, thick plate, more or less quadrilateral in form. In front and laterally the circumference of the ring is completed by a curved band called the *arch*. The lumen of the ring is circular below but elliptical above. The upper border of the **lamina** presents a broad, shallow, median notch. On each side of the notch there is an obliquely placed oval facet which articulates with the base of the arytenoid cartilage. The posterior surface of the lamina is divided by a median ridge into two depressed areas which give attachment to the posterior crico-arytenoid muscles. The **arch** of the cricoid is narrow and band-like in front, but laterally its upper border rises rapidly to join the upper border of the lamina.

The *inferior border* of the cricoid is nearly horizontal, although it commonly presents three slight, downward projections, one being on each side and one median. It is connected to the first ring of the trachea by an elastic membrane—the crico-tracheal ligament. On the *lateral surface* of the cricoid cartilage, at the place where the arch joins the lamina, a vertical ridge runs downwards from the arytenoid articular facet. On this, a short distance from the inferior border of the cartilage, a prominent circular facet articulates with the inferior horn of the thyroid cartilage (Fig. 582). The *inner surface* of the cricoid cartilage is smooth, and is lined with mucous membrane.

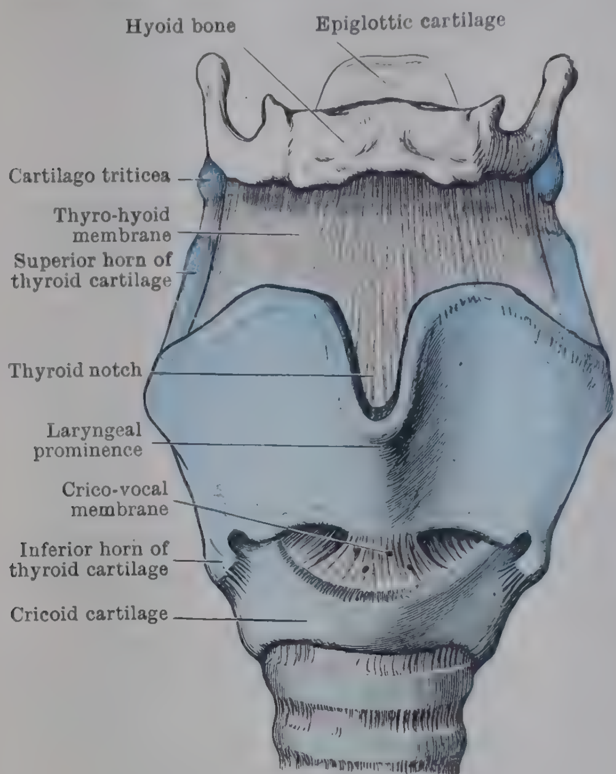

Fig. 579.—Anterior Aspect of Cartilages and Ligaments of Larynx.

The arch of the cricoid cartilage lies below the inferior border of the thyroid cartilage. The lamina is received into the interval between the posterior portions of the laminæ of the thyroid cartilage.

The **arytenoid cartilages** rest, one on each side of the median plane, upon the upper border of the lamina of the cricoid cartilage, in the interval between the posterior portions of the laminæ of the thyroid cartilage. Each has the form of a three-sided pyramid, the pointed **apex** of which curves postero-medially. It supports the corniculate cartilage. The **base** is triangular in outline. It is prolonged forwards into a small, sharp-pointed **vocal process** which gives attachment to the vocal ligament or supporting band of the vocal fold; and it is prolonged laterally into a stout, prominent angle, called the **muscular process**, which gives attachment to the lateral crico-arytenoid muscle in front and to the posterior crico-arytenoid muscle behind. Near the muscular process the base bears an elongated, concave **articular facet** for articulation with the upper border of the lamina of the cricoid cartilage. The *medial surface*, which is the smallest of the three, is triangular, flat, and vertical. It faces the corresponding surface of the opposite cartilage, from which it is separated by a narrow interval, and it is clothed with the lining mucous membrane of the larynx. The *posterior surface* is smooth and is concave in the vertical direction. It lodges and gives attachment to the transverse arytenoid muscle. The *antero-lateral surface* is the most extensive of the three (Fig. 582). Its middle part is marked by a deep depression in which a mass of mucous glands is lodged. Into this surface the vocalis and thyro-arytenoid muscles are inserted, whilst a small tubercle a short distance above the base gives attachment to the vestibular ligament—the feeble supporting ligament of the vestibular fold. The three surfaces of the arytenoid cartilages are separated from one another by an anterior, a

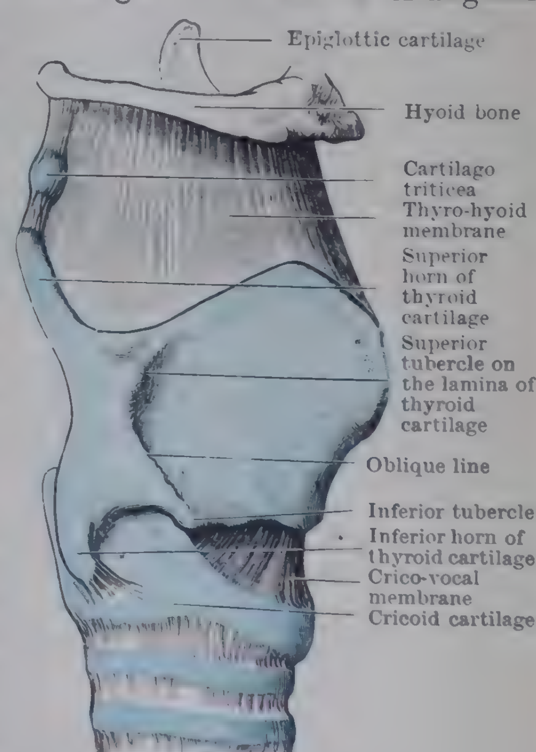

Fig. 580.—Profile View of Cartilages and Ligaments of Larynx.

posterior, and a lateral border. The *lateral border* is the longest, and it pursues a sinuous course from the apex to the muscular process at the base. A small nodule of elastic cartilage, called the **sesamoid cartilage**, commonly found on the lateral border of the arytenoid cartilage, is held in position by the investing perichondrium. The *anterior border* of the arytenoid cartilage is vertical and, at its base, reaches the vocal process.

The **corniculate cartilages** are a pair of small conical nodules of elastic fibro-cartilage; each surmounts the apex of an arytenoid and prolongs its upper, curved end in a postero-medial direction. Each corniculate cartilage is enclosed within the posterior part of the corresponding ary-epiglottic fold of mucous membrane.

The **cuneiform cartilages**, which may be very large, are not always present. They are a pair of rod-shaped pieces of elastic fibro-cartilage, each of which occupies a place in the corresponding ary-epiglottic fold immediately anterior to the arytenoid and corniculate cartilages. On the laryngeal surface of each cartilage a collection of mucous glands stands out in relief under the mucous membrane (Fig. 585).

Epiglottis.—The **epiglottis** is supported by a thin, leaf-like lamina of elastic fibro-cartilage, called the **epiglottic cartilage**, which is placed behind the root of the tongue and the body of the hyoid bone, and in front of the aperture of the larynx. When divested of the mucous membrane that covers it behind and also covers its upper part in front, the epiglottic cartilage has the outline of a bicycle-saddle. It is extensively pitted and has numerous foramina. Glands are lodged in the pits; blood-vessels and nerves pass through the foramina. The *broad end* of the epiglottic cartilage is directed upwards, and it is free. Its *margins* are, to a large extent, enclosed within the ary-epiglottic folds. The *anterior surface*, free only in its upper part which is covered with mucous membrane, looks towards the pharyngeal part of the tongue. The *posterior surface*, covered throughout its whole extent by the lining mucous membrane of the laryngeal cavity, looks towards the vestibule of the larynx. The *inferior extremity* or *stalk of the epiglottic cartilage* is pointed and is attached by a strong fibrous band—the thyro-epiglottic ligament—low down on the posterior surface of the thyroid cartilage below the median notch.

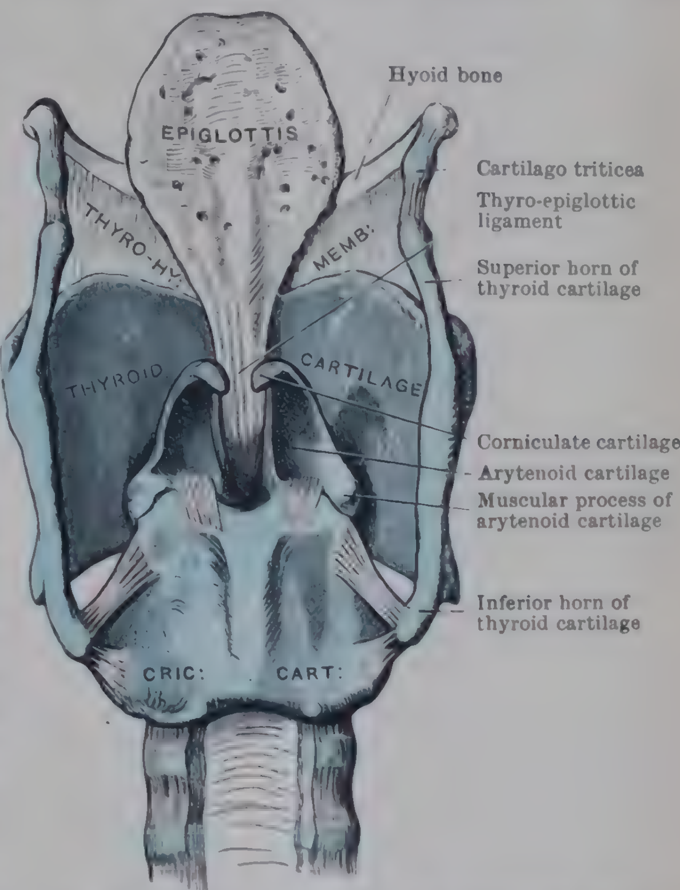

FIG. 581.—POSTERIOR ASPECT OF CARTILAGES AND LIGAMENTS OF LARYNX.

Structure and Ossification of Cartilages of Larynx.—The thyroid and cricoid cartilages and the greater part of the arytenoid cartilages are composed of hyaline cartilage. The apical parts and vocal processes of the arytenoid cartilages, and the corniculate, cuneiform and the epiglottic cartilages, are formed of elastic fibro-cartilage, and at no period of life do they exhibit any tendency towards ossific change. The thyroid, cricoid, and basal portions of the arytenoids, as life advances, may be more or less completely transformed into bone and so become visible in radiographs (Pl. LXI, p. 696). This transformation bears no constant relation to age and is already present in some subjects in the third decade. The commonest sites of ossification are the posterior and lower margins of the thyroid and the lamina of the cricoid cartilages; and in old age the thyroid, cricoid, and the hyaline parts of the arytenoids

ARTICULATIONS, LIGAMENTS, AND MEMBRANES OF LARYNX

Crico-Thyroid Joints.—These joints are formed by the apposition of the circular facets on the tips of the inferior horns of the thyroid cartilage to the elevated circular facets on the sides of the cricoid cartilage. Each joint has a ligamentous capsule lined with synovial membrane. Among the posterior fibres of the capsule there is a strengthening band. The movement that takes place at the crico-thyroid joints is mainly rotatory, the thyroid cartilage rotating around a transverse axis that passes through the centres of the two joints. Some gliding is possible here, especially in an antero-posterior direction.

Crico-Arytenoid Joints.—Each of these joints has a ligamentous capsule lined with synovial membrane. The cricoid articular surface is convex, whereas that of the arytenoid is concave; both are elongated or elliptical in form, and they are applied to each other so that the long axis of the one intersects or crosses that of the other at an acute angle. In no position of the joint do the two facets accurately coincide—a portion of the cricoid facet is always left uncovered. The capsule of the joint is strengthened behind by a band which, being inserted into the postero-medial part of the base of the arytenoid cartilage, effectually arrests excessive forward movement of that cartilage.

The movements that take place at the crico-arytenoid joints are gliding and rotatory. During easy, quiet breathing the arytenoid rests upon the lateral part of the cricoid facet. It can glide forwards and backwards upon the cricoid facet, and pass towards or from the median plane and its fellow of the opposite side. When it glides forwards the vocal process is tilted downwards towards the cricoid ring, and when it glides backwards it is tilted upwards. In the rotatory movement the arytenoid cartilage revolves around a vertical axis; by this movement the vocal process is swung laterally or medially so as to open or close the rima glottidis.

Between the arytenoid and corniculate cartilages there is a more or less rudimentary joint with a capsule, some fibres of which reach the cricoid cartilage. This joint commonly has no synovial lining.

Thyro-Hyoid Membrane.—This is a broad, membranous, and slightly elastic sheet which occupies the interval between the hyoid bone and the thyroid cartilage. The median part, composed largely of elastic fibres, is thickened to form the **median thyro-hyoid ligament**. This ligament is attached below to the margins of the thyroid notch, and above to the upper border of the body of the hyoid bone. In order to reach the upper border, the ligament ascends behind the body; and between the ligament and the body a *bursa* is interposed. On each side of the median ligament, the thyro-hyoid membrane is thin and loose. It is attached, below, to the upper border of the thyroid cartilage, and, above, to the upper border of the greater horn of the hyoid bone. It is pierced by the internal laryngeal nerve and by the superior laryngeal vessels. On each side the thickened cord-like lateral margin of the membrane, or **lateral thyro-hyoid ligament**, is composed chiefly of elastic fibres. It extends from the tip of the greater horn of the hyoid bone to the tip of the superior horn of the thyroid cartilage. In each lateral ligament the *cartilago triticea*, a small, oval cartilaginous or bony nodule, usually develops (Figs. 579-581).

The median thyro-hyoid ligament lies in front of the epiglottis, from which it is separated by a fatty pad (Fig. 585). The lateral part of the membrane is clothed on its deep aspect with pharyngeal mucosa (Fig. 584).

Crico-Vocal Membrane.—The crico-vocal membrane is attached below to the entire upper border of the arch of the cricoid cartilage from one arytenoid facet to the other. The median part, or **crico-thyroid ligament**, tense, strong, elastic, and of triangular shape, has its apex inserted into the lower border of the thyroid cartilage at the junction of the laminæ. From this attachment the lateral part of the crico-vocal membrane extends backwards to be inserted into the inferior border of the vocal process of the arytenoid cartilage. Between the anterior and posterior attachments the upper border of this part of the crico-vocal membrane is thickened and free and forms the **vocal ligament**—the supporting ligament of the vocal fold.

The crico-thyroid ligament, pierced by minute vessels and crossed by the crico-thyroid branch of the superior thyroid artery, directly unites the cricoid and thyroid cartilages. The lateral part of the membrane narrows the lumen of the larynx; it is clothed on its medial surface with the lining mucosa and on its lateral surface by the lateral crico-arytenoid muscle, which separates it from the thyroid lamina.

The **vocal ligament**, just defined as the upper border of the crico-vocal membrane, is attached in front, close to its fellow of the opposite side, to the middle of the angular depression between the two laminæ of the thyroid cartilage, and behind to the tip and upper border of the vocal process of the arytenoid cartilage. The vocal ligament is composed of elastic fibres, and embedded in its anterior extremity there is, commonly, a minute nodule of elastic fibro-cartilage. Its medial border is sharp and free, and it is clothed with mucous membrane which here is very thin and tightly bound to the ligament.

The **vestibular ligament** supports the vestibular fold. It is weak and indefinite, but is slightly longer than the vocal ligament. In front it is attached to the angular depression between the two laminæ of the thyroid cartilage above the vocal ligament and close to the attachment of the thyro-epiglottic ligament; it extends backwards to its insertion into a tubercle on the antero-lateral surface of the arytenoid cartilage a short distance above the vocal process. It is composed of fibrous and elastic tissue continuous with the areolar tissue in the ary-epiglottic fold, and it is covered with loosely attached mucosa.

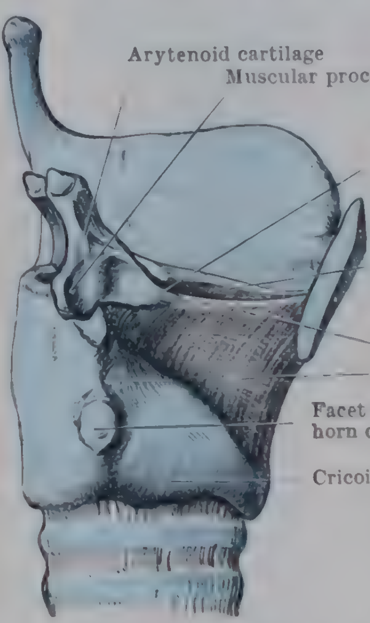

Fig. 582.—Dissection to show Crico-Vocal Membrane. The right lamina of the thyroid cartilage has been removed.

The **epiglottis** is bound by ligaments to the base of the tongue, to the wall of the pharynx, to the hyoid bone, and to the thyroid cartilage. The **glosso-epiglottic fold** is a prominent median fold of mucous membrane that extends from the free part of the anterior surface of the epiglottis to the back of the tongue. The **pharyngo-epiglottic folds** are a pair of folds of mucous membrane that pass from the lateral margins of the epiglottis to the lateral walls of the pharynx at the sides of the tongue; they enclose a certain amount of elastic tissue. By these three folds the depression between the back of the tongue and the epiglottis is marked off into a pair of fossæ, termed the **epiglottic valleculæ**, which are invariably filled in swallowing soft, semi-solid masses of food. It is, therefore, in them that foreign bodies, such as small fish-bones, should first be sought. A pair of **ary-epiglottic folds** also pass from the lateral margins of the epiglottis to the arytenoid cartilages. These very prominent folds of mucous membrane extend backwards and downwards and help to form the rim of the laryngeal inlet (Fig. 583). Between the ary-epiglottic fold and the lamina of the thyroid cartilage is the lateral food-gutter in which the opaque shadow of barium can be clearly seen on X-ray examination during the act of swallowing (Pl. LXIV, Fig. 1, p. 697).

The **hyo-epiglottic ligament** is a short, broad elastic band, partly broken up by adipose tissue, that connects the anterior surface of the epiglottic cartilage to the upper border of the hyoid bone (Fig. 585). The **thyro-epiglottic ligament** is strong and thick, and is composed mainly of elastic tissue; it extends downwards from the stalk of the epiglottic cartilage to be attached to the angle between the two laminæ of the thyroid cartilage below the median notch (Fig. 581).

The triangular interval between the anterior surface of the epiglottis and the

CAVITY OF LARYNX

The **cavity of the larynx** is smaller than might be expected from an inspection of the exterior of the larynx. It is divided into three portions by two horizontal folds of mucous membrane that project medially from each lateral wall of the cavity. The upper pair of folds are the **vestibular folds**; the lower, more definite pair are the **vocal folds** (Figs. 583, 584, 585). By controlling the exhalation of air, the vocal folds are of significance in voice-production. Changes in their relative position and in their tension are brought about by the action of muscles and by the recoil of elastic ligaments.

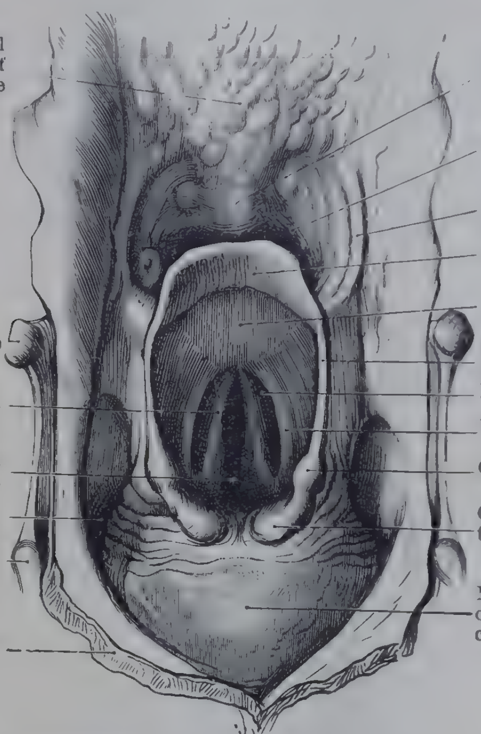

Fig. 583.—Laryngeal Inlet, exposed by Removal of Posterior Wall of Pharynx and viewed from above.

The **inlet of the larynx** opens off the pharynx, is obliquely set, and is more or less triangular in outline. The base of the triangle is anterior and is formed by the free border of the epiglottis. The apex is lower than the base and lies in the interval between the two arytenoid cartilages. The sides are formed by the **ary-epiglottic folds**. The two layers of mucous membrane that compose the ary-epiglottic folds enclose some areolar tissue, sphincteric muscle-fibres belonging to the ary-epiglottic muscles, and, posteriorly, the cuneiform and corniculate cartilages. These cartilages produce rounded prominences on the fold called the *cuneiform* and *corniculate tubercles.* When the ary-epiglottic sphincter is in action, these tubercles are approximated to the epiglottic tubercle and so assist it to complete the closure of the laryngeal inlet.

On each side of the laryngeal inlet there is a small pocket of the pharynx termed the **piriform fossa.** This fossa is part of the lateral food-gutter that leads from the oral pharynx, behind the tongue, and round the laryngeal inlet to the entrance of the gullet (Fig. 583; Pl. LXIV, Fig. **1**, p. 697). Foreign bodies may be caught in this pocket. It is bounded on the medial side by the arytenoid cartilage and the ary-epiglottic fold, and on the lateral side by the thyroid lamina and thyro-hyoid membrane. Stretching across the anterior border of the fossa in a fold of mucous membrane is the internal laryngeal nerve.

The **vestibule of the larynx** is the **uppermost compartment** of the laryngeal cavity. It extends from the laryngeal inlet to the vestibular folds. Its inferior part is compressed from side to side, hence its width diminishes from above downwards, and, owing to the obliquity of the laryngeal inlet, its vertical height is less behind than in front. *In front* it is bounded by the posterior surface of the epiglottis. Its upper part is shaped like the spout of a jug, being concave from side to side and convex from above downwards; its lower part is concave and it tapers towards the anterior ends of the vestibular folds, but above these there is a marked swelling, called the **tubercle of the epiglottis**, which overlies the upper part of the thyro-epiglottic ligament. Each *side-wall* of the vestibule of the larynx is formed by the ary-epiglottic fold. For the most part it is smooth and slightly concave. Posteriorly it diminishes considerably in vertical depth where the cuneiform and corniculate elevations appear—the latter behind the former (Figs. 583, 585). The *posterior wall* of the

laryngeal vestibule corresponds to the interval between the upper parts of the arytenoid cartilages. Its width depends largely on the position of these cartilages; when they are placed near each other the loose mucous membrane that covers the posterior wall is thrown into longitudinal folds.

The **middle compartment of the larynx**, much the smallest of the three, is the space between the level of the vestibular folds above and that of the vocal folds below (Figs. 584, 585). Each side-wall of this compartment, called the *sinus of the larynx*, bulges laterally in the shape of a canoe laid on its side, undercutting the vestibular fold more than the vocal fold. The *saccule of the larynx* opens by a slit-like mouth into the anterior part of the sinus. The saccule is a diverticulum of mucous membrane that extends upwards between the vestibular

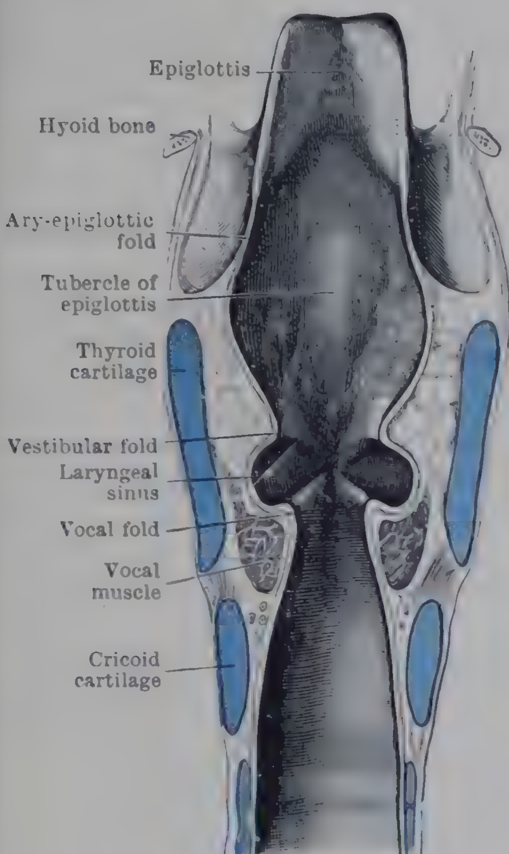

Fig. 584.—Coronal Section through Larynx to show its Compartments.

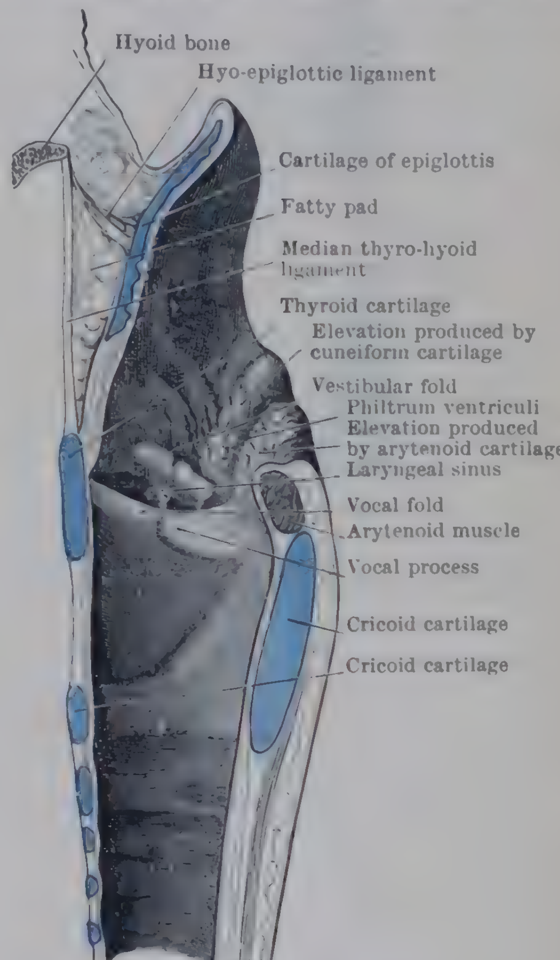

Fig. 585.—Median Section through Larynx to show Side-Wall of its Right Half.

fold medially and the thyro-arytenoid muscle laterally. It ends blindly, usually at the upper border of the thyroid cartilage, but it may protrude outwards through the thyro-hyoid membrane. The laryngeal saccule is very much larger in many of the Primates, and it may attain an enormous size in the great apes and extend even into the axilla (Negus, 1929, 1949; Brash, 1947).

The **vestibular folds** or "false vocal cords" are two prominent folds of mucous membrane that extenp antero-posteriorly, one on each side-wall of the laryngeal cavity. In front they reach the angle between the two laminæ of the thyroid cartilage, but behind they do not extend so far as the posterior wall of the larynx; each ends at the lower end of the elongated elevation produced by the cuneiform cartilage. The vestibular fold is soft and rather flaccid, and it presents a free border which is slightly arched—the concavity looking downwards. Deep to the mucosa of that fold there are: (1) the vestibular ligament; (2) numerous glands which are chiefly aggregated in its middle part; and (3) a few muscle-fibres.

The interval between the two vestibular folds is termed the **rima vestibuli** and is considerably wider than the interval between the two vocal folds. It follows that when the cavity of the larynx is examined from above, with the laryngoscope,

The **vocal folds** or "true vocal cords", placed below the vestibular folds, extend from the angle between the laminæ of the thyroid cartilage in front to the vocal processes of the arytenoid cartilages behind. Each vocal fold is sharp and prominent, and the mucous membrane that covers it is very thin and firmly bound down to the subjacent vocal ligament. In colour it is pale, almost pearly white, whilst behind it the point of the vocal process, which stands out clearly in relief, presents a yellowish tinge. In cross-section the vocal fold is triangular, and its free border looks upwards as well as medially. The right and left vocal folds and the interval between them are called the **glottis.**

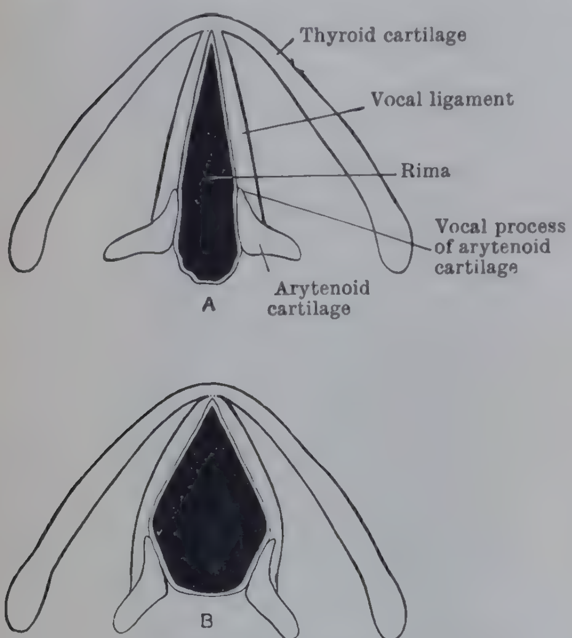

FIG. 586.—DIAGRAMS OF RIMA GLOTTIDIS.
A. During ordinary easy breathing. B. Widely opened.

The vocal folds, because they control the stream of air, are significant in voice-production. The vestibular folds, being part of the protective mechanism by which the airway is closed against the entry of food or foreign bodies, take no part in voice production. Indeed, they can in great part be destroyed and no appreciable difference in the voice results.

Rima Glottidis.—This name is applied to the elongated fissure through which the middle compartment of the larynx communicates with the lower compartment. It is placed a little below the middle of the laryngeal cavity, and it constitutes the narrowest part of that cavity. Its anterior part is bounded by the vocal folds; its posterior part is bounded by the bases and vocal processes of the arytenoid cartilages. The anterior part—between the vocal folds—constitutes more than half of its length and is called the **intermembranous part**. The broader, shorter posterior part—between the arytenoid cartilages—is termed the **intercartilaginous part.** By changes in the position of the arytenoid cartilages the form of the rima glottidis undergoes constant alterations (Fig. 586). In ordinary easy breathing it is lanceolate in outline; it widens during inspiration and narrows during expiration. When the rima is opened widely, the broadest part of the fissure is at the extremities of the vocal processes of the arytenoids, and there each side of the rima glottidis presents a marked angle. During phonation the two vocal folds are approximated to each other so that the rima is reduced to a linear chink (Fig. 591, A).

The length of the rima glottidis differs very considerably in the two sexes, and upon this depends the different character of the voice in the male and female. According to Moura (1879), the following are the average measurements in the quiescent condition of the rima :—

Male—Length of entire rima glottidis, 23 mm.	intermembranous, 15·5 mm. intercartilaginous, 7·5 mm.
Female—Length of entire rima glottidis, 17 mm.	intermembranous, 11·5 mm. intercartilaginous, 5·5 mm.

By stretching the vocal folds, however, the length of the rima glottidis may be increased in the male to 27·5 mm., and in the female to 20 mm.

The position of the rima glottidis may be indicated on the surface by marking a point on the median line of the neck 8·5 mm. below the thyroid notch in the male, and 6·5 mm. in the female (Taguchi, 1889).

The **lowest compartment** of the cavity of the larynx extends from the rima glottidis to the lower border of the cricoid cartilage. It is narrow and compressed laterally at the rima, but below this it gradually widens out until it becomes circular like the trachea, with which it is continuous. It is bounded by the sloping medial surfaces of the crico-vocal membrane and by the medial surface of the cricoid cartilage—both lined with smooth mucous membrane.

The **mucous membrane** lining the larynx is continuous above with that of the pharynx, and below with that of the trachea. Over the posterior surface of the epiglottis it is closely adherent, but elsewhere, above the level of the vocal

folds, it is loosely attached by submucous tissue. Over the vocal folds the mucous membrane is very thin and is tightly bound down.

In certain inflammatory conditions the lax submucous tissue in the upper part of the larynx becomes infiltrated with fluid, producing an œdema of the glottis which may even threaten suffocation from occlusion of the upper part of the cavity. The close adhesion of the mucous membrane to the vocal folds, however, prevents the œdema from extending below the level of the rima glottidis. Hence, as a last resort, an opening made into the respiratory passage below this level will always restore a free airway.

Above the level of the rima glottidis the laryngeal mucous membrane is extremely sensitive, and contact with a foreign body immediately induces an explosive cough. In the lower compartment of the larynx the mucous membrane, like that of the trachea, is lined with columnar ciliated epithelium. Over the vocal folds there is stratified squamous epithelium. In the sinus of the larynx and in the inferior part of the vestibule columnar ciliated epithelium again appears. The upper part of the epiglottis and the upper parts of the side-walls of the vestibule are covered with stratified squamous epithelium similar to that in the mouth and pharynx.

The mucous membrane of the larynx has a plentiful supply of acinous glands, and in only one place, namely, over the surface of the vocal folds, are they completely absent. For the most part the glands are aggregated in groups.

MUSCLES OF LARYNX

Of the many muscles connected with the larynx, two groups may be recognized—extrinsic and intrinsic.

The **extrinsic muscles** are those that attach the larynx to other parts, and, strictly speaking, they include all muscles attached to the hyoid bone, since physiologically it is a part of the larynx.

The **intrinsic muscles** all lie within the compass of the larynx itself and perform the functions outlined below. They are composed of striated muscle-fibres and are innervated by the accessory nerve through the laryngeal branches of the vagus. With the exception of the crico-thyroid muscle, they all lie under cover of the thyroid cartilage.

a. **Sphincters**

- i. Of *inlet*—
  - Oblique arytenoids
  - Ary-epiglottics
  - Thyro-epiglottics
- ii. Of *vestibule*—
  - Thyro-arytenoids

b. **Adjusters**

- i. Of *larynx*—
  - Crico-thyroids
- ii. Of *rima glottidis*—
  - Posterior crico-arytenoids
  - Lateral crico-arytenoids
  - Transverse arytenoids
  - Vocal muscles

More or less inconstant muscle-bundles, partially separated from one or other of the foregoing muscles by extension of attachment, are sometimes dignified by special names and descriptions. There is no particular reason for including them in a practical account.

The muscles of the larynx ensure a free passage for the stream of air in respiration, control the speed of expiration in speech and singing, shut off the air-stream in fixation of the chest, adjust the position of the larynx to that of the hyoid bone and tongue in movements of the throat, and provide an effective sphincter against the entrance of foreign material during swallowing. In closing the laryngeal inlet, the arytenoid cartilages are closely approximated, drawn forwards, and inclined towards the epiglottis. Thus, the laryngeal inlet is converted into a T-shaped fissure. The median limb of the T is the interval between the closely approximated arytenoid cartilages; the cross limb is bounded in front by the epiglottis and behind by the cartilages in the ary-epiglottic folds. The apices of the arytenoid cartilages, with the corniculate cartilages, are pressed against the tubercle of the epiglottis, and the lateral margins of the epiglottis are pulled backwards so as to make the transverse limb of the fissure distinctly

named in the list above. The thyro-arytenoid muscles, assisted by the oblique arytenoid muscles, form a true sphincter vestibuli. The oblique arytenoid, the ary-epiglottic, and the thyro-epiglottic muscles pull upon the epiglottis to produce tight application of its tubercle to the arytenoid and corniculate cartilages.

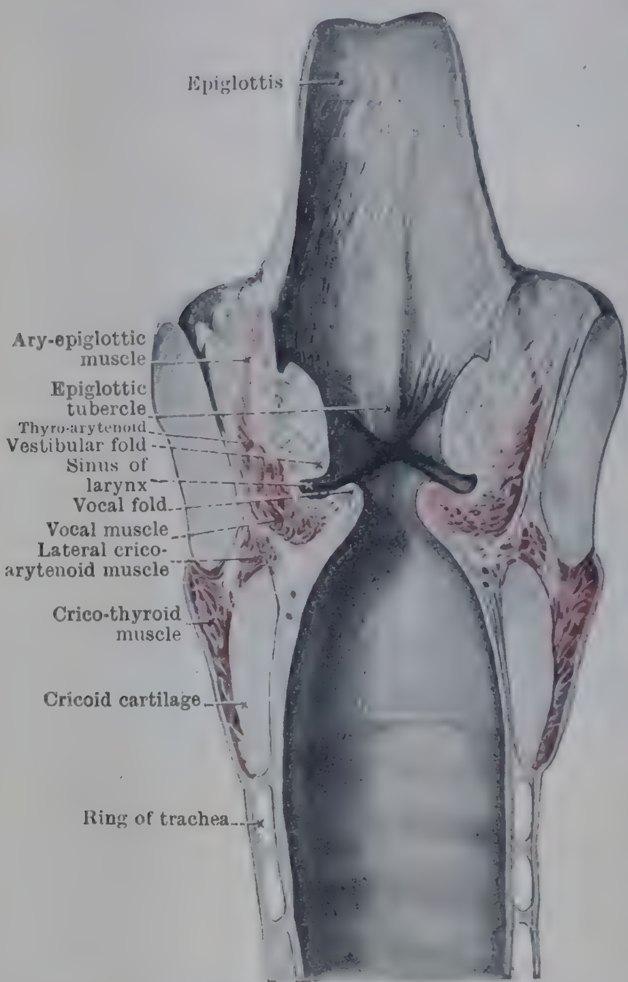

Fig. 587.—Coronal Section of Larynx to show Situation of Muscles.

Innervation of Larynx.—The nerve-supply of the larynx (Dilworth, 1921) is derived from the superior and recurrent laryngeal branches of the vagus nerve.

The **superior laryngeal nerve,** *via* its internal laryngeal branch, is the 'sensory' or receptor nerve from the mucous membrane of the larynx; its *external laryngeal* branch furnishes the 'motor' or effector fibres to the crico-thyroid muscle. All the other muscles of the larynx receive their 'motor' or effector nerve-fibres from the **recurrent laryngeal nerve.** The left recurrent laryngeal nerve winds tightly round the arch of the aorta and is commonly involved in aneurysm of the arch; the right nerve winds tightly round the right subclavian artery.

The recurrent laryngeal nerve may be damaged also in cancer of the gullet, thickening of the pleura, mediastinal tumors, extension of tumors from the neck and breast, wounds and operations in the neck, distension of the left atrium of the heart, progressive nervous diseases affecting the cervical spinal cord and medulla, and in toxic conditions like diphtheria, influenza, and lead poisoning. In recurrent laryngeal palsy the posterior crico-arytenoid is first affected and the corresponding vocal fold remains in the position of phonation. Later, when the palsy spreads to the other muscles supplied by the nerve, the vocal fold is fixed in the cadaveric position, *i.e.*, midway between adduction and abduction. The voice is hoarse but not lost since, during phonation, the healthy vocal fold crosses the median plane to meet its fellow. If both recurrent laryngeal nerves are damaged the vocal folds are fixed in the cadaveric position and phonation is impossible. There is no stridor except on deep inspiration.

Paralysis of the superior laryngeal nerve is very rare, but is stated to be caused by cold or overstrain of the voice as well as by lesions of the medulla oblongata. If the external laryngeal branch alone is damaged there is difficulty in producing high notes and the voice soon becomes tired. This is due to loss of flexion of the thyroid cartilage upon the cricoid normally produced by contraction of the crico-thyroid muscles whenever the root of the tongue is raised. If the internal laryngeal nerve also is damaged there is loss of laryngeal sensation.

Attachments of Laryngeal Muscles

The **crico-thyroid muscles** bridge over the crico-thyroid interval. Each is covered laterally and in part by the thyroid gland and by the sterno-thyroid and sterno-hyoid muscles. Between the right and left crico-thyroid muscles there is a median triangular area in which the crico-thyroid ligament is visible.

The crico-thyroid muscle **arises** from the lateral surface of the arch of the cricoid cartilage. Its fibres radiate backwards and upwards to be **inserted** into the inferior border and the adjacent part of the medial surface of the lamina of the thyroid cartilage, and into the anterior border of the inferior horn. The muscle is partly continuous with the inferior constrictor.

The cricoid cartilage is held fixed against the vertebral column by the crico-pharyngeus (*i.e.*, the lowest fibres of the inferior constrictor), except during the act of swallowing, when it is in momentary relaxation. Hence, when the anterior fibres of the crico-thyroid muscle contract, the thyroid cartilage rotates downwards on the cricoid, like a visor; but during the act of swallowing the cricoid rotates on the thyroid. The posterior fibres of the crico-thyroid muscle cause

[Facing p. 697

the thyroid cartilage to glide forwards (Negus, 1929). While this action does, in certain combinations with other muscles, increase the tension of the vocal folds, its chief function is to render the larynx as a whole more flexible in movements of the throat.

The **thyro-arytenoid muscle** forms a common mass with the vocal muscle, and the two can be separated only by artificial means.

It lies in the lateral wall of the larynx, medial to the lamina of the thyroid cartilage and lateral to the sinus of the larynx, the vocal muscle, and the crico-vocal membrane; its inferior border is in contact with the lateral crico-arytenoid muscle; its superior border extends farther upwards than the vocal fold and is in contact with the inferior border of the thyro-epiglottic muscle.

It **arises** from the inferior half of the medial surface of the lamina of the thyroid cartilage, close to the angle, and also from the lateral part of the crico-vocal membrane. The muscle-fibres pass backwards and upwards to be **inserted** into the lateral border and muscular process of the arytenoid cartilage; some of the fibres, however, turn round that cartilage and become continuous with the transverse arytenoid muscle.

The muscle, acting alone, would approximate the arytenoid cartilage to the thyroid and hence was formerly said to antagonize the crico-thyroid. But since it acts when the position of the arytenoid is stabilized by contraction of the crico-arytenoids and transverse arytenoid, the arytenoid cartilage obviously cannot move.

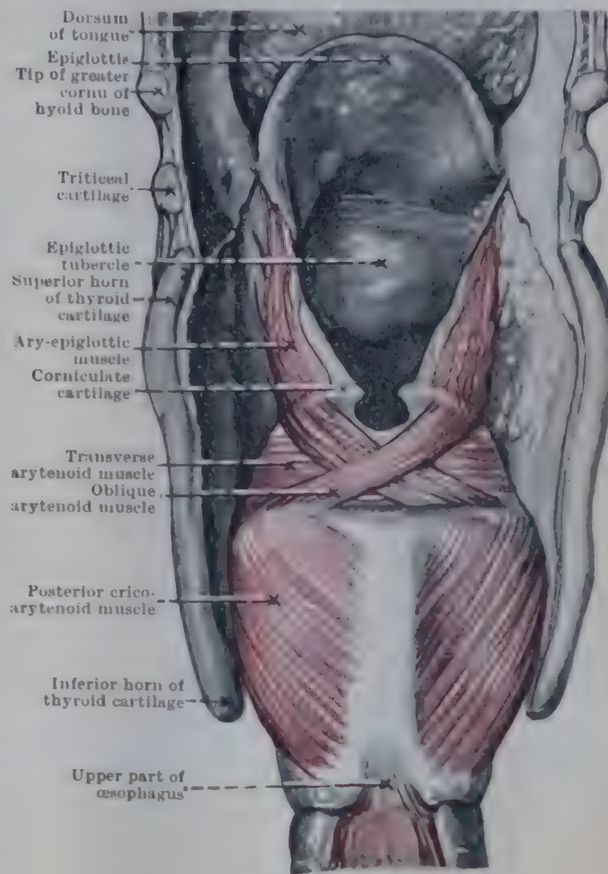

FIG. 588.—MUSCLES ON BACK OF LARYNX.

The thyro-arytenoid muscles narrow the vestibule of the larynx and force the vestibular folds into close contact; thus, they constitute a sphincter of the vestibule.

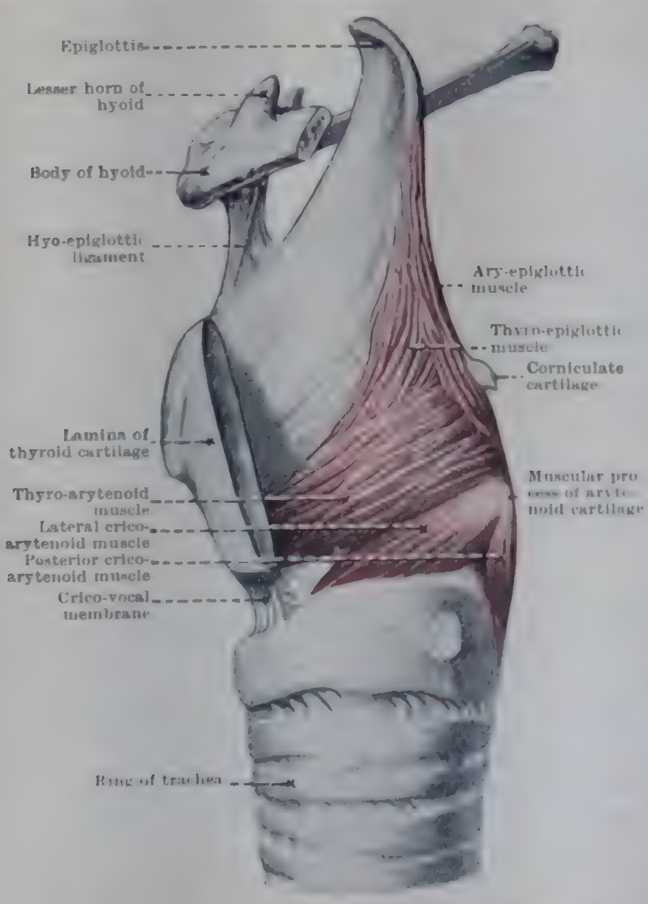

FIG. 589.—MUSCLES OF SIDE-WALL OF LARYNX.

The **vocal muscle** of each side is a triangular, somewhat prismatic muscle which forms a common muscular mass with the thyro-arytenoid. It is closely applied to the lateral aspect of the vocal ligament, and receives its prismatic form from that adaptation.

The vocal muscle **arises** from the inferior part of the angle between the two laminæ of the thyroid cartilage, and also from the corresponding vocal ligament, whence the fibres run backwards to be **inserted** into the lateral aspect of the vocal process and the depression on the antero-lateral surface of the arytenoid cartilage.

The muscle produces and adjusts tension throughout the vocal ligament and, with the assistance of the transverse arytenoid in approximating the vocal fold to its fellow of the opposite side, reduces the rima to a mere chink or even closes it altogether.

Each **posterior crico-arytenoid muscle** arises, by a broad origin, from the medial and inferior parts of the depression on the posterior surface of the lamina of the cricoid cartilage at the side of the median ridge. The fibres converge upwards and laterally to be **inserted** into the muscular process of the corresponding arytenoid cartilage. The highest fibres are short and nearly horizontal; they are inserted into the back of the muscular process. The intermediate fibres are the longest and are very oblique; they are inserted

direction and are inserted into the front of the muscular process in common with the lateral crico-arytenoid.

The posterior crico-arytenoid draws the muscular process of the arytenoid cartilage medially and backwards, swings the vocal process and the vocal fold laterally, and thereby opens the rima glottidis.

Each **lateral crico-arytenoid muscle arises** from the posterior half of the upper border of the arch of the cricoid cartilage, and also from the lateral part of the crico-vocal membrane. The muscle-fibres run backwards and upwards, and converge to be **inserted** into the anterior surface of the muscular process of the arytenoid cartilage. The muscle is commonly inseparable from the thyro-arytenoid muscle.

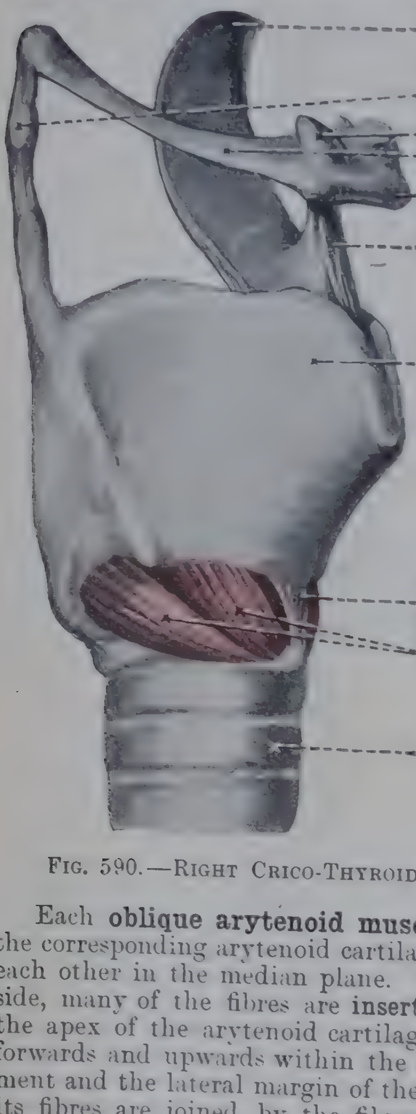

FIG. 590.—RIGHT CRICO-THYROID MUSCLE.

The lateral crico-arytenoid muscle draws the muscular process of the arytenoid cartilage forwards and laterally, turning the vocal process of the same cartilage medially, and approximating it to its fellow of the opposite side, thus assisting in the closure of the rima glottidis.

The **transverse arytenoid muscle** is an unpaired muscle which bridges the interval between the two arytenoid cartilages. The anterior surface of the muscle is in contact with the posterior surfaces of the arytenoid cartilages and, between them, with the mucous membrane of the larynx. Its posterior surface is partly concealed by the oblique arytenoid covered by the mucous membrane of the pharynx. The inferior border extends to the lamina of the cricoid cartilage, and its upper border does not quite reach the apices of the arytenoid cartilages.

The **attachments** of the muscle are to the posterior surface of the muscular process and the lateral edge of the arytenoid cartilage on each side. All the fibres run in a transverse direction, and some turn round the arytenoid cartilage to become continuous with the thyro-arytenoid.

The transverse arytenoid muscle approximates the arytenoid cartilages, thereby tending to close the rima glottidis.

Each **oblique arytenoid muscle arises** from the posterior part of the muscular process of the corresponding arytenoid cartilage. The two muscles proceed upwards and medially, and cross each other in the median plane. Reaching the apex of the arytenoid cartilage of the opposite side, many of the fibres are **inserted** there; others are joined by a fresh slip that arises from the apex of the arytenoid cartilage and forms with it the **ary-epiglottic muscle**, which extends forwards and upwards within the ary-epiglottic fold to terminate in the thyro-epiglottic ligament and the lateral margin of the epiglottic cartilage. As the muscle approaches the epiglottis its fibres are joined by the fibres of the thyro-epiglottic muscle and some fibres from the stylo-pharyngeus also are mingled with those of its upper border.

The oblique arytenoid and ary-epiglottic muscles form the sphincter of the laryngeal inlet.

Each **thyro-epiglottic muscle arises** from the medial surface of the lamina of the thyroid cartilage immediately above the origin of the thyro-arytenoid. The fibres run upwards and backwards to be **inserted** partly into the margin of the ary-epiglottic fold and partly into the lateral margin of the epiglottis, being intermingled with the fibres of the ary-epiglottic muscle.

The thyro-epiglottic muscle is part of the sphincter of the inlet of the larynx.

Growth-Alteration and Sexual Differences in Larynx.—A considerable amount of variation may be noticed in the size of the larynx in different people. It is quite independent of stature, and it explains to a great extent the difference in the pitch of the voice in different persons. But quite apart from those individual variations, there is a sexual difference in the size of the larynx. The larynx of a man is not only absolutely but also relatively larger than the larynx of a woman in all its diameters, more particularly in the antero-posterior diameter. To a large extent the increase is produced by strong development of the laryngeal prominence in men. The greater antero-posterior diameter of the male larynx necessarily implies a greater length of the vocal folds and a lower or deeper tone of the voice in men than in women.

In a new-born child the larynx is relatively large and, in comparison with the calibre of the trachea, very large. The epiglottis varies much in size at birth: it may be large or may be quite diminutive, and it is always soft in texture. The valleculæ and the piriform fossæ are so small as to be almost rudimentary. During the first six years of the child's

life great changes take place. The calibre of the trachea is much increased and the tracheal cartilages are stiffened. The epiglottis also grows considerably and becomes stiffer. The larynx itself grows at a slower rate, so that by the age of six years the calibre of the trachea is almost uniform in size with that of the larynx. As the larynx grows, the vocal folds increase in length and the vocal processes of the arytenoid cartilages become relatively shorter.

From the age of six years (or four years in well-developed children) till adolescence there is little growth in the larynx, but in the male at puberty renewed vigour of growth results in the comparatively large size of the larynx. At the same time the valleculæ and the piriform fossæ greatly increase in size in both sexes.

In a man who has been castrated when young, the larynx attains a size exceeding that of a woman only to a small degree, and the high pitch of the voice is retained.

Observation of Laryngeal Movements

When the cavity of the larynx is illuminated and examined with a laryngoscopic mirror, the parts which surround the inlet of the larynx, as well as the interior of the organ, come into view. Not only that, but when the vocal folds are widely separated it is possible to inspect the interior of the trachea as far as its bifurcation.

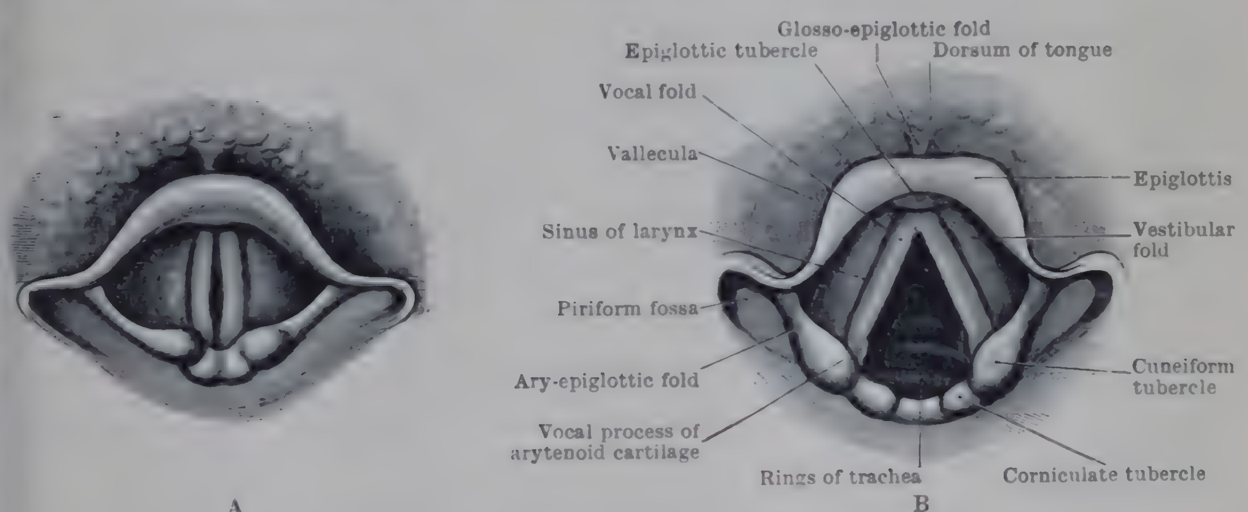

FIG. 591.—CAVITY OF LARYNX SEEN WITH LARYNGOSCOPE.

A. Rima glottidis closed. B. Rima glottidis widely opened.

In such an examination the upper border of the epiglottis is a conspicuous object. Behind this the bulging on the anterior wall of the vestibule, formed by the tubercle of the epiglottis, may also be seen. The glosso-epiglottic fold, with an epiglottic vallecula on each side of it, also is seen in the interval between the epiglottis and the back of the tongue. The ary-epiglottic folds—sharp and sloping – are clearly visible, and in the posterior portion of each can be seen the two prominent tubercles which are formed by the enclosed cuneiform and corniculate cartilages. Posterior to these tubercles is the back-wall of the pharynx; lateral to each fold a piriform fossa is visible. In the interior of the larynx the vestibular and vocal folds are easily recognized, and between them, on each side, the entrance to the laryngeal sinus appears as a dark line on the side-wall of the larynx. The vestibular folds are red and fleshy-looking; the vocal folds during phonation are tightly stretched and pearly white—the white colour being usually more apparent in the female than in the male. The outline and yellowish tinge of the vocal process, at the attachment of the vocal fold, and the outline of the anterior part of the base of the arytenoid cartilage may be seen. The vocal folds during inspiration are seldom at rest. In quiet breathing the lanceolate outline of the rima (Fig. 586, A) is very characteristic, widening during inspiration and narrowing during expiration. In forced or deep inspiration the rima opens widely, presenting a pentagonal outline (Fig. 586, B) and thus permitting the airway to be used to full capacity. It should be borne in mind that the picture afforded by the laryngoscope does not give a true idea of the level at which the different parts lie. The cavity is foreshortened, and its depth appears diminished.

On the X-ray screen the respiratory airway is viewed from the side (Plate LXI, p. 696). In quiet breathing the laryngeal vestibule is fairly widely open, though not dilated as in forced inspiration. The epiglottis and ary-epiglottic folds are conspicuous objects. The arytenoid cartilages with their surmounting corniculate cartilages are obvious, and sometimes the cuneiform cartilages also are visible. In a good soft-tissue radiograph the sinus itself, between vestibular and vocal folds, is clearly evident, and leading to this is the *philtrum* of the sinus, *i.e.*, a groove

pipe, though the form of its upper orifice—the laryngeal inlet—varies to conform to the shape of the laryngeal and oral parts of the pharynx where the vowel-sounds in speaking and singing are produced.

In speaking or singing the airway must be maintained unimpeded. It is in this connection that the epiglottic valleculæ (Pl. LXI, p. 696) become of service, for they act as reservoirs for drooling saliva during inhibition of swallowing movements. When the saliva is mixed with a radio-opaque substance, such as barium sulphate, the overflowing vallecula is observed to lose some of its fluid into the lateral gutter or piriform fossa (Fig. 583, Pl. LXIV, Fig. 1, p. 697), flow being directed thither by the slope of the epiglottis.

In mastication, a bolus of food in its semi-solid stage begins to slip past the shepherding veil of the soft palate and slides down the posterior third of the tongue towards or into the valleculæ. When the food has reached the epiglottis and valleculæ, swallowing can no longer be inhibited. The entire laryngeal vestibule can be seen to close, all air being eliminated as far down as the vocal folds. The orifice of the gullet is drawn upwards, and sometimes the column of the palato-pharyngeus (and possibly stylo-pharyngeus) muscle can be clearly seen producing this raising of the throat, by which action the laryngeal inlet, the epiglottis remaining erect, is drawn upwards to be partially overhung by the posterior third of the tongue. At this stage the soft palate rises to permit free passage of the bolus and to close the pharyngeal isthmus. The bolus then tips itself over the epiglottis. Some barium is observed to slip down the lateral food-gutter and some passes right over the closed laryngeal inlet. If, however, there is an inadvertent relaxation of the sphincter of the inlet, barium at once forms a momentary dark shadow, convex downwards in the upper vestibule; but it never descends past the vestibular folds. It is, indeed, immediately ejected by a convulsive cough.

The swallowing of fluid differs in no essential from the swallowing of solid food.

From these observations certain functions of the laryngeal muscles may be inferred :—

(*a*) For service *in swallowing*, there is evidently a sphincter of the laryngeal inlet (ary-epiglottics, oblique arytenoids) which may, in swallowing, be taken off its guard. At a lower level, there is a second sphincter (thyro-arytenoids) which obliterates the cavity of the vestibule and acts as a second line of defence. It is rare, indeed, for any foreign body to pass both guards; if this happens, bronchoscopic intervention is necessary. Also, in swallowing, the raising of the larynx under shelter of the tongue suggests activity of the thyro-epiglottic muscles. It should be noted that, in swallowing, the epiglottis is pressed against the base of the tongue; it does *not* fall backwards as a lid to the laryngeal inlet (Stuart & McCormick, 1892), notwithstanding a recent revival of this old notion (Johnstone, 1942). Indeed, the greater part of the epiglottis can be removed without any noticeable effect on the individual (Negus, 1929).

(*b*) *In breathing*, the size and shape of the rima glottidis are evidently controlled by the posterior and lateral crico-arytenoids and the transverse arytenoid.

(*c*) *In vocalization*, the crico-arytenoids probably fix the arytenoid cartilages. These act as bases from which the vocal muscles (a part of the thyro-arytenoid) produce the proper tension in the vocal folds, and the crico-thyroids tilt the larynx to conform with the adaptation of pharyngeal form to produce the vowel-sounds. Functional changes in the vocal folds have been examined radiographically by Mitchinson & Yoffey (1948).

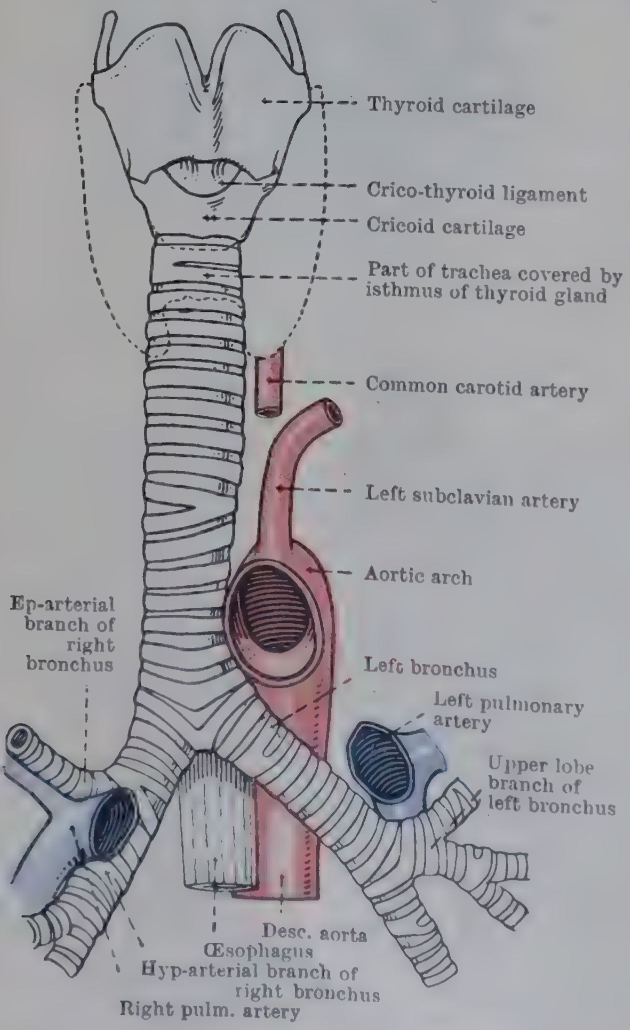

FIG. 592.—TRACHEA AND BRONCHI.
The dotted line gives the outline of the thyroid gland.

TRACHEA

The **trachea** or **windpipe** is kept patent by a series of 16 to 20 **C**-shaped cartilaginous bars embedded in its wall. Behind, where the bars are deficient, the tracheal wall is flattened. In the young child the cartilaginous bars are soft and readily compressible, so that they are felt through the skin with difficulty—a point which must be remembered in tracheotomy. The trachea begins at the lower border of the cricoid

cartilage, opposite the lower border of the body of the sixth cervical vertebra. From here it descends through the neck and the superior mediastinum of the thorax, and it ends, at the level of the upper border of the body of the fifth thoracic vertebra, opposite the sternal angle, by dividing into right and left bronchi. The length of the trachea in men is approximately four and a half inches (11-12 cm.), and in women half an inch less (10 cm.), but its length varies with the movements of the head and neck.

The bifurcation of the trachea is not fixed in position and neither are the roots of the lungs, but they undergo a downward shift during inspiration, as was demonstrated by Macklin (1932). Further, on changing from the recumbent to the upright posture the bifurcation commonly sinks to the level of the body of the sixth thoracic vertebra and it may go lower. In this it shares in the general lowering of the heart and other viscera caused by gravitational pull (Lachman, 1946).

About the middle of its length the trachea exhibits a slight expansion or dilatation, and close to the bifurcation it is again slightly expanded.

The differences in the calibre of the trachea are determined by the surrounding structures. The cervical part is narrowed owing to its being clasped by the thyroid gland, to which in goitre it becomes bound by a rather dense fascia—an attachment which maintains its patency when the cartilaginous bars have become locally absorbed. After operation there is danger of suffocation through collapse of the weak-walled "scabbard" trachea. On the left side of the trachea, near the bifurcation, there is an impression, sometimes strongly marked, due to contact with the aortic arch; on the right side, about its mid-length, there may be an impression for the innominate artery. In the dead subject the lumen of the tube is considerably greater than in the living. (For measurements of the trachea, see p. 704).

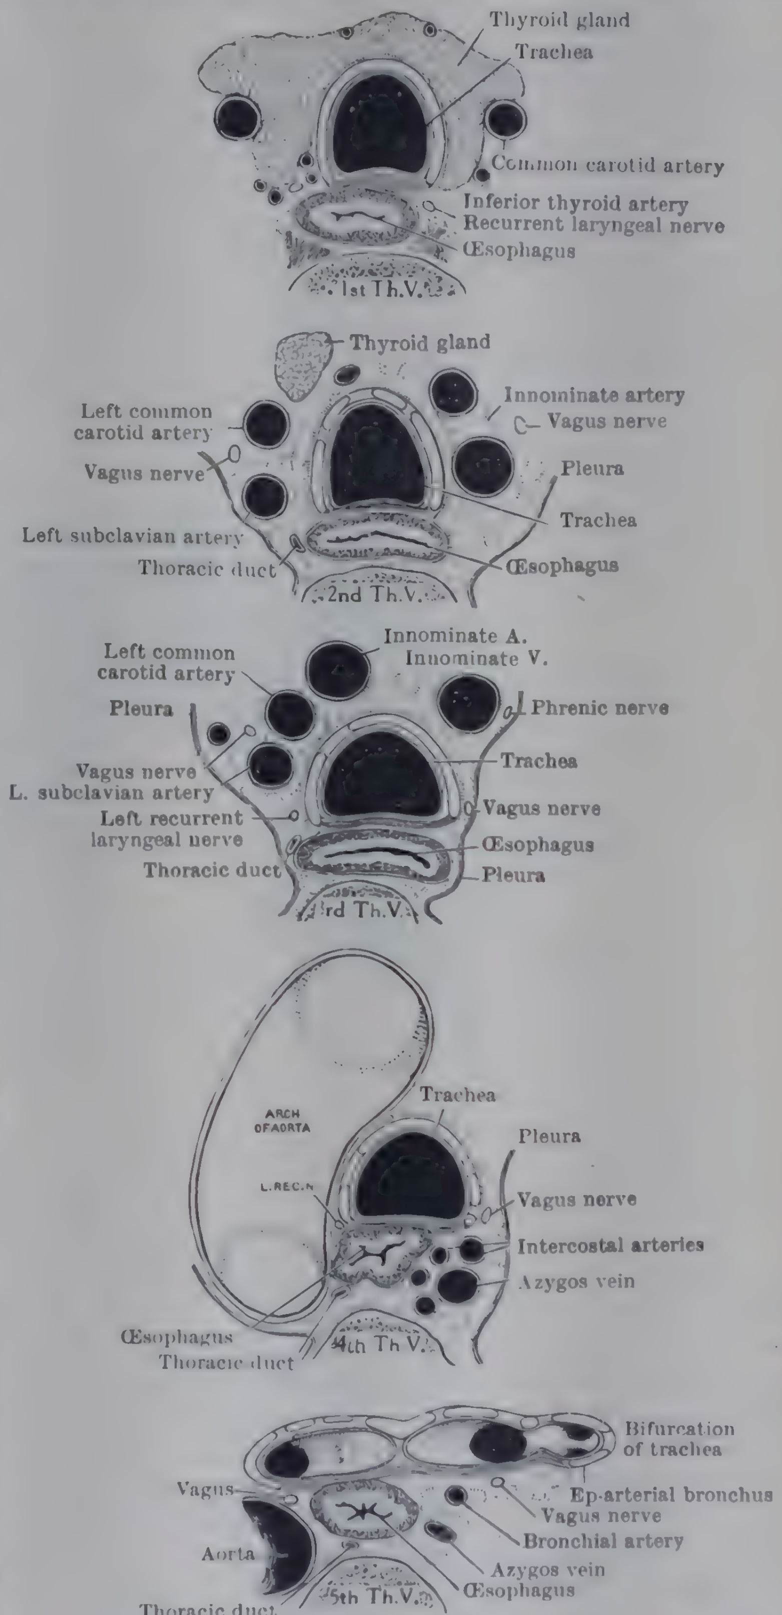

Fig. 593.—Transverse Sections through Trachea and Neighbouring Structures at Levels of Upper Five Thoracic Vertebræ. See also Fig. 509, p. 594.

recedes rapidly from the surface. This is due to its following the curvature of the vertebral column, from which it is separated by the œsophagus.

Relations of Trachea.—The **cervical part** of the trachea measures from 2 to $2\frac{1}{2}$ inches in length when the chin is held so that the face looks directly forwards, but its length is considerably increased when the head is thrown backwards. The thyroid gland clasps this portion of the trachea, the anterior surface of the second, third, and fourth rings being covered by the isthmus, and each side of the trachea as low as the fifth or sixth ring being covered by the lobe of the gland. On each side of the cervical part of the trachea lies the common carotid artery. The recurrent laryngeal nerve passes upwards in the groove between the trachea and the œsophagus. The trachea is separated from the bodies of the vertebræ by the œsophagus, which deviates slightly to the left as it passes downwards.

Overlying the isthmus of the thyroid gland there are two thin muscular strata composed of the sterno-hyoid and sterno-thyroid muscles, as well as the deep

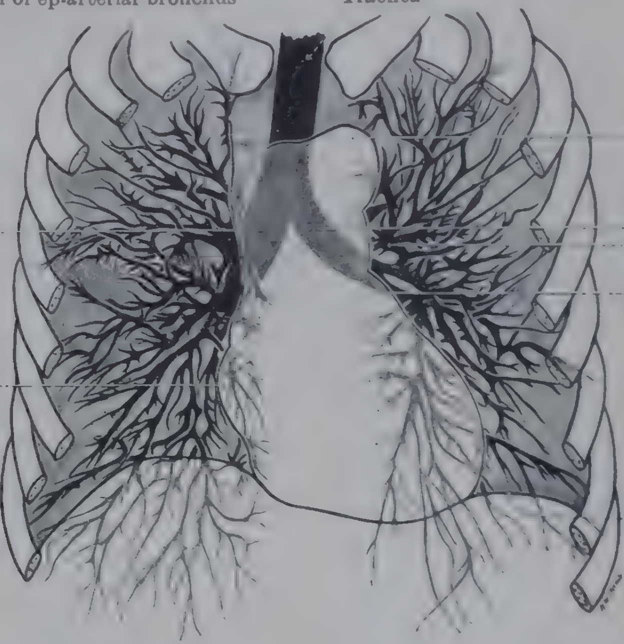

FIG. 594.—TRACING FROM RADIOGRAPH OF CHEST IN FULL INSPIRATION.

and superficial fasciæ and the skin. In the median plane of the neck, between the approximated margins of these muscles, there is a narrow diamond-shaped space within which the trachea is covered merely by the fasciæ and skin. It is important to note that in the lower part of the neck the deep cervical fascia is composed of two layers—a strong stratum applied to the anterior surface of the sterno-hyoid and sterno-thyroid muscles, and a weaker superficial layer stretching across between the two sterno-mastoid muscles. Deep to these muscular and fascial layers the inferior thyroid veins pass downwards and the inconstant thyroidea ima artery passes upwards on the anterior surface of the trachea. At the level of the upper border of the manubrium sterni the innominate artery crosses the trachea obliquely.

The **thoracic part** of the trachea is situated in the hinder part of the superior mediastinum and is separated from the bodies of the vertebræ by the œsophagus. On the anterior and lateral aspects of the trachea immediately above its bifurcation lies the deep cardiac plexus of nerves. At the level of the fourth thoracic vertebra the arch of the aorta clings first to the front of the trachea and then to its left side. The three great branches that spring from the arch ascend in contact with the trachea. Thus, the innominate and the left common carotid arteries lie at first on the front of the trachea, and then, gradually diverging as they proceed upwards, come to lie on its right and left sides respectively. In front of these arteries are the left innominate vein and the remains of the thymus. On the right side, the trachea has the right vagus descending obliquely backwards in contact with it, the azygos vein crossing it at the bifurcation, and the right mediastinal

pleura covering it. On the left side it is separated from the left mediastinal pleura by the arch of the aorta and the left subclavian artery, and the left recurrent laryngeal nerve ascends in the angle between it and the œsophagus.

Structure of Trachea.—The walls of the trachea and extrapulmonary bronchi consist of three not very distinct layers, named from within outwards (1) the mucous coat, (2) the submucous coat, and (3) the supporting coat.

The **mucous coat** is lined with a thick pseudo-stratified columnar *ciliated epithelium* which contains numerous mucus-secreting goblet-cells and rests upon a thick *basement membrane*. The cilia produce an upward movement of the mucus. This basement membrane separates the epithelium from a fibro-elastic *tunica propria*, which contains varying amounts of lymphoid tissue. The elastic fibres of the tunica propria form a dense network in which most of the fibres run longitudinally, and it is these longitudinal fibres that chiefly bring about the recoil of the trachea when stretched (Macklin, 1922). Although the elastic fibres permeate the whole tunica propria, they tend to be concentrated in its outer part and to separate it from the submucous coat.

The **submucous coat** is a fibro-elastic tube that contains numerous tubulo-acinous

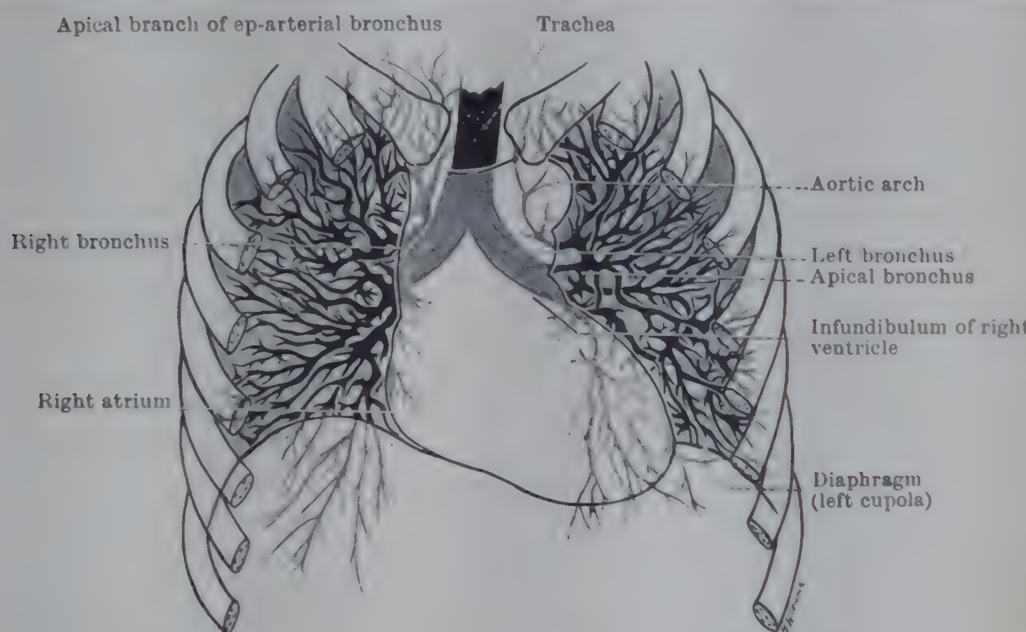

FIG. 595.—TRACING FROM RADIOGRAPH OF CHEST IN FULL EXPIRATION.

glands—both mucous and serous. The glands congregate in the intervals between the tracheal cartilages and also posteriorly; their ducts pass through the tunica propria and open on to the epithelial surface. The elastic fibres of this coat are rather scanty.

The **supporting coat**, though containing a fine network of elastic fibres, is dense and mainly composed of white collagenous fibres. It forms a complete tube which is continuous above with the perichondrium that invests the cricoid cartilage. Embedded in its substance are from 16 to 20 **C**-shaped rings of hyaline cartilage, open posteriorly where applied to the œsophagus and having rounded ends. These *tracheal cartilages* or rings prevent the trachea from collapsing during inspiration. It is common for a ring to branch and perhaps to join an adjacent ring. The coutour of a tracheal ring on cross-section is straight externally and convex internally—the opposite of a wedding-ring—hence each ring bulges slightly into the lumen of the trachea. The intervals between adjacent rings are narrower than the rings themselves. The lowest tracheal cartilage inclines downwards in the median plane in front, and from this median peak a cartilaginous strip is carried backwards in the fork between the two bronchi, forming a ridge called the *carina*. Bands of *plain muscle*, which mostly run transversely internal to the supporting coat, are attached to the inner surface of the tracheal cartilages near their free-ends. Many tubulo-acinous glands grow backwards beyond the submucous coat and come to lie between the muscle-fibres and external to them.

Vessels and Nerves.—The **arteries** of the trachea come chiefly from the *inferior thyroid* but also from the superior thyroid, internal mammary, and bronchial. Its **veins** end mainly in the *inferior thyroid* veins. Its **lymph-vessels** end in the *tracheo-bronchial* and *paratracheal* glands and also in the pretracheal, prelaryngeal, and lower deep cervical glands. Its nerves are the vagi directly and via their recurrent laryngeal branches, and

Measurements of Trachea.—The trachea is 4·0 cm. long at birth; 4·5 cm. between the firs[t] and second years; 5·7 cm. between the sixth and eighth years; 7·2 cm. between the fourteent[h] and sixteenth years; and from 9·0 to 15·0 cm. in the adult. Hence, from birth, through puberty to adult life it increases roughly from 4, through 6, to 12 cm. The sagittal and coronal diameter[s] of the trachea are: 5·7 × 6·0 mm. at birth; 9·4 × 8·8 mm. between the first and second years 10·4 × 11·0 mm. between the sixth and eighth years; 10·7 × 13·5 mm. between the fourteent[h] and sixteenth years; and 16·5 × 14·4 mm. in the adult. Hence, in general, the coronal diamete[r] is greater than the sagittal until adult life.

Until the third or fourth year the cross-sectional area of the trachea is equal to that of th[e] two main bronchi; but from then until the tenth year the bronchi have slightly the larger area after puberty the ratio continues to increase; and in the adult the sectional area of the tw[o] main bronchi is 40 per cent greater than that of the trachea (Engel, 1947).

BRONCHI

The two main or primary **bronchi** proceed obliquely infero-laterally from the bifurcation of the trachea, each towards the hilum of the corresponding lung. Like the trachea, they are kept permanently patent by the C-shaped cartilages in their walls. The two bronchi differ from each other in length, in width, and in direction (Figs. 592, 594, 606).

The first collateral branch of the right bronchus (the upper lobe bronchus) arises 1 inch or more from the trachea; whereas that of the left bronchus arises 2 inches or less from the trachea. There are from six to eight cartilages in the right bronchus and from nine to twelve in the left. The right bronchus is wider than the left in the proportion of 100 to 78·4, and it takes a more vertical course. It therefore lies more in the line of the trachea: and to this, as well as to its greater width, is due the greater tendency of foreign bodies to lodge in the right bronchus. The average angle formed by the right bronchus with the median plane is 24·8°, whereas the average angle formed by the left bronchus is 45·6°. The more horizontal course of the left bronchus is probably determined by the bulging of the heart to the left side of the median plane.

Relations of the Bronchi.—A cluster of tracheo-bronchial lymph-glands occupies the angle between the bronchi, and along each bronchus an irregular chain of glands is carried to the hilum of the lung. On the posterior surface of each bronchus the vagus nerve breaks up into the posterior pulmonary plexus. Arching above the right bronchus, from behind forwards, is the vena azygos; whilst arching above the left bronchus, from before backwards, is the arch of the aorta. In its course laterally and downwards the left bronchus crosses the anterior surfaces of the œsophagus and descending thoracic aorta. The left pulmonary artery crosses in front of the left bronchus above its first collateral branch and, after turning round its lateral side, runs along its posterior surface (Fig. 606). All branches of the left bronchus, therefore, lie below the left pulmonary artery and may, in consequence, be termed **hyp-arterial**. The right pulmonary artery, on the contrary, crosses in front of the stem of the right bronchus below its first collateral branch. This branch may, therefore, be termed the **ep-arterial bronchus**, but all the others are classified as hyp-arterial.

Structure of Extrapulmonary Bronchi.—This is identical with the structure of the trachea.

Vessels and Nerves.—The **arteries** are the bronchial arteries (p. 720). The **bronchial veins** end in the azygos and upper hemiazygos veins. The **lymph-vessels** end in the broncho-pulmonary, tracheo-bronchial, and paratracheal glands. The **nerves** come from the vagus and sympathetic via the pulmonary plexuses.

Radiographic Examination of Bronchi (see p. 721, Pls. LXII, LXIII, p. 696 and Figs. 59[4] and 595).

THORACIC CAVITY

The **cavity of the thorax** is the space above the diaphragm enclosed by the ribs. It contains (*a*) the two lungs, each in its pleural coverings, and (*b*) a thick, median mass of tissue, called the *mediastinum*, interposed as a septum between the lungs and containing the heart. The **thoracic inlet** is the kidney-shaped space bounded by the first thoracic vertebra behind, the manubrium in front, and the first ribs and their cartilages at the sides (Fig. 597). The **thoracic outlet**, closed by the diaphragm, is bounded by the last thoracic vertebra behind, the xiphi-sternal junction in front, and the twelfth ribs and the last six costal cartilages at the sides (p. 147).

PLATE LXV

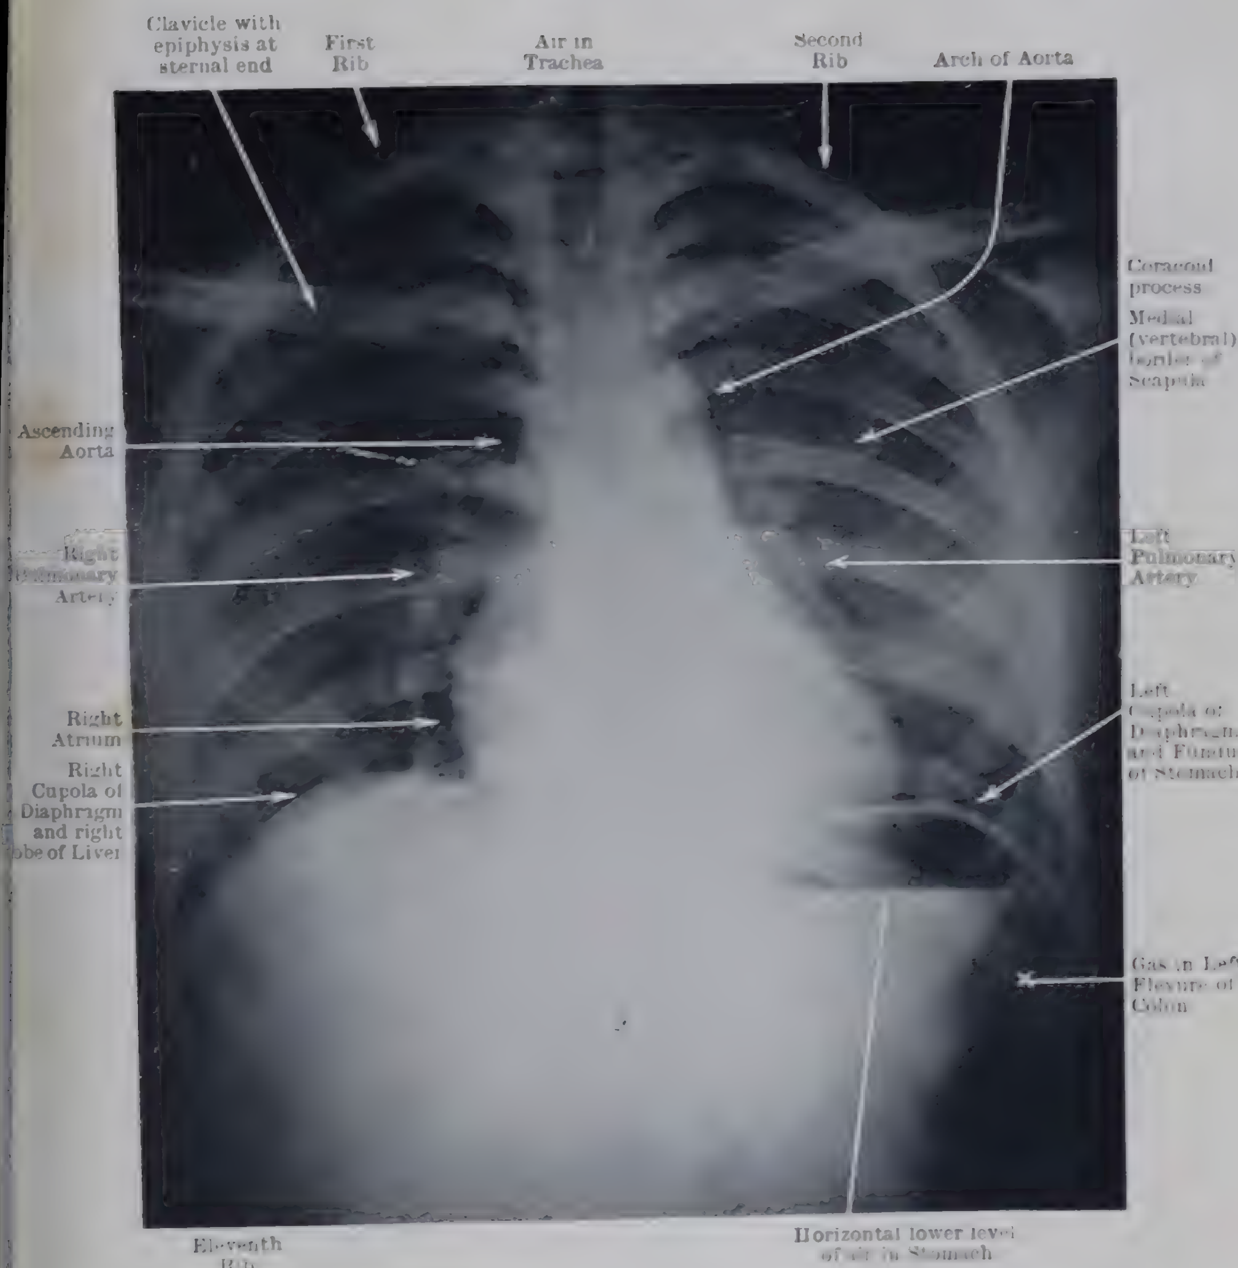

PLATE LXV.—ANTERIOR RADIOGRAPH OF THORAX OF YOUTH AGED 18, IN POSITION OF SEMI-INSPIRATION.

Compare with Plates LXVI, (inspiration) and LXVII, p. 720 (expiration), noting the differences in level of the Diaphragm and in the shape of the Heart. Cf. also Plates LXII, p. 696 and LXVIII, Fig 1, p. 721.

PLATE LXVI

PLATE LXVI.—ANTERIOR RADIOGRAPH OF THORAX OF YOUNG MAN IN POSITION OF FULL INSPIRATION.

Compare with Plate LXVII, p. 720, noting the descent of the Diaphragm, the narrowing and better definition of the whole mediastinal shadow (including the Heart) and the more horizontal position of the Ribs.

The dimensions of the thoracic cavity depend upon the phase of respiration in which they are measured (pp. 354, 454).

MEDIASTINUM

The **mediastinum** is a thick mass of tissue that forms a septum between the lungs and extends from the vertebral column to the sternum. It contains:—the heart enveloped in its pericardium; the thoracic aorta with the great vessels that spring from its arch; the pulmonary trunk; the great veins in the neighbourhood of the heart; the thymus or its remains together with lymph-glands and lymph-vessels; the trachea, œsophagus, and thoracic duct; the vagi, left recurrent laryngeal, cardiac, and phrenic nerves. Owing to the bulging of the heart to the left side and to the position of the thoracic aorta on the left of the median plane, the mediastinum encroaches on that side and the left lung is reduced in width. It is customary to divide the mass of tissue arbitrarily into four parts, termed the superior, anterior, middle, and posterior mediastina, according to their relations to the pericardium.

The **superior mediastinum** is that part which lies above the pericardium. Its boundaries are as follows:—*Anteriorly*, the manubrium sterni, with the attached sterno-hyoid and sterno-thyroid muscles; *posteriorly*, the bodies of the first four thoracic vertebræ; *below*, an imaginary plane which extends from the disc between fourth and fifth thoracic vertebræ to the manubrio-sternal joint; *laterally*, the mediastinal pleura.

The superior mediastinum is crossed by strands of fibrous tissue which bind the manubrium loosely to the pericardium over the roots of the great vessels. This fibrous tissue, termed the *superior sterno-pericardial ligament*, has significance only in persons afflicted with an adherent pericardium (Pick's disease).

The structures in the superior mediastinum are: (1) the aortic arch and the three great arteries that spring from it; (2) the innominate veins and part of the superior vena cava; (3) the trachea, œsophagus, and thoracic duct; (4) the phrenic, vagus, and cardiac nerves, and the left recurrent laryngeal nerve; (5) the thymus or its remains.

The **middle mediastinum** lodges the pericardium and its contents, and also the phrenic nerves with their accompanying vessels which lie outside the pericardium.

The **anterior mediastinum** consists of fibro-areolar tissue between the pericardium and the body of the sternum. It is invaded by the pleural sacs which approach each other on the anterior aspect of the pericardium. In the anterior mediastinum there are a few lymph-glands, some lymph-vessels, and minute twigs from the internal mammary artery. Like the superior mediastinum, it is crossed by fibrous strands which loosely bind the upper end of the xiphoid process to the pericardium. This fibrous tissue is the *inferior sterno-pericardial ligament*—significant only in adherent pericardium.

The **posterior mediastinum** is situated behind the pericardium and the diaphragm. It is a downward prolongation of the hinder part of the superior mediastinum, and many of the structures in the one are continued into the other. It is bounded *anteriorly* by the pericardium and the vertical part of the diaphragm; *posteriorly*, by the bodies of the last eight thoracic vertebræ; and *laterally*, by the mediastinal pleura. It contains the descending thoracic aorta, the posterior intercostal arteries, the azygos and hemiazygos veins, the thoracic duct, and the œsophagus with the two vagi.

Varying and Variable Positions of Mediastinal Viscera.—*In the cadaver* lying on its back in the dissecting room, the thorax is in the position of full expiration, the diaphragm being relaxed is pushed cranially and dorsally by the weight of the abdominal viscera and is pulled in the same directions by the elastic recoil of the lungs. The large arteries of the mediastinum are decreased in length and calibre due to the absence of the dilating force of the blood-pressure. *In life*, however, the positions of the mediastinal viscera as revealed by X-rays, vary with the position of the diaphragm, with the body-build, and with age. Thus, the diaphragm descends during inspiration and the pericardial sac, being attached to it, descends too, taking

with it the heart and the aortic arch, and the bifurcation of the trachea descends also. On changing from the supine to the erect posture there is a similar sequence of descents due to gravitational pull. On the other hand, if the abdominal muscles are in contraction or if the abdomen is distended (*e.g.*, due to a full gastro-intestinal canal, a large liver, or pregnancy) the diaphragm will stand high. Those whose body-build is of the tall, thin, slender type have a low diaphragm; whereas, those who are short, stout, and stocky have a high one. With increasing age the viscera tend to sink lower (Lachman, 1946).

When the living subject stands erect, leans forward, or lies prone, his heart lies close behind the sternum and costal cartilages. The anterior mediastinum is accordingly reduced and the posterior mediastinum increased in the antero-posterior plane, the œsophagus is withdrawn from the vertebral column and the retro-œsophageal pleural recesses (p. 709) are opened. When the subject reclines or is recumbent, his heart recedes from the anterior chest-wall and, in consequence, the anterior mediastinum is increased while the posterior mediastinum is reduced in the antero-posterior plane and the œsophagus is applied to the vertebral column.

For other variations in the shape and position of the heart see page 1240.

PLEURÆ

Each lateral portion of the thoracic cavity is lined with a membrane, called the **pleura**, which extends over costo-sternal, diaphragmatic, and mediastinal surfaces, thereby forming a closed bag or sac around the *pleural cavity.* The lung in embryonic life buds off from the alimentary tract and, as it grows, pushes before it a portion of the mediastinal pleura, which is thus invaginated into the potential pleural cavity and becomes the *visceral* or *pulmonary pleura* in contradistinction to the *parietal pleura*, which lines the bounding walls.

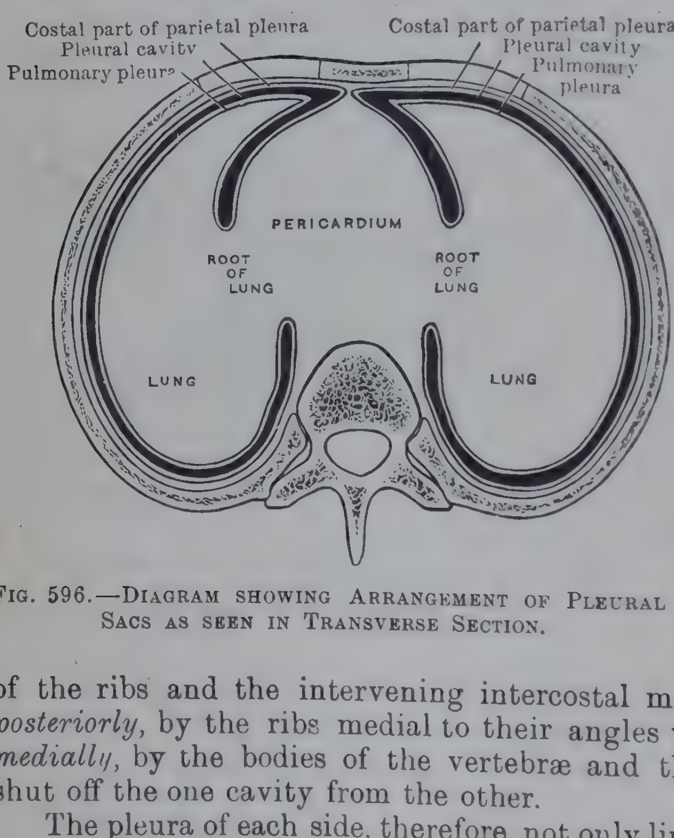

FIG. 596.—DIAGRAM SHOWING ARRANGEMENT OF PLEURAL SACS AS SEEN IN TRANSVERSE SECTION.

Each **pleural cavity** is bounded *inferiorly* by the corresponding cupola of the diaphragm; and as the right cupola rises to a higher level than the left, the right pleural cavity is less deep vertically than the left. *Anteriorly* the wall of each cavity is formed by the costal cartilages and the sternum; *laterally*, by the shafts of the ribs and the intervening intercostal muscles as far as the costal angles; *posteriorly*, by the ribs medial to their angles with the intervening muscles, and *medially*, by the bodies of the vertebræ and the mediastinum, which completely shut off the one cavity from the other.

The pleura of each side, therefore, not only lines the corresponding pleural cavity, but, at the pulmonary root, is prolonged on to the lung so as to give it a complete investment. The inner surface of the pleura (*i.e.*, the free surface facing the pleural cavity) is coated with squamous mesothelium and presents a smooth, glistening, and polished appearance; further, it is moistened with a small amount of serous fluid. In consequence of this, the surface of the lung covered with pulmonary pleura can glide on the wall of the cavity, lined as it is with parietal pleura, with a minimum of friction. In the pathological condition known as pleurisy the inner surface of the pleura is roughened with inflammatory exudate, and "friction sounds" are heard when the ear is applied to the chest.

The **pulmonary pleura** is comparatively thick in man. It lines the fissures of the lungs and thus completely separates the different lobes of the lungs from

one another. A tube or sleeve of pleura connects the pulmonary pleura with the mediastinal pleura. The upper two-thirds of this sleeve envelop the root of the lung; the lower third, with its walls in apposition, forms the pulmonary ligament (Figs. 602, 603).

The **parietal pleura** lines the wall of the cavity in which the lung lies, and is appropriately divided into cervical, costal, diaphragmatic, and mediastinal portions.

The **cervical pleura** (Fig. 597) rises into the root of the neck, through the inlet of the thorax, and forms a dome-shaped roof for the pleural cavity. Its highest point or summit reaches the level of the neck of the first rib; but, owing to the great obliquity of the first costal arch, this point is from one to two inches above its anterior extremity, and from a half to one and a half inches above the medial third of the clavicle. The cervical pleura is protected on the lateral side by the scalenus anterior and scalenus medius muscles, whilst the subclavian artery, arching laterally, lies in a groove on its medial and anterior aspects a short distance below its summit. At a lower level the innominate vein also lies upon its medial and anterior aspects.

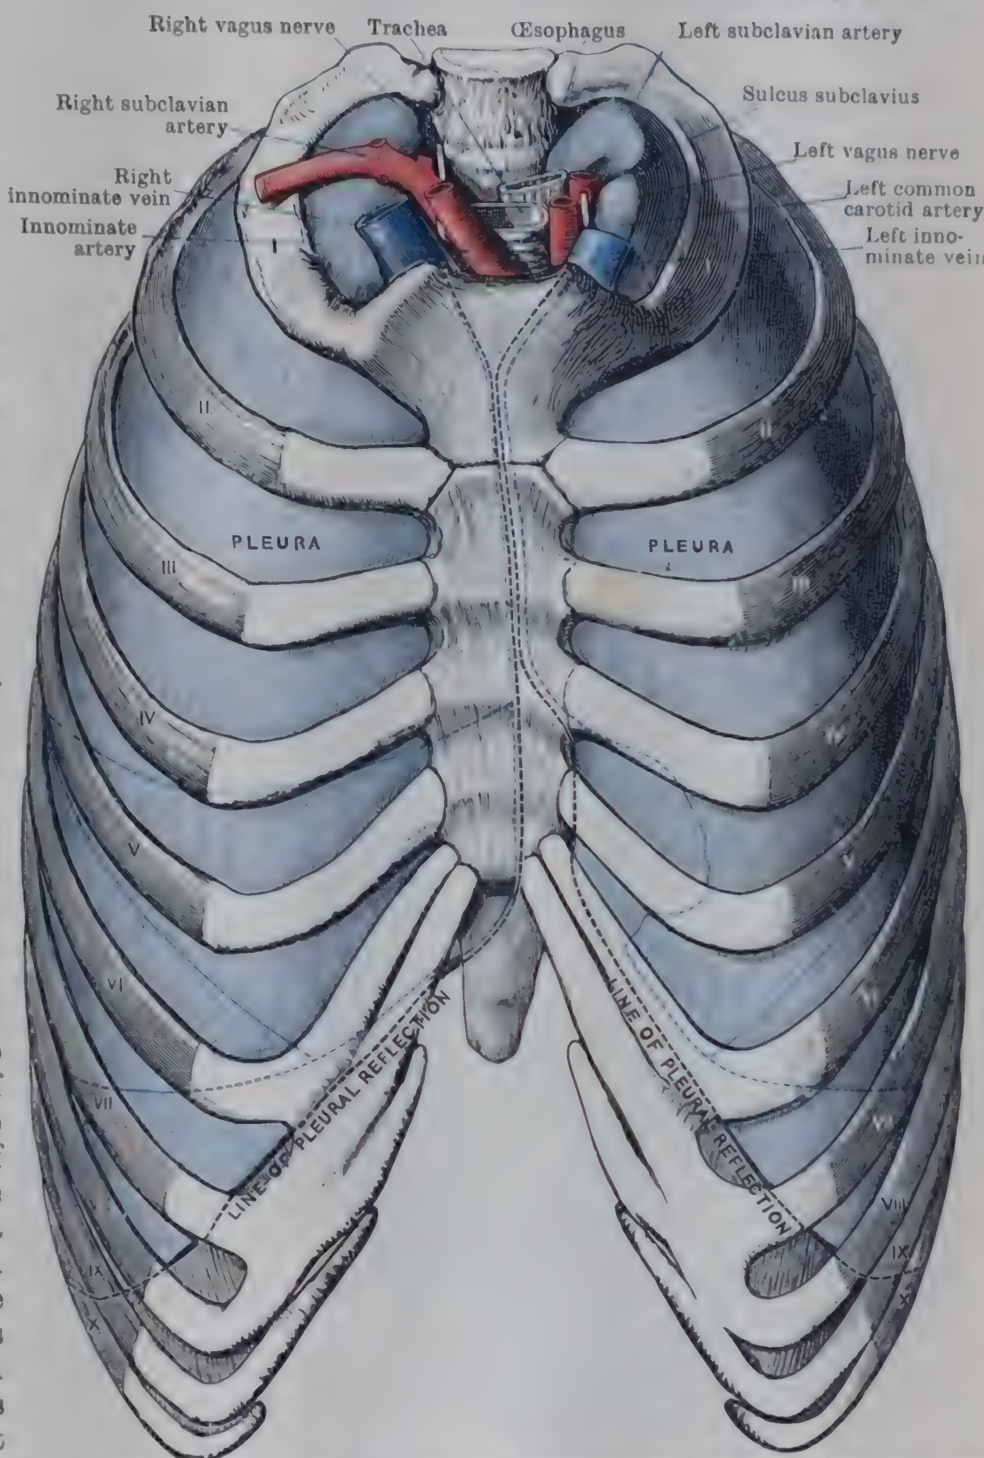

FIG. 597.—PLEURAL SACS IN SUBJECT HARDENED BY FORMALIN INJECTION, TO SHOW THEIR RELATIONS TO THORACIC WALL AND INLET. The anterior and diaphragmatic lines of pleural reflexion are exhibited by black dotted lines, whilst the outlines of the lungs and their fissures are indicated by the blue lines.

The cervical pleura is strengthened by the suprapleural membrane (Sibson's fascia)—an aponeurotic expansion attached to the inner margin of the first rib and derived from a small muscular slip (scalenus pleuralis) that arises from the transverse process of the seventh cervical vertebra.

The **costal pleura** is the strongest and thickest part of the parietal pleura. It lines the inner surfaces of the costal arches (*i.e.*, ribs and their costal cartilages) and

of the intervening muscles. In front it reaches the sternum, whilst behind it passes from the ribs over the sides of the bodies of the vertebræ. It is easily detached from the parts that it lines, except as it passes from the heads of the ribs on to the vertebral column. There, it is rather tightly bound down.

The **diaphragmatic pleura** covers the portion of the thoracic surface of the diaphragm that lies lateral to the base of the pericardium, but it does not dip down to the bottom of the narrow interval between the thoracic wall and the diaphragm. In other words, a strip of the thoracic surface of the diaphragm adjoining its costal attachment is free (Fig. 599).

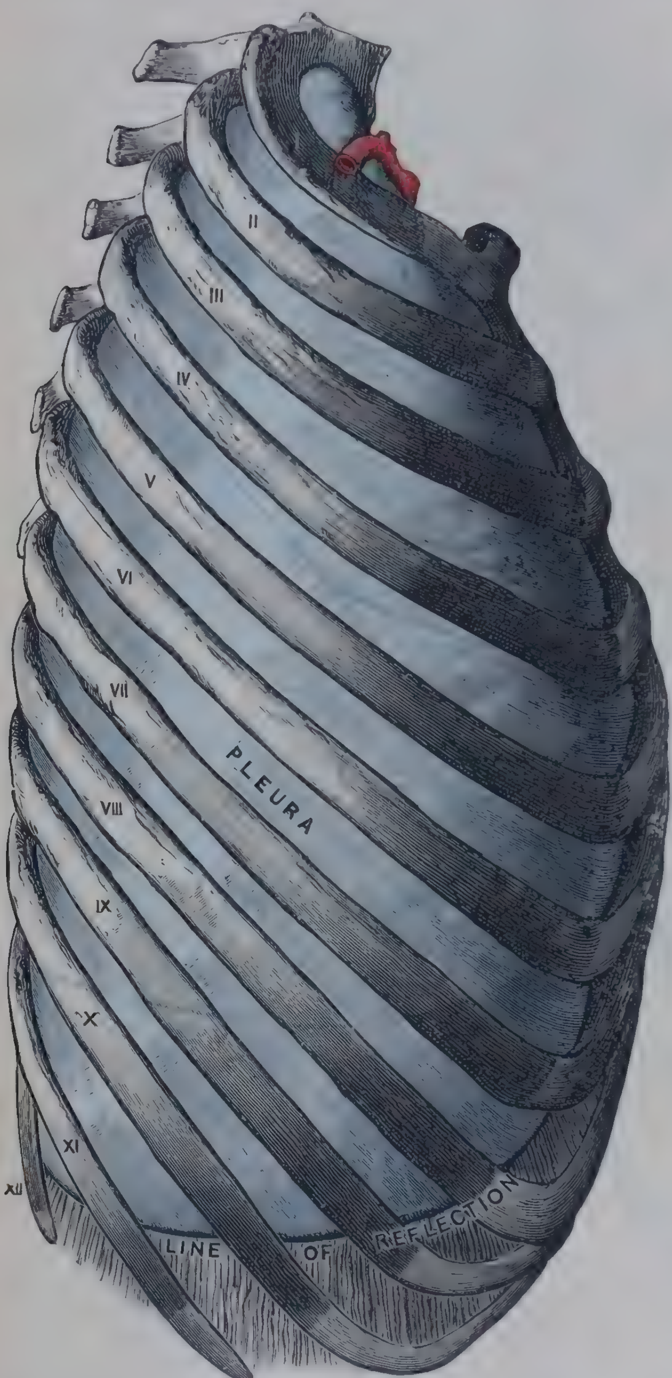

FIG. 598.—LATERAL VIEW OF RIGHT PLEURAL SAC IN SUBJECT HARDENED BY FORMALIN INJECTION. The blue lines indicate the outline of the right lung, and also the position of its fissures.

The **mediastinal pleura** covers the lateral face of the mediastinum and the structures contained in it. It is continuous with the pulmonary pleura around the root of the lung (Figs. 596, 602). It is continuous with the costal pleura both anteriorly and posteriorly—anteriorly, along the abrupt **line of sternal reflexion**; posteriorly, along the bodies of the thoracic vertebræ. Although posteriorly there is no sharp delimitation of mediastinal from costal pleura, the indefinite junction of the two is called the **vertebral line of pleural reflexion** (Fig. 596). Inferiorly the mediastinal pleura is continuous with the diaphragmatic pleura at the base of the pericardium.

Above the root of the lung the mediastinal pleura passes directly from the sternum to the vertebral column. In this region the *left mediastinal pleura* is applied to the arch of the aorta and the left phrenic and vagus nerves; to the left superior intercostal vein and the left common carotid and left subclavian arteries; to the œsophagus and the thoracic duct. The *right mediastinal pleura* is applied, above the root of the lung, to the upper part of the superior vena cava, to the lower part of the right innominate vein and the end of the left; to the innominate artery; to the vena azygos as it hooks forwards above the bronchus; to the right vagus and phrenic nerves; and to the right side of the trachea.

Below and in front of the root of the lung the mediastinal pleura covers the pericardium (pericardial pleura) and is rather firmly attached to it. As the phrenic nerve descends along the side of the pericardium, it also is covered with pleura. As already stated, the mediastinal pleura gives an investment to the root of the lung and becomes continuous with the pulmonary pleura.

The two layers of pleura that invest the root of the lung come into

apposition with each other below the root, and are prolonged downwards as a fold termed the **pulmonary ligament**. This fold stretches from the pericardium to the inferior part of the mediastinal surface of the lung, and ends inferiorly in a free border. Lymph-vessels from the pleura of the lower lobe pass between the layers of this fold to reach the posterior mediastinal lymph-glands.

Behind the root of the lung and the pulmonary ligament the mediastinal pleura on the *right side* passes over the œsophagus to clothe, in part, the anterior aspect of the vertebral bodies, whilst on the *left side* it passes over the descending aorta in order to gain the left side of the vertebral bodies, and just above the diaphragm it covers the left side of the œsophagus. At this level, then, the œsophagus is covered on both sides with a layer of pleura, and the two layers meet between the œsophagus and the aorta to form a thin partition between the right and left pleural cavities. This partition, formed by the meeting of the right and left pleurae behind the œsophagus, commonly extends upwards to the level of the fourth thoracic vertebra. In consequence, there are commonly right and left *retro-œsophageal pleural recesses*, occupied by lung. These are demonstrable by X-rays, particularly during inspiration and with the subject erect, for the recesses deepen then. The right recess may cross the median plane (Lachman, 1946).

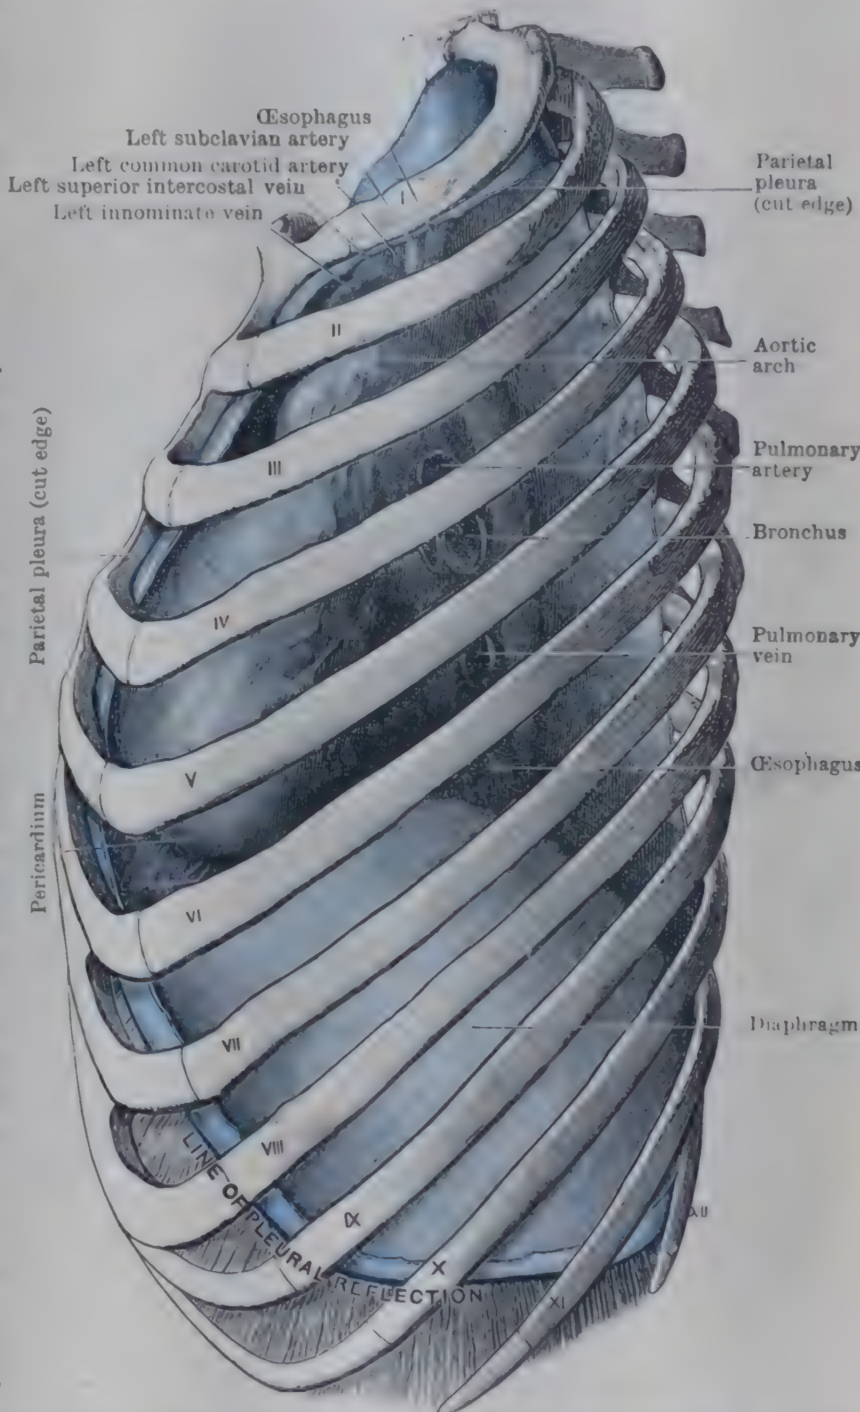

FIG. 599.—LEFT PLEURAL SAC IN SUBJECT HARDENED BY FORMALIN INJECTION. The sac has been opened by the removal of the costal part of the parietal pleura; and the lung also has been removed to display the mediastinal pleura.

Lines of Pleural Reflexion.—The pleural cavities are not symmetrical. The left is narrower than the right, and it thus happens that the lines of pleural reflexion do not accurately correspond on the two sides of the body. The vagueness of the vertebral line of reflexion has been mentioned (p. 708). The sternal and diaphragmatic reflexion-lines are subject to variations in different subjects.

In the vicinity of the manubrium sterni the two pleural sacs are separated from each other by an angular interval. The lines of reflexion at the inlet of the thorax pass behind the sterno-clavicular joints. From these points the lines, as they are traced downwards, converge behind the manubrium, until at last they meet a short distance above its inferior

border. There the two sacs come into contact with each other, and the lines of reflexion coincide. Thence they proceed downwards, on the back of the body of the sternum, with a slight deviation to the left of the median plane, until a point immediately above the level of the sternal attachments of the fourth costal cartilages is reached, and there the two sacs part company. The line of reflexion of the *right pleura* is continued downwards in a straight line to, or just above, the xiphoid process, where the sternal reflexion-line passes into the right diaphragmatic reflexion-line. Opposite the sternal attachment of the fourth costal cartilage, the reflexion-line of the *left pleura*, parting from the right reflexion-line, inclines infero-laterally to a point situated 11 mm. lateral to the sternal end of the 6th intercostal space, and there passes into the left diaphragmatic reflexion-line. In this descent the reflexion-line passes 6 mm. medial to the sternal margin at the level of the 4th intercostal space and 2 mm. lateral to the sternal margin at the level of the 5th intercostal space. The foregoing are average positions: thus, 70 per cent of 95 cases were found to lie within 1 cm. of this line, and the total range of the position of the line at the levels of the 5th and 6th interspaces is 5 cm. (Woodburne, 1947).

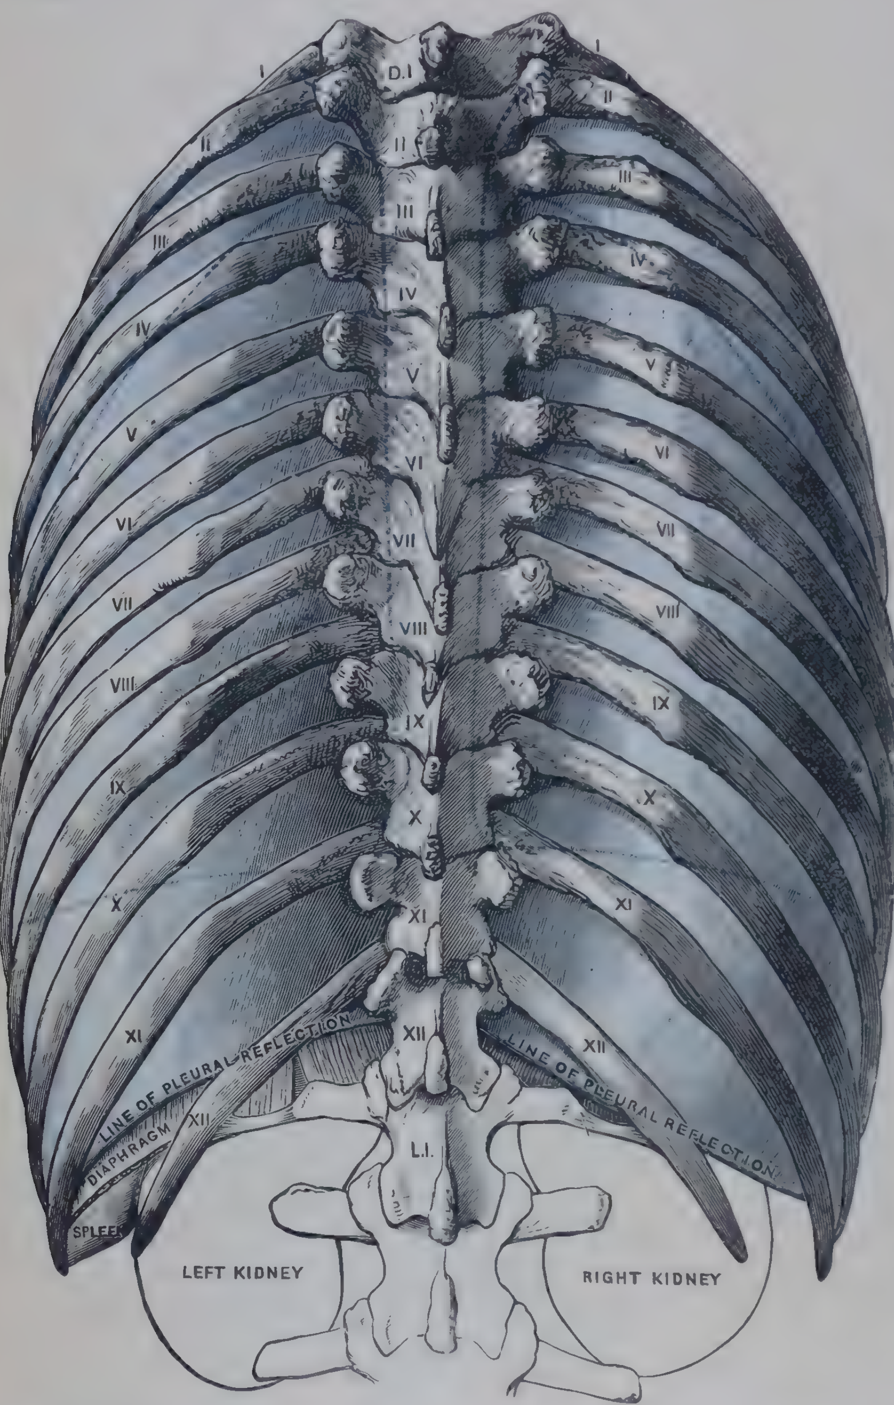

Fig. 600.—Pleural Sacs from Behind in Subject hardened by Formalin Injection. The blue lines indicate the outlines and the fissures of the lungs.

Sternal Line of Pleural Reflexion.—From the back of the sternum the right pleura is reflected, in the upper part of the chest, on to the remains of the thymus, the right innominate vein and the superior vena cava, and, at a lower level, directly on to the front of the pericardium. The left pleura is reflected from the back of the manubrium sterni on to the left common carotid artery and the aortic arch, and, at a lower level, directly on to the front of the pericardium.

Diaphragmatic Line of Reflexion.—From the back of the xiphisternal joint, the diaphragmatic line of reflexion crosses the seventh costal cartilage and reaches the eighth costal arch near its costo-chondral junction, in the mid-clavicular line. Beyond this point the line of diaphragmatic reflexion is carried downwards and laterally across the ninth and tenth ribs near their anterior extremities. As it crosses the tenth rib or, perhaps, as it proceeds across the tenth intercostal space, the line of pleural

reflexion reaches its lowest point, which lies in the mid-axillary line two fingers' breadth above the costal margin. Thence, as it curves backwards towards the vertebral column, it passes slightly upwards, cutting across the eleventh rib and reaching the twelfth rib. Its relation to the twelfth rib varies with the length of that rib: unless the last rib is unusually short the pleura lines its medial half, and the line of reflexion falls below that portion of the rib so as to reach the vertebral column midway between the head of the last rib and the transverse process of the first lumbar vertebra (Fig. 600). There, therefore, the line of diaphragmatic reflexion falls below the inferior border of the thoracic wall; and this is a point of practical importance in operations on the kidney. (See "Pleuræ" in Section on Surface and Surgical Anatomy.) In the living subject, according to radiographic evidence, this most posterior part of the reflexion-line runs either horizontally, or with medial ascent, or upward concavity at any level from the upper margin of the twelfth thoracic vertebra to the lower margin of the second lumbar vertebra (Lachman, 1942).

It is commonly stated that the left pleural sac reaches a lower level than the right, but this is by no means the rule: the right may reach lower than the left.

Along the line of the diaphragmatic reflexion, the **phrenico-pleural fascia** passes from the bare part of the diaphragm and from the costal cartilages to the surface of the costal pleura, so as to hold it firmly in its place.

Pleural Recesses.—Along the sternal and diaphragmatic lines of reflexion the pleura bends so acutely that the two parts come into contact with one another to form **recesses** of the pleural cavity. These recesses are occupied by the anterior and inferior borders of the lung in deep inspiration only, and in some places not even then (pp. 713, 714). They are known as the *costo-mediastinal recess* and the *costo-diaphragmatic recess*; their names sufficiently indicate their positions in relation to the parts of the parietal pleura that bound them. The *retro-œsophageal recesses* are described on page 709.

Structure of Pleura.—The **pulmonary pleura** is the connective tissue capsule of the lung. Its outermost or *serous layer* is a sheet of thin, mesothelial cells. This rests on a *collagenous membrane* which contains some elastic fibres. Deeper still there is an *elastic membrane*. This is separated from the subjacent alveoli of the lung by a *subpleural areolar layer*. Septa from the subpleural layer extend into the lung and partly surround the (secondary) lobules; and through these septa twigs of the bronchial artery, radicles of the pulmonary vein, communicating lymph-vessels, and also nerves are enabled to pass to or from the pleura.

The **parietal pleura**, like other serous membranes, is composed of a stratum of fibrous tissue in which bundles of fibres cross each other in various directions and are intermixed with a considerable quantity of elastic tissue.

On the inner or free surface there is a continuous sheet of mesothelial cells. The pleura so formed is attached to the parts that it lines by a *subserous layer* of areolar tissue.

Vessels and Nerves.—The *intercostal* **arteries** and various branches of the *internal mammary* artery supply the parietal pleura; the **veins** correspond. **Lymph-vessels** are abundant in the subserous layer. **Nerves**: The costal pleura and the peripheral part of the diaphragmatic pleura are supplied by the *intercostal* nerves. The central part of the diaphragmatic pleura and the mediastinal pleura are supplied by the *phrenic* nerve. At operation, probing the costal pleura elicits pain at the point of contact; on probing the peripheral part of the diaphragmatic pleura pain is referred to the lower part of the chest-wall or to the anterior abdominal wall; and on probing the central part of the diaphragm and lower part of the mediastinal pleura (presumably the upper part also) it is referred to the lower part of the neck. The visceral pleura is insensitive to touch.

LUNGS

When healthy and sound each **lung** (pulmo) lies free within the corresponding pleural cavity, and is attached only by its root and the pulmonary ligament. Adhesions between the pulmonary and parietal layers of pleura are due to pleurisy.

The right lung is larger than the left, in the proportion of about 11 to 10. It is also shorter and wider. The difference is due partly to the great bulk of the right lobe of the liver, which forces the right dome of the diaphragm to a higher level than the left dome, and partly to the heart and pericardium bulging more to the left than to the right, thus diminishing the width of the left lung.

The lung is light, soft, and spongy in texture; when pressed between the finger and thumb it crepitates, and when placed in water it floats. Pulmonary tissue is remarkable for its elasticity.

The surface of the adult lung presents a mottled appearance. The ground

colour is a light slate-blue, but scattered over this there are numerous dark patches of various sizes, and also fine, dark, intersecting lines. The coloration of the lung differs considerably at different periods of life. In early childhood the lung is rosy-pink, and the darker colour and the mottling of the surface, which appear later, are due to the pulmonary substance, and particularly its interstitial areolar tissue, becoming more or less completely impregnated with atmospheric dust (see p. 716). Owing to the fact that the upper lobes of the lungs maintain a practically constant relationship to the enclosing ribs and intercostal spaces in inspiration and expiration alike, the pigmentation on the surface of these lobes tends to lie in bands beneath the intercostal spaces. In the lower lobes, which, owing to the action of the diaphragm, expand in a vertical direction across the ribs, this band-like pattern is distinct only on the upper part of the lobes, where vertical expansion is but feeble in extent.

The fœtal lung differs from that of a new-born child who has breathed, for it is firm to the touch, and sinks in water. With the first inspiration, air enters the lung—beginning with the antero-lateral parts. Then, successively, the diaphragmatic, the apical, and the posterior parts come into action until at the end of a fortnight the entire lung is fully functional. It is only when air and an increased supply of blood are introduced into the lung that it assumes its characteristic soft, spongy, and buoyant qualities.

Form of Lungs.—The lungs are necessarily adapted to the walls of the pleural cavities in which they are placed and, when hardened by embalming fluid, they bear on their surfaces the imprint of ribs, vertebræ, and structures in the mediastinum. In this condition, each lung presents an *apex*, a *base* circumscribed by the *inferior border*, *costal* and *medial surfaces* sharply delimited from each other in front by the *anterior border* and less clearly a little behind the hilum by an unobtrusive *posterior border*, which may be rendered more evident by appropriate illumination as in Figs. 602, 603. Curiously enough, this border waited long to be given its name; and the bulky, rounded posterior part of the lung, lying in the deep hollow at the side of the vertebral column was wont to be named the "posterior border".

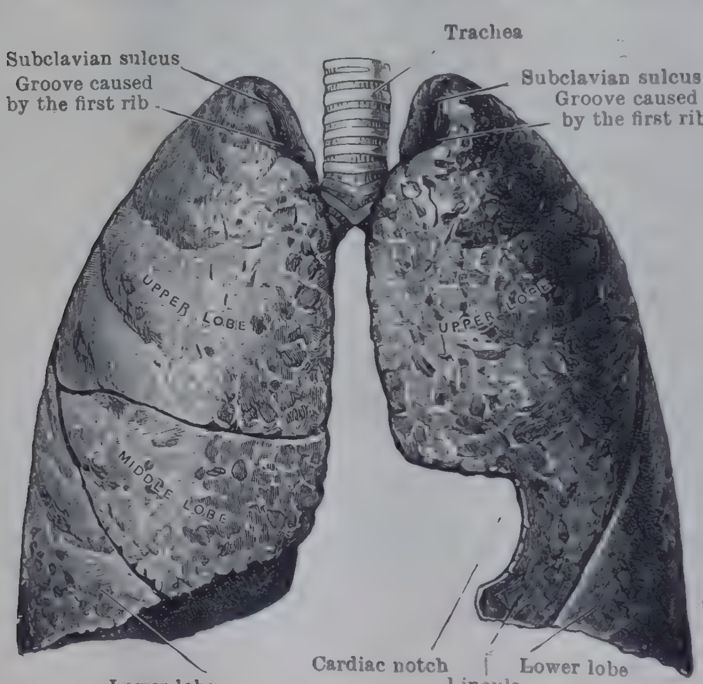

FIG. 601.—TRACHEA, BRONCHI, AND LUNGS OF A CHILD, HARDENED BY FORMALIN INJECTION.

The **apex of the lung** is blunt and rounded. It rises through the thoracic inlet, bounded by the first costal arch, to the full height of the cervical pleura in the root of the neck. The subclavian artery arches laterally across its anterior aspect a short distance below its summit, and there produces a groove called the *subclavian sulcus*. Slightly below this a shallower and wider groove marks the position of the innominate vein, and, on the left lung, the end of the left subclavian vein also. Although those vessels impress the lung they are separated from it by the cervical pleura.

As examined from behind, the apex of the lung usually extends as high as a line drawn from the highest portion of the acromion of the scapula to the tip of the spine of the seventh cervical vertebra. It may, however, be slightly higher or lower than this line.

The lateral limit of the apex of the lung, and consequently of the pleura, is medial to the superior angle of the scapula.

The **base** or **diaphragmatic surface** presents a semilunar outline, being curved around the base of the pericardium. It is adapted to the thoracic surface of the diaphragm, and is consequently deeply concave. As the right dome of the diaphragm lies higher than the left, the basal concavity of the right lung is deeper than that of the left lung. Laterally and behind, the diaphragmatic surface of each lung is limited by a thin salient margin, called the *inferior border*, which extends downwards for some distance into the *costo-diaphragmatic recess* of the pleural cavity. The inferior border of the lung moves freely in a vertical direction during respiration. It is practically horizontal and only approximately fills the costo-diaphragmatic recess in deep inspiration. In the preserved cadaver, the thorax assumes a form approximately midway between that of full inspiration and full expiration; and the inferior border of the lung crosses the sixth rib in the mamillary line; the eighth rib in the mid-axillary line; the tenth rib in the scapular line; and it reaches the vertebral column at the level of the tenth thoracic spine (Figs. 597-600).

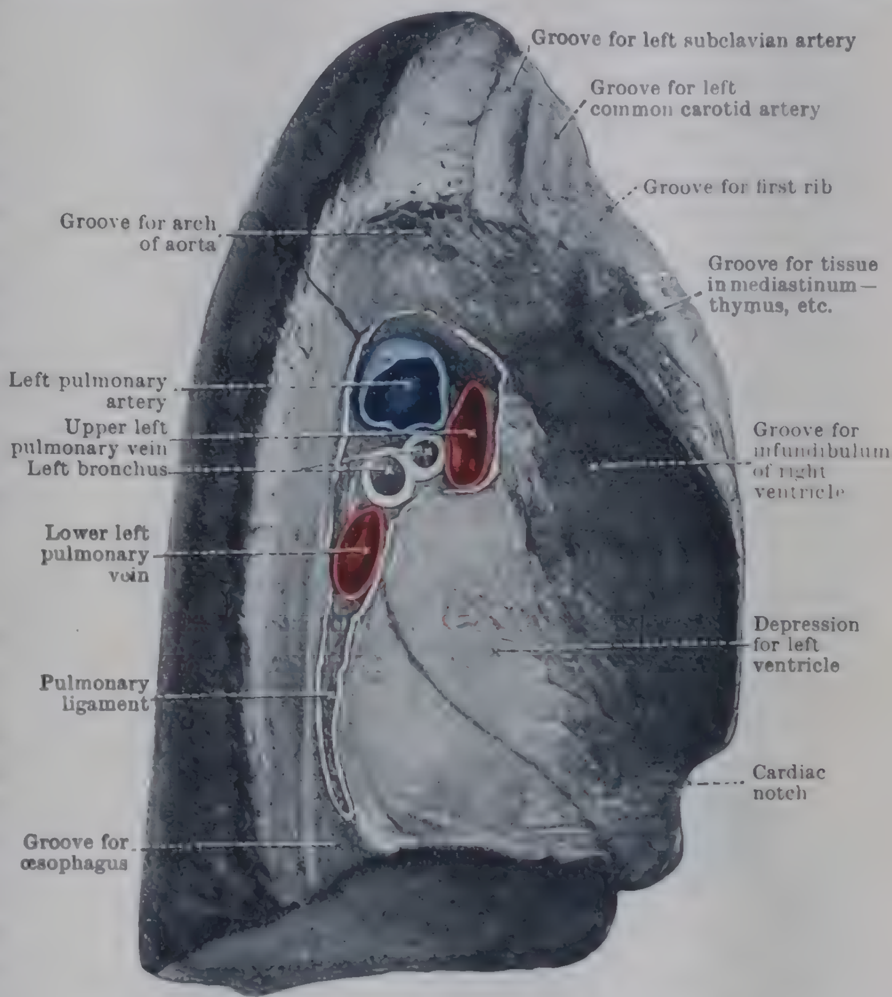

FIG. 602.—MEDIAL SURFACE OF LEFT LUNG HARDENED *IN SITU*.

The diaphragmatic surfaces of the lungs establish important relations with certain of the viscera that occupy the upper part of the abdominal cavity, the diaphragm alone intervening. Thus, the diaphragmatic surface of the right lung rests upon the right lobe of the liver; whilst that of the left lung rests upon the left lobe of the liver, the fundus of the stomach, the spleen, and, in some subjects, the left colic flexure.

The **costal surface** is extensive and convex. It is accurately adapted to the part of the wall of the pleural cavity that is formed by the sternum, the costal arches and the intervening muscles, the imprints of which are left upon it in the preserved cadaver.

The **medial surface** is applied to the sides of the vertebral bodies and to the mediastinal septum. The **mediastinal part** of this surface presents markings in accordance with the inequalities of the septum (Figs. 602 and 603). Thus, it is deeply hollowed out in adaptation to the pericardium. This pericardial hollow or depression comprises the greater portion of the mediastinal part, and, owing to the greater bulging of the heart to the left side, it is much deeper and more extensive in the left lung than in the right lung. Above and behind the pericardial depression is the hilum of the lung. The **hilum** is a wedge-shaped area within which the blood-vessels, nerves, and lymph-vessels, together with the bronchus, enter and leave the lung. Amidst these structures there are some lymph-glands. The hilum is surrounded by the reflexion of the pleura from the lung on

to the pulmonary root. Behind the hilum and the pericardial area, a longitudinal strip of each lung is applied to the posterior mediastinum. On the *right lung* the strip is grooved longitudinally by the right border of the œsophagus; on the *left lung* a broader longitudinal groove is produced by the descending aorta, and, close to the base in front of the aortic impression, a small flattened area makes contact with the left border of the œsophagus immediately above the diaphragm.

The portion of the mediastinal part of the lung that lies above the hilum and the pericardial depression is applied to the superior mediastinum, and the markings are accordingly different on the two sides. On the *left lung* a broad deep groove, produced by the aortic arch, curves backwards above the hilum, and becomes continuous with the aortic groove behind the hilum. From the groove for the aortic arch a narrower, deeper, and much more sharply marked groove runs upwards to become continuous with the groove that arches laterally across the front of the apex. This is the **subclavian sulcus**, and it contains the left subclavian artery when the lung is in place. In front of the subclavian sulcus there is a small area applied to the left common carotid artery and the phrenic and vagus nerves. On the *right lung* also there is a curved groove immediately above the hilum. This groove is narrow and more distinctly curved than the aortic groove on the left lung. It lodges the arch of the vena azygos. From the anterior end of the azygos groove a wide, shallow groove extends upwards to the apex of the lung a short distance below its summit. This is the imprint of the superior vena cava and the right innominate vein. Close to the summit there may be, on its medial aspect, a sulcus for the upper end of the innominate artery.

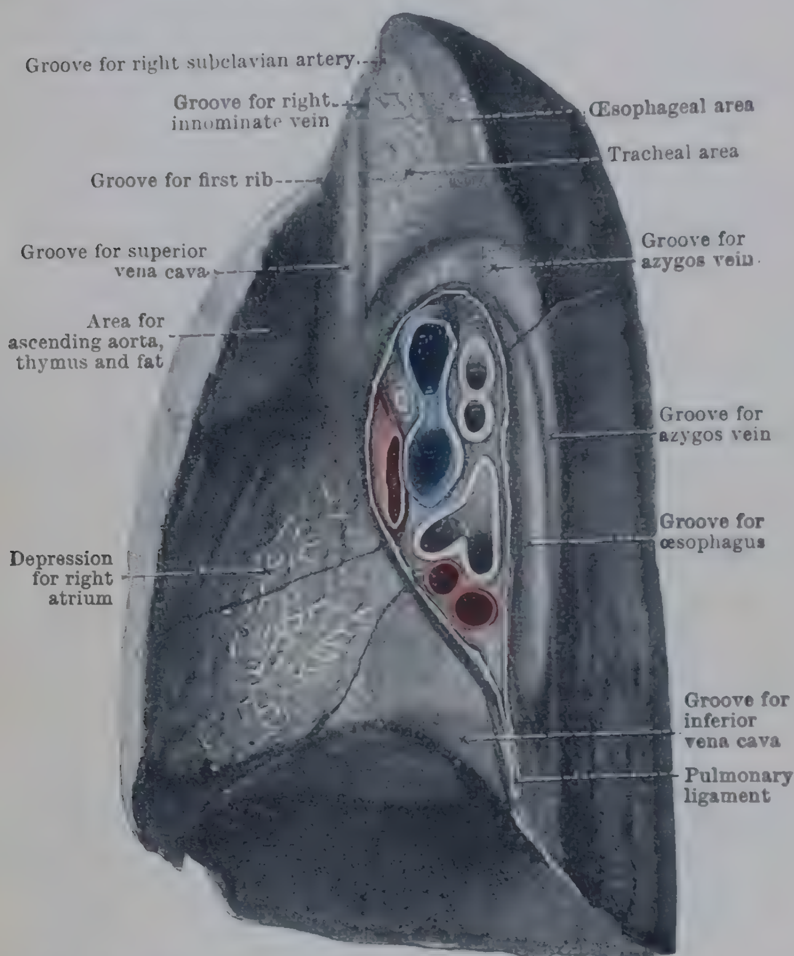

FIG. 603.—MEDIAL SURFACE OF RIGHT LUNG HARDENED *IN SITU*.

In addition to the hilum, it must now be evident that the mediastinal part of each lung presents three districts which correspond respectively to (1) the middle mediastinum (*i.e.*, the pericardial hollow), (2) the posterior mediastinum, and (3) the superior mediastinum; and that in each of these districts impressions corresponding to structures contained within the mediastinum may be noticed.

The **posterior border** of the lung divides the costal from the medial surface; as explained already (p. 712), it is an ill-defined margin.

The **anterior border** of the lung is short and exceedingly thin and sharp. It begins abruptly, an inch or more below the summit, opposite the sterno-clavicular joint, and extends to the base, where it becomes continuous with the inferior border. The thin front part of the lung is carried forwards and medially into the *costo-mediastinal recess* of the pleural cavity. The anterior border of the right lung completely fills this recess (except in deep expiration) and, in the upper part of the chest, is separated from the corresponding border of the left lung only by the two

layers of mediastinal pleura that are reflected from the sternum to the pericardium. The anterior border of the left lung, in its lower part, shows a deficiency of variable size, called the **cardiac notch**, which lies in front of the left side of the heart and pericardium. At the site of the notch, the left costo-mediastinal recess of the pleural cavity is, accordingly, unoccupied by lung. The tongue-like portion of the upper lobe of the lung, situated between the cardiac notch and the oblique fissure, is called the **lingula** (Figs. 601, 606).

In childhood, when the thymus is active and large, the anterior borders of the lungs, in expiration, are pressed apart by the thymus. But in inspiration, owing to expansion of the chest, the anterior borders of the lungs approximate each other and compress the thymus from the sides so that it sinks deeply into the intervening superior mediastinum. After the age of three years, however, the thymic shadow is no longer visible in radiographs of healthy children.

Fissures and Lobes of Lungs.—The *left lung* is divided into two lobes, an *upper* and a *lower*, by a long, deep, **oblique fissure** that penetrates its substance to within a short distance of the hilum. On the upper and lower sides of the hilum this fissure cuts right through the lung and appears on the medial surface. *In the cadaver*, this fissure (Figs. 600, 597), when viewed from the costal surface, is seen to begin behind about two and a half inches below the apex, about the level of the vertebral end of the third rib, and to continue downwards and forwards in a slightly spiral manner to the inferior border, which it reaches a short distance from its anterior end. *In the living subject*, however, the oblique fissure is distinctly lower. Thus, as seen at operations on the chest when healthy lungs have been kept inflated by the anaesthetist, it usually begins at the level of the vertebral end of the fifth rib or fifth interspace and thereafter it follows the line of the sixth rib. It may, however, begin as high as the fourth rib or even at the third interspace, and it is often as low as the sixth rib or sixth interspace (Brock, 1946). The fissure ends near the sixth costo-chondral junction, where it cuts the inferior border of the lung from two to four inches from the mid-sternal line. The **upper lobe** lies above and anterior to the fissure. It is conical in form, with an oblique base; and it includes the apex and the entire anterior border of the lung. The **lower lobe** lies below and behind the fissure. It is the more bulky of the two; and it includes almost the entire base and the greater part of the thick, posterior part of the lung.

The *right lung* is divided into three lobes, an *upper*, a *middle*, and a *lower*, by two interlobar fissures. One of them, the **oblique fissure**, is very similar in its position and relations to the fissure in the left lung. Its upper end, however, is a little farther from the apex; its incline is less steep; and its lower end is a little farther from the anterior border. It separates the lower lobe from the middle and upper lobes. The other fissure, the **horizontal fissure**, begins in the oblique fissure near the mid-axillary line, and proceeds forwards to end at the anterior border of the lung at the level of the fourth costal cartilage. It separates the upper lobe from the **middle lobe**, which is triangular or wedge-shaped in outline and situated anteriorly.

Variations.—The usual *fissures* of the lung may be either incomplete or absent, and supernumerary fissures may be present. Thus, the fissure between the middle and the upper lobe of the right lung was absent in 21 per cent of specimens and incomplete in 67 per cent; the fissure between the middle and the lower lobe was incomplete in 12·5 per cent; and the fissure between the upper and the lower lobe was incomplete, notably at its upper end, in 30 per cent of right and left lungs, according to observations made on 227 lungs (Kent and Blades, 1942). On the other hand, clefts or partial fissures have been observed between most contiguous bronchopulmonary segments (p. 717) and also between certain subsegments; notably, between the superior (dorsal) segment and the remainder of the lower lobe in both lungs; between the lingular segment and the remainder of the left upper lobe, thereby forming a *left middle lobe*; between the lateral and medial segments of the right middle lobe; and partially detaching the medial basal (cardiac) segment of the right lower lobe to form a **cardiac lobe**—a lobe that is constant and large in many of the domestic animals. Rarely, the arch of the azygos vein, suspended within a fold of pleura, cuts downwards into the apical part of the right lung, thereby separating an accessory lobe, the **lobe of the vena azygos** (see Stibbe, 1919), which is detectable on X-ray examination (Fig. 2, Pl. LXVIII, p. 721). (For abnormalities, see Foster-Carter, 1946.)

Weight.—The right adult lung, when filled with blood, weighs about 22 ounces, the left 20 ounces. In the nearly bloodless condition after electrocution the right lung weighs only about 8 ounces and the left 7 ounces.

Pigmentation.—Although at every breath foreign material is inhaled, little reaches the

alveoli of the lungs. Most is entangled in the mucus of the respiratory passages and washed by ciliary action upwards to the pharynx. Fine particles which succeed in reaching the alveoli are believed to be engulfed by alveolar phagocytes (dust-cells), which convey them to the nearest lymph-vessels, in the walls of the alveolar ducts and respiratory bronchioles. Having entered these, the phagocytes are swept on to the lymph-glands at the hilum. It is presumed that many die on the way, since pigments are usually found in and around the walls of the lymph-vessels. During expansion, the upper lobe maintains almost unchanged its relation to the overlying costal arches and intercostal spaces. Consequently, the pigmentation beneath the visceral pleura rather sharply defines the intercostal spaces. The lower lobe, following the diaphragm in its descent, modifies its relation to the overlying thoracic wall, and its subpleural pigmentation is therefore more diffuse. In certain disease-processes (*e.g.*, congestive heart-failure) alveolar phagocytes containing hæmoglobin pigment are coughed up. At birth, the surface of the lung is pinkish-white, but later in life it acquires a mosaic pattern of black lines which demarcate the bases of the (secondary) lobules of the lung. Hence, it would appear that some phagocytes, laden with foreign material obtained from the more peripheral alveoli, are carried by the vessels in the interlobular septa in the reverse direction (*i.e.*, away from the hilum) to the subpleural lymph-vessels and there deposited. The colour of the lung is determined largely by the colour of the inhaled pigment: in coal-miners the surface of the lung may be very nearly uniformly black, in hæmatite-miners red, and in zinc-oxide workers white.

Expansion of Lung in Respiration.—Although the texture of the lung is uniform throughout, the presence of the great blood-vessels and bronchi in the part around the hilum prevents that area from taking any active part in respiration. The middle zone of the lung, surrounding the hilar area, has but limited functional value. It is the outer zone, near the visceral pleural surface, that is most active in respiration. Probably only about 3 mm. depth of the superficial zone is active in quiet respiration and about 30 mm. depth in forced breathing. The walls of the pleural cavity are not uniformly expansile. The costo-sternal and diaphragmatic walls obviously move most freely; whereas, the region bounded above by the cupola, posteriorly by the vertebral ends of the ribs, and medially by the bodies of the vertebræ and the adjacent part of the mediastinum displays almost no expansile movement. Hence, the parts of the lung most free to expand are the costo-sternal and the diaphragmatic. During inspiration the root of the lung moves downwards and forwards, and it is this root movement that makes it possible for the apical and postero-medial parts of the lung to expand. Indeed, if for any pathological reason the root of the lung is fixed, the latter regions can hardly expand. During inspiration the bronchi (cf. Figs. 594 and 595) and the pulmonary vessels elongate and increase in calibre (Macklin, 1932). Further, the bronchi undergo a slight rotatory movement which can be recognized in cinematographic films.

Roots of Lungs.—The term **root of the lung** is applied to a number of structures which, enveloped in a tube of pleura, pass from the mediastinum to the hilum and constitute a pedicle for the lung. The phrenic nerve passes downwards a short distance anterior to the pulmonary root, whereas the vagus nerve breaks up into the posterior pulmonary plexus on its hinder aspect under the investing pleura. The anterior pulmonary plexus is placed in front of the root of the lung under the pleura. From the inferior border of the root of the lung the pulmonary ligament extends almost to the diaphragm. These relations are common to the roots of both lungs, but there are others which are peculiar to each lung. On the *right* the superior vena cava lies in front of the pulmonary root, and the vena azygos arches over it. On the *left* the aorta arches over the root, and the descending thoracic aorta passes behind it.

Contents.—The large structures in each pulmonary root are: (1) the two pulmonary veins; (2) the pulmonary artery; (3) the bronchus. There are also one or more small bronchial arteries and veins, the pulmonary nerves and lymph-vessels, and some broncho-pulmonary lymph-glands.

Relations.—The **bronchus** in the root of the lung lies behind the pulmonary vessels. The **pulmonary artery** is differently situated on the two sides. On the right it gives off a branch corresponding to the ep-arterial bronchus but itself lies below that bronchus. On the left, where there is no ep-arterial bronchus, the pulmonary artery enters the hilum above the bronchus. On both sides the **lower pulmonary vein** lies at a lower level than the artery and the bronchus, whereas the **upper** lies in front of the artery and slightly below it (Figs. 602 and 603).

The Bronchial Tree and Broncho-Pulmonary Segments.—The trachea bifurcates into a right and a left primary or *main bronchus*, one for each lung. The main bronchi divide into secondary or *lobar bronchi*, of which there are three on the right side (upper, middle, and lower) and two on the left side (upper and lower) for the respective lobes of the lungs. Each lobar bronchus divides into two or more tertiary or *segmental bronchi* for the supply of the subdivisions or segments of the lobes of the lungs. Of these segments, ventilated by tertiary bronchi, there are characteristically ten in the right lung and eight in the left (Fig. 604), and they are called **broncho-pulmonary segments.** Their number is not absolute, because of minor variations in the pattern of branching. Hence, in more general terms, a broncho-pulmonary segment may be described as the portion of lung served by a principal branch of a lobar bronchus (Foster-Carter & Hoyle, 1945). The pattern is, however, fundamentally identical in both lungs; but in the left lung the apical and the posterior segmental bronchi arise by a common stem, and so do the anterior basal and the medial basal (cardiac) segmental bronchi, thus accounting for the reduced number of segmental bronchi in the left lung. The segmental bronchi continue to divide into smaller and still smaller subsegmental bronchi until finally they end in lung units, described below.

For the anatomy of the bronchial tree, see Neil, Gilmour & Gwynne (1939); Neil & Gilmour (1946, 1949), Brock (1946), and Boyden (1949); and for the older views on the manner of the intrapulmonary branching of the bronchi, consult Aeby (1880), Ewart (1889) and Huntington (1920), summarized and illustrated by Smyth (1949).

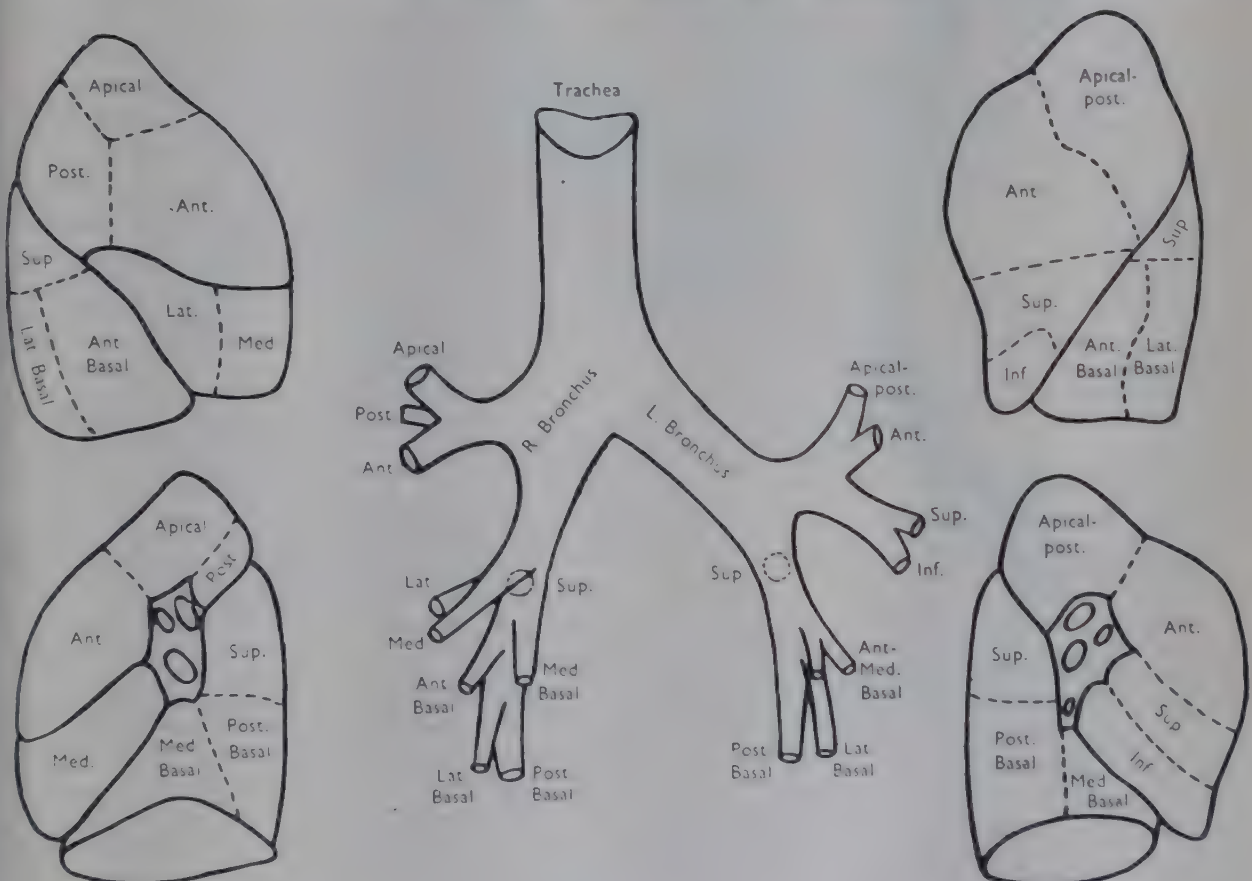

FIG. 604.—THE BRONCHO-PULMONARY SEGMENTS. (After Jackson & Huber, 1943.)
Each bronchial branch is designated by the name of the subdivision of the lung supplied by it.

Clinical Significance.—Within recent years the broncho-pulmonary segments have acquired an increased clinical significance to the physician in making a differential diagnosis of pulmonary disease, to the bronchoscopist in locating and removing a foreign body from a bronchus, and to the surgeon about to drain a localized abscess of the lung or to excise one or more diseased segments (Brock, 1946).

Nomenclature.—The recent revival of interest has naturally been accompanied by an evolving nomenclature to which many have contributed and in which there are many synonyms. This seems to have reached its simplest, most concise, and most easily remembered form in the terms suggested by Jackson & Huber (1943) and employed here, where each segment is referred to its position in its own lobe. No term is duplicated. The term *anterior* is preferred to the synonym *pectoral*; *lateral* to *axillary*; *superior* to *dorsal*; and *medial basal* to *cardiac* (cf. Brock, 1946).

The three right and two left lobar bronchi arise as the main bronchus approaches the

hilum of the lung. The right upper lobe bronchus arises nearly an inch from the trachea; whereas the left upper lobe bronchus arises about twice that distance from the trachea. The relation of the pulmonary artery to the upper lobe bronchus is different on the two sides: for, as the artery turns backwards to reach the posterior surface of the bronchus, it passes below the right upper lobe bronchus but above the left one. Hence, the right upper lobe bronchus has been called the *ep-arterial bronchus* (Aeby, 1880); all other bronchi on both sides being *hyp-arterial bronchi*. The ep-arterial bronchus is to be regarded as a branch that has migrated cranialwards on the main bronchial stem.

Just as the inferior lobe bronchus appears to be the direct continuation of the main bronchus, so the posterior basal bronchus appears to be the direct continuation of the inferior lobe bronchus and, therefore, to be the terminal and tapering part of the main stem of the bronchus, other bronchi being collateral branches. In its descent in the lung the stem curves postero-medially to the base of the lung, in conformity with the moulding of the lung by the heart.

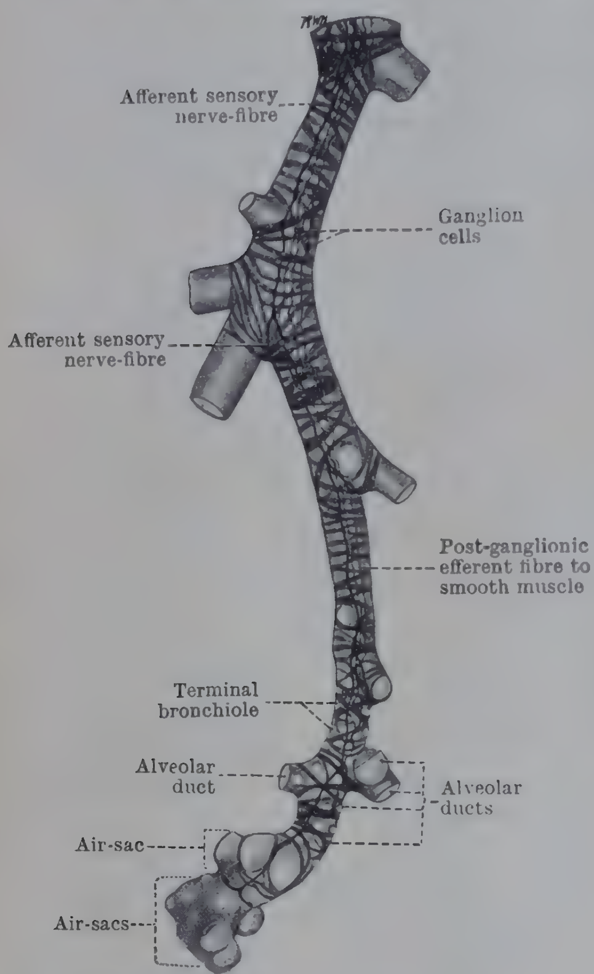

Fig. 605.—Reconstruction of a Bronchus, expanded in Inspiration, with its Muscles and Nerves. (After W. Snow Miller, 1921, 1947.)

Structure of Lung.—The lung is so constructed that the blood that reaches it through the pulmonary artery is brought into the most intimate relation with the air that enters it through the trachea and bronchi. An interchange of materials between the blood and the air is thus made possible, and the object of respiration is attained. As a result of the interchange, the dark, impure blood that flows into the lung through the pulmonary artery becomes bright red and arterial before it returns to the heart through the pulmonary veins.

The lungs are lobed, each lobe being an elastic, spongy mass enclosed in a capsule of pulmonary pleura and subpleural areolar tissue. From this subpleural layer fine areolar septa penetrate into the substance of the lung, and these, with the areolar tissue that enters at the hilum upon the vessels and bronchi, constitute a supporting framework for the organ.

A branching tree of tubes permeates the lung and constitutes the **conducting part of the lung**. The main tube and the first few generations of its branches are termed *bronchi*; the succeeding and smaller branches are termed *bronchioles*. The **respiratory part of the lung** consists essentially of a capillary network supported by elastic and reticular fibres and partitioned like a honeycomb. The pulmonary artery brings blood to the network; the pulmonary veins return it to the heart. The bronchioles divide ultimately within the lung substance into a number of tubules, called *alveolar ducts*, which branch, and even re-branch, and end in rounded cavities, called *alveolar sacs* (air-sacs), on whose walls there are outpouchings or *alveoli*. Alveoli occur also on the alveolar ducts and on the bronchioles that immediately precede them, which are accordingly called *respiratory bronchioles*. The name *terminal bronchioles* is applied to the precursors of the latter.

Lobules of Lung.—The lobes of the lung are made up of a number of broncho-pulmonary segments, each of which, by the progressive branching of its bronchus, is divisible into smaller and still smaller subsegments until areas called *secondary lobules* are reached, each of which is subdivided into many smaller *primary lobules* or *lung-units*. On the surface of the lung, black lines, resulting from pigment deposited in the interlobular septa, enclose polygonal areas, 1 cm. or more in diameter, which are the bases of secondary lobules. These polygonal areas are indefinitely marked off by finer black lines into smaller polygonal areas, 2 or 3 mm. in diameter, which are the bases of primary lobules. Although no pigment is present in the fœtal lung, the lobular character

of the lung is particularly well marked in the fœtus, and with a little care one can separate its surface lobules from one another by gently tearing through the intervening areolar tissue. The lobules thus isolated are pyramidal. The bases of the pyramids abut against the subpleural areolar tissue, whilst each apex, directed towards the hilum, receives a bronchiole. This bronchiole branches several times, the last generation of branches being respiratory bronchioles. The portion of lung, including its vessels and nerves, supplied by a respiratory bronchiole is a *primary lobule* or **lung-unit** (Snow Miller, 1947).

Structure of Intrapulmonary Bronchi.—When the large bronchi enter the lung, they become cylindrical and lose the posterior flattening which is characteristic of the extrapulmonary bronchi. They possess the same coats as the trachea and extrapulmonary bronchi (p. 703); but as the tubes become smaller by repeated divisions, the coats become thinner and differently arranged.

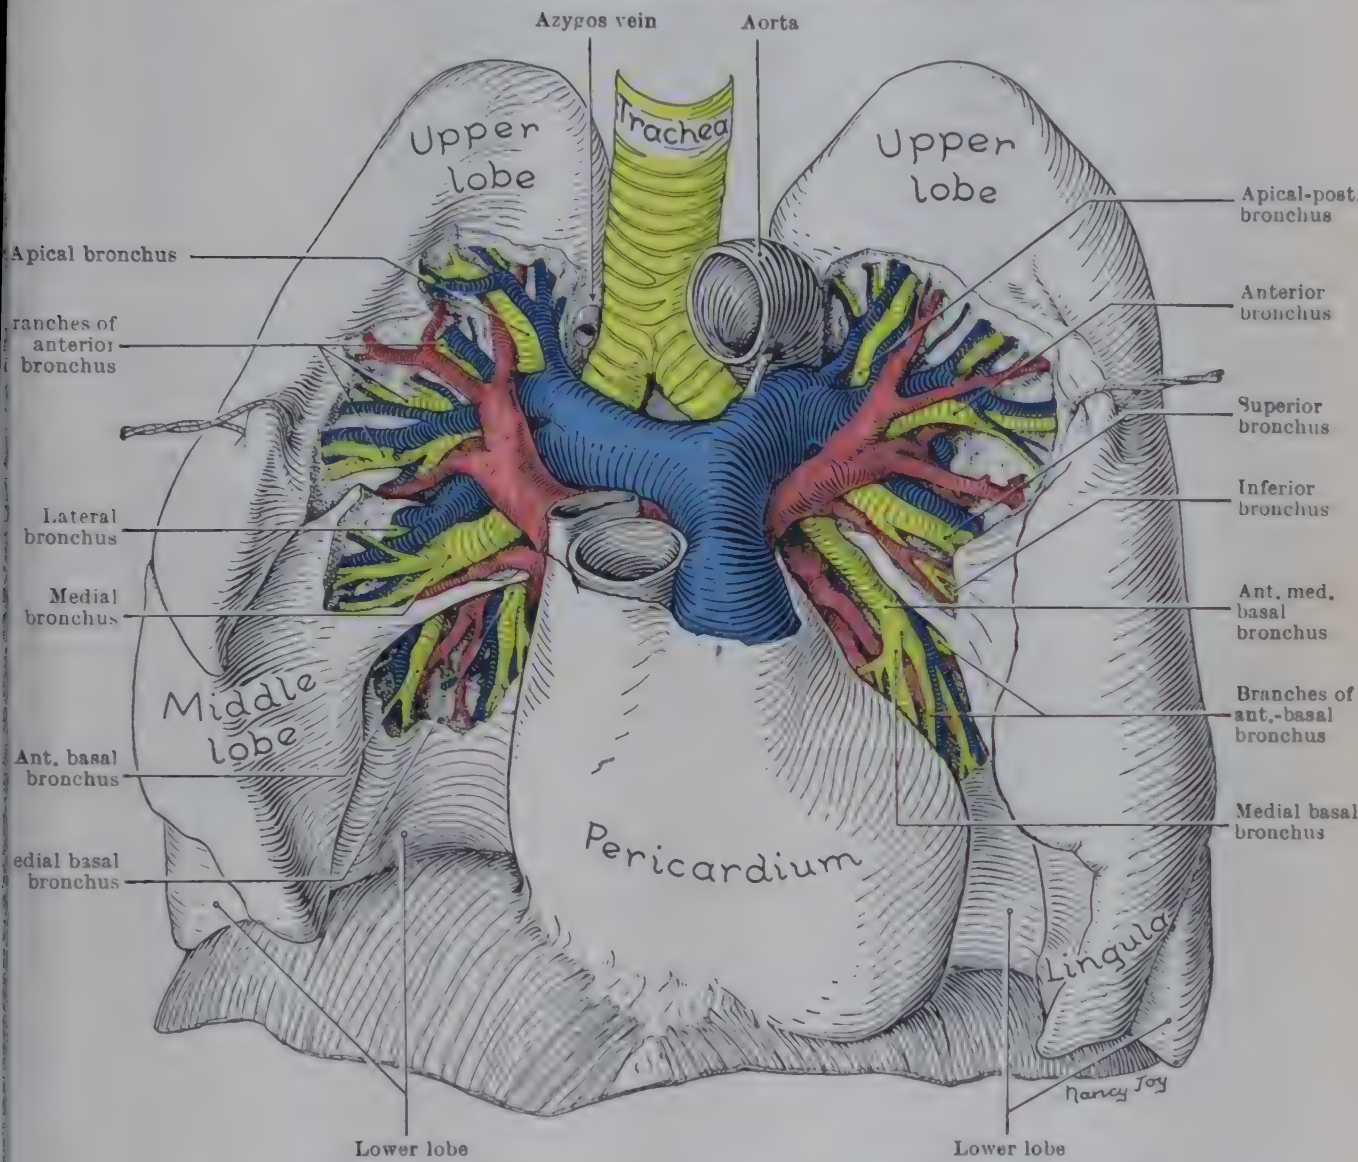

FIG. 606.—DISTRIBUTION OF BRONCHI AND PULMONARY BLOOD-VESSELS IN THE LUNGS.
(From a dissection by Miss A. I. Scott.)

In the *supporting coat* the **C**-shaped cartilages, characteristic of the trachea and extrapulmonary bronchi, give place to a mosaic of irregular plates which completely surround the bronchus. They become progressively fewer and correspondingly smaller in the smaller tubes until, in bronchi of 1 mm. diameter, they disappear altogether. The glands cease to exist about the same point. The *muscle-fibres* form a continuous lattice work in the bronchi; this becomes relatively more conspicuous in the non-cartilaginous bronchioles, and may be traced to the ends of the alveolar ducts, where it forms sphincters. Spasm of these sphincters accompanies asthmatic attacks. The *mucous coat* becomes greatly thinned in the smaller bronchioles. It contains numerous longitudinally arranged elastic fibres and is disposed in longitudinal folds, so that when the tube is cut across the lumen presents a stellate appearance. The mucous coat is lined with ciliated columnar epithelium as far as the beginning of the respiratory bronchioles, where it becomes non-ciliated and cuboidal. The ciliated epithelium, however, extends beyond the last goblet-cell. There is controversy whether or not the epithelium of the bronchial tree is continued into the respiratory portion of the lung. Certainly no continuous epithelial lining can be seen in the alveoli, though isolated cells (septal cells or alveolar phagocytes) are apparent

here and there on the alveolar wall amid the capillary network. Fine perforations in the septa, called *alveolar pores,* that bring contiguous alveolar sacs into communication with each other are described by some and denied by others (Engel, 1947).

Vessels and Nerves of Lung.—The bronchial arteries, usually one on the right side (of variable origin) and two on the left from the aorta, accompany the intrapulmonary bronchi as two or three longitudinal anastomosing branches, dividing when these divide and extending to the respiratory bronchioles. The function of the bronchial artery is to supply oxygenated blood, under high pressure, to the conducting part of the lung and to the other non-respiratory tissues (*i.e.*, bronchial tree, areolar tissue, lymph-glands, and, *via* the interlobular septa, the pulmonary pleura) for their nourishment. (See Cauldwell *et al.*, 1948.)

The **pulmonary artery**, on the other hand, brings venous blood under low pressure to the respiratory parts of the lung (*i.e.*, the parts that possess alveoli) to be oxygenated. The bronchial and pulmonary arteries effect capillary anastomoses on the respiratory bronchioles, but the branches of the pulmonary artery do not anastomose with each other. The terminal divisions of the artery join a dense capillary plexus which is spread over the alveoli. This vascular network is so close that the meshes are barely wider than the capillaries that form them. In the partitions or septa between adjacent alveoli there is only one layer of the capillary network, and thus the blood flowing through the network is exposed on both aspects to the air in the alveoli. There is a principal artery (or arteries) for each broncho-pulmonary segment. Ten arteries are to be identified in each lung and they are best named after the segments they supply. For the most part, the arteries follow the peripheral distribution of the bronchi, but their sites of origin and their proximal courses (*i.e.*, in the hilar region) are liable to certain variations (described in elaborate detail by Appleton, 1944, 1945, and by Boyden *et al.*, 1945, 1946, 1948).

The **pulmonary veins** return to the heart the blood delivered both by the pulmonary artery and by the bronchial artery, excepting the bronchial blood to the first one or two divisions of the bronchi; this blood is returned by **bronchial veins** to the azygos, hemiazygos, or intercostal veins. The radicals of the pulmonary vein, therefore, arise in the capillary plexus over the alveoli, in the walls of the alveolar ducts, in the pulmonary pleura, and in the areolar tissue.

Ten principal veins are to be identified in each lung. In their peripheral course, the veins do not lie with the arteries but occupy intersegmental planes and receive tributaries from the adjacent segments. Hence, to remove a segment at operation one set of tributaries must be ligated. In their proximal course, the veins accompany the bronchi and are named after the bronchi that lie superior and adjacent to their stems, excepting the first two veins of the right upper lobe which are called the apical anterior and the inferior vein. Certain veins run subpleurally in the interlobar fissures and on the mediastinal surface.

When fissures are incomplete it is common to find a vein passing from one lobe to the other. Arteries also not uncommonly cross intersegmental planes. Hence, a broncho-pulmonary segment should not be regarded as a broncho-vascular unit.

Variations.—The arteries are more variable than the bronchi, and the veins than the arteries. For details, Appleton and Boyden in particular, should be consulted.

The upper and lower pulmonary veins of either lung sometimes unite to form a single trunk which opens into the left atrium; the vein of the middle lobe may open independently. Again, one or both pulmonary veins of one or both sides may open into the right atrium or into one of its tributaries, *e.g.*, the superior vena cava, left innominate vein, left superior intercostal vein, coronary sinus, or inferior vena cava, or into an adjacent vein; but, unless 50 per cent or more of the pulmonary blood can find its way to the left atrium, life is not sustained for many weeks (*i.e.*, unless the interatrial septum is absent or the foramen ovale and the ductus arteriosus are patent—Brody, 1942; Brantigan, 1947).

The **lymph-vessels** of the lung are numerous, and they are divided into two groups—superficial and deep.

The *superficial lymph-vessels* are comparable to the lymph-vessels found in the capsules of other organs. They form a network which outlines the bases of the (secondary) lobules, and they are abundantly supplied with valves. Lymph-vessels in the interlobular septa bring the superficial network into free communication with the deep vessels—though these septal vessels occasionally have valves or valve-like structures, it is questionable whether they function as valves. In general, valves are so arranged in the lymph-vessels of the adult human lung that the lymph-flow is always directed towards the hilum (Harvey & Zimmerman, 1935).

Of the *deep lymph-vessels*, one set, beginning at the alveolar ducts, accompanies the bronchial tree; a second set accompanies the pulmonary artery; a third accompanies the pulmonary vein; and a fourth lies in the septa between the (secondary) lobules of the lung and communicates with the superficial network. These deep vessels have few valves; they intercommunicate freely, and they run to the hilum, where they end in the broncho-pulmonary lymph-glands situated either just outside the lung or within the lung substance. The blood-capillaries over the alveoli, being respiratory in function rather than nutritive, have no corresponding lymph-vessels.

From the broncho-pulmonary glands, the lymph-flow passes to the superior and inferior tracheo-bronchial glands, and from these it continues upwards through the paratracheal lymph-glands on each side of the trachea to the mediastinal lymph-trunk. One or two vessels from the lower lobe of each lung pass through the pulmonary ligament to end in the posterior mediastinal glands.

Further, lymphoid tissue is scattered throughout the lung-substance at the sites of division of bronchi and bronchioles, on the alveolar ducts, and where venous radicles arise beneath the

PLATE LXVII

PLATE LXVII.—ANTERIOR RADIOGRAPH OF THE SAME THORAX AS IN PLATE LXVI, IN POSITION OF FULL EXPIRATION.

Compare with Plate LXVI, p. 705, noting the rise of the Diaphragm, the broadening of the whole mediastinal shadow (including the Heart) and the greater density of the Lungs.

PLATE LXVIII

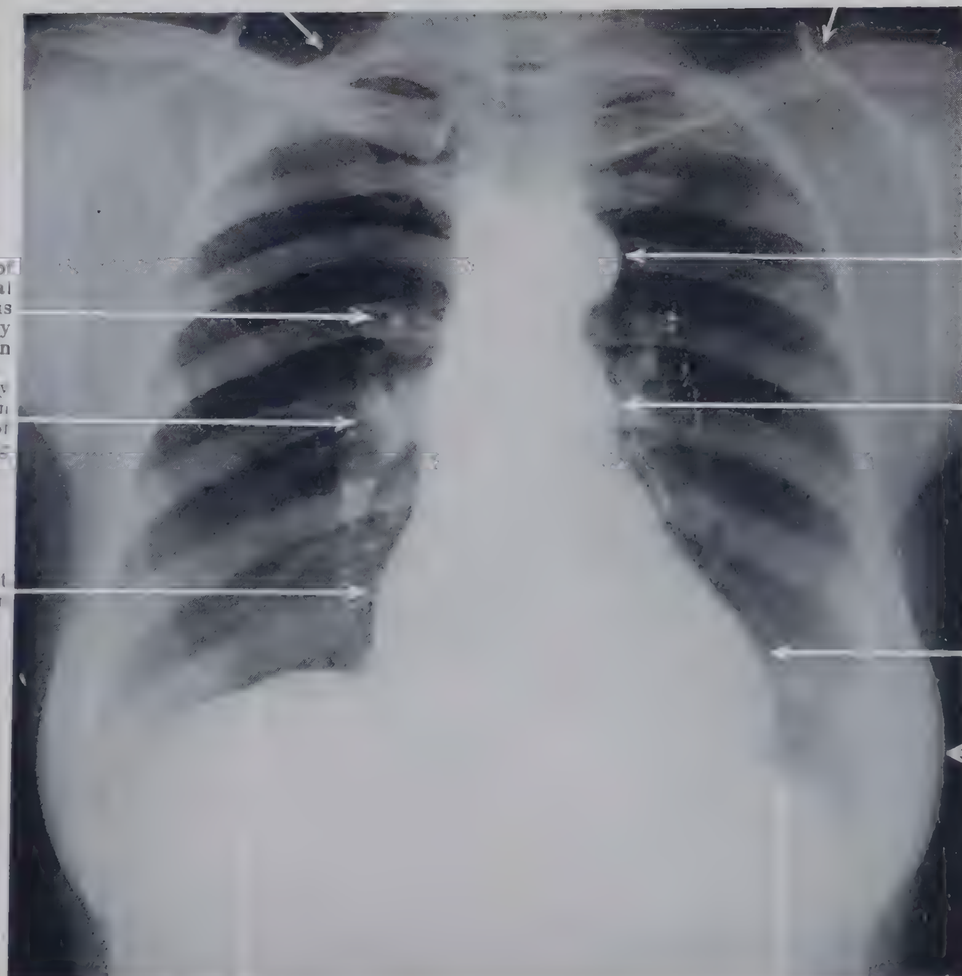

FIG. 1.—ANTERIOR RADIOGRAPH OF THORAX, OF WOMAN AGED 32, SHOWING GENERAL FORM OF MEDIASTINAL AND LUNG-ROOT SHADOWS AND SHADOWS OF BREASTS.

Note the position of the breast-shadows and compare with Plates LXII, p. 696, and LXV, p. 704.

FIG. 2.—RADIOGRAPH OF RIGHT CERVICO-THORACIC REGION, OF WOMAN AGED 35, SHOWING, IN ADDITION TO CERVICAL RIB, THE SHADOWS OF VENA AZYGOS AND PLEURAL FOLD THAT INDICATE THE PRESENCE OF A "LOBE OF THE VENA AZYGOS" IN THE RIGHT LUNG.

Cf. Plate IV, Fig. 1, p. 105, and see pp. 715, 1333.

[Facing p. 721

pleura. This lymphoid tissue is increased in old age, when it forms sheaths for the bronchial tree and pulmonary vessels, and also becomes diffused in the bronchial walls between the epithelium and the plain muscle.

The **nerves** of the lung come from the anterior and posterior pulmonary plexuses, and they comprise both efferent and afferent **vagal** and **sympathetic** fibres. The preganglionic fibres of the sympathetic issue from the upper three or four thoracic segments of the spinal cord, and the postganglionic fibres leave the middle cervical, inferior cervical, and upper four thoracic sympathetic ganglia. The afferent sympathetic fibres take the reverse course.

The fibres of the **pulmonary plexuses** are distributed along (*a*) the bronchial tree, and (*b*) the pulmonary vessels. The *plexus along the bronchial tree* includes ganglion-cells (postganglionic neurones of the vagus) which provide constrictor fibres to the muscles of the bronchial tree and secretory fibres to the glands; postganglionic fibres of the sympathetic have the opposite effects. Afferent vagal endings ("plain muscle-spindles"), present throughout the entire bronchial tree, are excited by the stretching of the lung during inspiration (Hering-Breuer reflex); afferent vagal fibres, having free nerve-endings in the epithelium throughout the bronchial tree, are concerned in the cough-reflex. The *plexus along the pulmonary vessels* brings vagal and sympathetic efferent fibres (postganglionic) to the vessels—most of the vasodilator fibres being vagal and most of the vasoconstrictor fibres being sympathetic. Afferent fibres, having free nerve-endings in the pulmonary pleura, pass *via* the interlobular septa to this plexus. Their central connexions are unknown. The pulmonary pleura is, nevertheless, insensitive to touch.

Radiographic Examination of Thorax.—In radiographs of the chest the ribs are clearly visible as they sweep round from the vertebral column to the costal cartilages. The posterior portions of the ribs are more compact than the anterior portions and therefore cast a denser shadow. The costal cartilages are not visible unless they are calcified. The clavicles are clearly seen, and the scapulæ and the shoulder joints may be included in whole or in part, depending on the size of the film used. When the chest is radiographed, the film is usually placed in front of the patient and the shoulders are displaced forwards so that the shadows of the scapulæ do not obscure the lung-fields.

In addition to the bony structures of the thoracic wall, some of the soft tissues may be visible. Thus, the lower end of the sterno-mastoid and the fold of the skin as it passes over the clavicle may be seen. The female breast casts a shadow, the density of which varies with the development of the organ (Pls. LXII, p. 696, LXVIII, Fig. 1); the nipple may be visible in both sexes. In the male, the lower margin of the pectoralis major, if well developed, may cast a shadow.

In health, the **lungs**, because of their air-content, do not absorb radiation to any extent, and in consequence the lung-fields, on each side of the shadow of the mediastinum, appear dark in radiographs. The translucency of the lungs is distinctly greater at the end of inspiration because of the increase of their air-content; and, for the same reason, the lung-fields appear specially dark in *emphysema*—a pathological condition in which the alveoli are permanently dilated. On the other hand, anything that diminishes the relative amount of air in the lung (congestion, pneumonia, etc.) reduces its permeability to the passage of the rays.

The lung-fields are not homogeneous, however, for the beam, while it passes easily through the substance of the lung, is absorbed to some extent by the blood-vessels. The **blood-vessels** give rise to the X-ray "pattern" of the lung; and they can be seen as white shadows ramifying from the hilum, branching and becoming narrower as they extend out to the periphery of the field (Pl. LXV, p. 704).

When a vessel is seen end-on it casts a circular shadow that is homogeneously dense; it should never be confused with the shadow of a calcified lymph-gland, which is irregular in both outline and density. The vessel that accompanies the ep-arterial bronchus is often seen end-on near its origin (Pl. LXVIII, Fig 1). Where the shadow of one vessel crosses that of another, an area of increased density is produced; this superimposition of the shadows of blood-vessels occurs throughout the lung-field and is a main factor in the production of the "lung-pattern".

The white shadows cast by the blood-vessels are often attributed to bronchi; but **bronchi**, since they are filled with air, do not absorb radiation and therefore, in general, they merge into the dark lung-field. When bronchi are, in fact, recognizable, it is not because they cast a shadow but because their air-content makes them *more* radio-translucent than the surrounding tissues, so that they appear as darker areas in contrast to the white shadows of the blood-vessels (Pls. LXVI, p. 705, LXVII). In this connection it is interesting to note that the **trachea** is easily recognized as a median, dark area passing from the neck into the superior mediastinum (Pl. LXV). The fact that the trachea is radio-translucent makes it obvious that bronchi, with thinner walls, cannot produce the ramifying white shadows in the lung-field. Occasionally a bronchus—particularly the

ep-arterial bronchus—is visible end-on, and it is then recognized as a circular dark area surrounded by a white line (Pl. LXVIII, Fig. 1). The white line is produced by the wall of the bronchus which, because of its direction, can absorb sufficient radiation to enable it to cast a shadow.

The bronchi can be rendered plainly visible by the injection of an iodized oil through the trachea. This procedure—harmless to the patient, provided too much oil is not used—makes the relation of the bronchi to the blood-vessels evident; and, by its means, not only the main bronchi and their primary branches but even the **bronchioles** may be displayed (Pls. LXII, LXIII, p. 696). During inspiration the main bronchi and their primary intra-pulmonary branches are lengthened and spread out a little; in expiration they shorten and tend to come together as the volume of the lung diminishes. Figs. 594 and 595 give a general impression of the respiratory alternation in the form of the lungs and of the bronchial tree. (See also Peirce & Stocking, 1939.)

The **broncho-pulmonary lymph-glands** are not visible unless they are enlarged by disease. Even small glands, however, if calcified, may be recognized as irregular, mottled shadows near the hilum of the lung.

The **pleura**, unless it is thickened by disease, is hardly visible in an ordinary radiograph. The cervical pleura, however, may cast a recognizable shadow as the X-ray beam passes tangentially through it; and the pulmonary pleura also may be seen in the interlobar fissures when its double layer presents an edge to the beam. Thus, in the usual anterior radiograph of the chest, only the horizontal fissure of the right lung is visible, but in lateral views the oblique fissures also may be recognized. Thickening of the pleura by disease increases the density of its shadow, and it may then appear as a double line. Pleural effusions also may be recognized by an increased density of the lower lateral part of the lung-field, and the fluid in the pleural cavity may obscure the costo-diaphragmatic recess and the outline of the diaphragm.

The domes of the **diaphragm** delimit the lower margins of the lung-fields. The right dome is higher than the left. When the radiograph has been taken with the patient erect, the air-bubble in the fundus of the stomach (p. 620) is usually conspicuous under the left dome (Pl. XLVIII, p. 599).

Foreign bodies in the accessible bronchi may be seen by direct view through a broncho-scope, but radiography is required to locate them if they have passed into the smaller bronchi or, as in the case of bullets or shell-fragments, if they are embedded in the lung-substance.

The radiography of the **mediastinum** (heart and great vessels) is dealt with after the description of the heart in the Section on the Blood-Vascular System.

DEVELOPMENT OF RESPIRATORY SYSTEM

The larynx, trachea, bronchi, and lungs all arise from a median longitudinal groove, called **the laryngo-tracheal groove**, which makes its appearance in the ventral wall of the primitive pharynx at its œsophageal end when the embryo is about 3·0 mm. in length. The groove is soon pinched off from the fore-gut by lateral constrictions and is thus converted into the primitive respiratory tube (Fig. 607). This conversion begins at the caudal end and proceeds headwards, but it leaves the cephalic end of the tube in communication with the fore-gut.

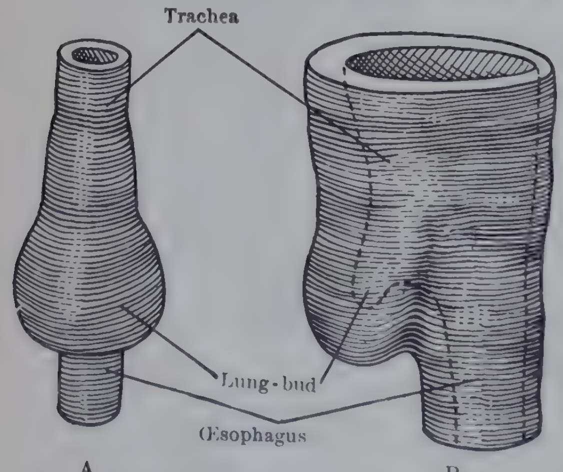

FIG. 607.—DEVELOPMENT OF RESPIRATORY TUBE IN 4·25 MM. HUMAN EMBRYO. (After Grosser, 1912.) A, ventral view; B, lateral view.

The cephalic end of the primitive respiratory tube forms the larynx; the succeeding portion forms the trachea; whilst the caudal end—the 'lung-bud'—bifurcates into two bulbous swellings called the pulmonary diverticula. These grow tailwards, one on each side of the heart, into mesodermal masses derived from the dorsal attachment of the septum transversum. The epithelium of the respiratory tube and of its future branches is of entoderm derived originally from the fore-gut; the remaining elements of the lungs are derived from the mesodermal masses.

Larynx. At first the cephalic end of the laryngo-tracheal groove lies caudal to the fourth pair of pharyngeal arches in a region representing the fifth and sixth arches; but these soon move headwards to a position between the ventral ends of the fourth pair of pharyngeal arches. The *laryngeal muscles*, however, are

derived from the sixth pair of arches and, hence, are supplied by the nerves of these arches, namely, the recurrent laryngeal nerves. The slit-like opening of the primitive respiratory tube becomes the *rima glottidis* of the fully-developed larynx, whilst the parts of the larynx above this level are pharyngeal upgrowths (Fig. 608).

In embryos of about 5 mm. in length, a median elevation bulges headwards from the ventral wall of the pharynx and receives the ventral ends of the third and fourth pharyngeal arches. The opening of the primitive respiratory tube is immediately dorsal to this elevation, while upgrowths, in which the fifth and sixth arches are represented, bound the opening laterally. The median elevation gives rise to the *epiglottis*, and the lateral upgrowths become the *ary-epiglottic*

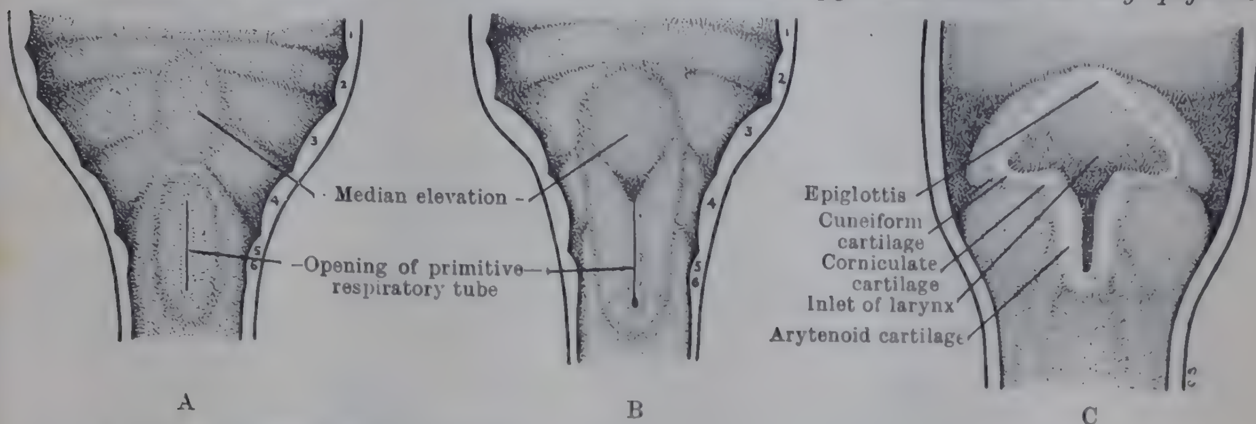

FIG. 608.—DEVELOPMENT OF LARYNX. (A and B, after Frazer, 1940 ; C, after Arey, 1946.)
A, 6 mm. human embryo ; B, 8·5 mm. human embryo ; C, 40 mm. human embryo.

folds. About the fourth month, excavation of the medial side of each of these folds begins and gives rise to the corresponding *sinus* (ventricle) of the larynx. The lower margin of each sinus becomes a *vocal fold.*

At the end of the fourth week the cartilaginous framework of the larynx is indicated by mesodermal condensations, though actual cartilage does not appear until the seventh week. The arytenoid and corniculate cartilages, which form in the upgrowths above the level of the glottis, the cricoid cartilage, and the cartilages of the trachea are all continuous at first. The *epiglottic* and *cuneiform cartilages* develop in the median elevation and likewise are originally continuous.

The *thyroid cartilage* first appears as a pair of separate mesodermal plates, one on each side of the larynx, connected ventrally by dense mesoderm. Some time after chondrification has begun in the plates, a cartilaginous element arises in this dense ventral mesoderm and above it two smaller nodules of cartilage appear. As chondrification proceeds, the thyroid cartilage is formed by the fusion of all these initially separate components. The cartilages of the fourth pair of pharyngeal arches are represented in the plates, and perhaps those of the fifth pair. A foramen in the fully developed thyroid lamina is the result of incomplete chondrification, probably attributable to the passage of a small blood-vessel. The superior horn of the thyroid cartilage is at first continuous with the greater horn of the hyoid bone, and part of the connecting bar remains as the *cartilago triticea.*

The precartilaginous rudiments of the *cricoid* and *arytenoid cartilages*, though at first continuous with each other, become differentiated by the appearance of a separate cartilaginous centre for each arytenoid and an incomplete ring (for a time deficient behind) for the cricoid. The cricoid thus resembles developmentally a tracheal ring, to which it probably corresponds morphologically. Chondrification proceeds in the cricoid from two centres, one on each side. These centres soon unite ventrally, but chondrification proceeds more slowly into the posterior lamina. The *corniculate cartilages* are merely detached portions of the arytenoid cartilages.

Trachea.—The trachea is developed from the intermediate portion of the respiratory tube.

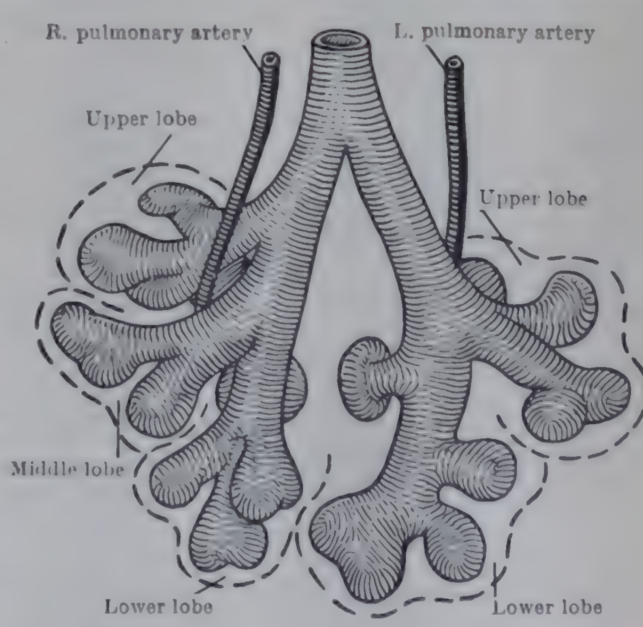

FIG. 609.—DEVELOPMENT OF LOBES OF LUNGS IN 14 MM. HUMAN EMBRYO. (From Arey, 1946, after Ask.)

Lungs.—The bronchi and lungs are developed from the two diverticula at the caudal end of the laryngo-tracheal groove and from the mesodermal tissue into which these grow. Both diverticula elongate, and almost immediately subdivide into vesicles—the right into three

and the left into two - thus early indicating the lobes of the respective lungs (Fig. 609). As the primitive respiratory tube lies in the median plane in the posterior attachment of the septum transversum, each pulmonary diverticulum grows laterally and backwards into the corresponding pleural canal (pericardio-peritoneal canal), *i.e.*, the future pleural cavity, carrying before it a covering of mesoderm. From this mesoderm are derived the blood-vessels and other tissues which build up the lung; from the entodermal lining of the primitive respiratory tube the epithelial lining of the air-passages is derived. The entodermal pulmonary diverticula branch and re-branch and push their way into the pulmonary mesoderm until the complete bronchial tree is formed (Fig. 610).

When the ramification is complete, the bulbous ends of the various branches represent alveoli clustering around the alveolar ducts into which each terminal bronchiole divides.

At first the lung is devoid of air-cells, but between the sixth month and full-term the alveoli make their appearance on the alveolar ducts. By the close of the fourth month of intra-uterine life the columnar cells which line the trachea and bronchi have become ciliated.

Growth of the lung is not interrupted at birth, but since the terminal branches are now expanded by air there must be a new form of budding. At any stage of post-natal growth the terminal branches bear evidence, in the alveoli projecting from them, that they were once alveolar ducts. These alveoli become obliterated by the advance of the muscle-sheet which extends over the length of the alveolar duct (Fig. 605).

It was the general belief that the cuboidal cells, which at one stage of fœtal life form a

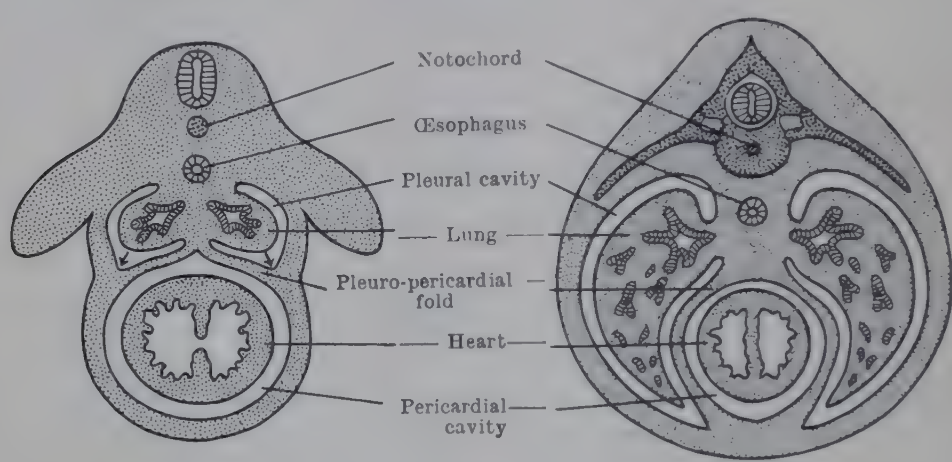

FIG. 610.—VENTRAL EXTENSION OF PLEURAL CAVITIES DURING DEVELOPMENT. (Schematic ; after Patten, 1946.)

continuous lining for the alveoli of the lungs, become flattened at birth but remain in continuity. Recent studies, however, indicate (*a*) that towards the end of fœtal life the cells that line the last two generations of the entodermal tree become discontinuous and that capillaries push their way between these cells and help to line the alveoli; (*b*) that at the time of birth the alveolar ducts, the air-sacs, and the alveoli are lined with a capillary network —the epithelial cells persisting only singly or in isolated groups; and, further, (*c*) that in late fœtal life the lungs are not gland-like and completely unexpanded but have an opened-up appearance (which is reasonable, since respiratory movements take place during fœtal life) and though they sink in water, it is because they contain amniotic fluid, not air.

Pleural Cavities.—In the embryo there is a continuous body-cavity or cœlom. Its head-ward part, which becomes the pericardial cavity, communicates by means of a right and a left pleuro-pericardial opening with the pleural passage (pericardio-peritoneal canal) on each side, and these lead tailwards into the peritoneal cavity.

When the heart and pericardium are carried ventro-caudally, the pleural passages become greatly elongated, and their cephalic ends now open into the dorsal part of the pericardial cavity by the pleuro-pericardial openings, and their caudal ends open into the peritoneal cavity by the pleuro-peritoneal openings. As the common cardinal vein (duct of Cuvier) runs ventrally towards the septum transversum to enter the heart, it crosses lateral to the pleural passage.

The growing lung-bud pushes the medial wall of the pleural passage laterally, immediately caudal to this vein, and, after passing lateral to the vein, the bud expands within the body-wall in three directions: *headwards*, on the lateral side of the common cardinal vein, to form the apical part of the lung; *ventrally*, to form the anterior part, which thus detaches or dissects the pericardium and phrenic nerve from the body-wall (Fig. 610); and *tailwards*, to form the base of the lung. (See also p. 93 and Figs. 108-110.

The pleural cavity enlarges within the body-wall to keep pace with the ever-growing lung, and its openings into the peritoneal and pericardial cavities become closed. The pleuro-peritoneal opening is closed by the pleuro-peritoneal membrane which grows across it from the dorsal mesentery and septum transversum to a ledge formed on the body-wall caudal to the base of the lung—in post-natal anatomy its site is the vertebro-costal trigone (p. 452). Closure occurs earlier on the right side, and the liver covers the right opening: hence congenital diaphragmatic hernia, due to failure to close, is rare on the right side but not on the left.

The pleuro-pericardial opening is closed by the pleuro-pericardial membrane which grows medially across it, from the laterally situated ridge which contains the common cardinal vein to the medial wall of the opening just cranial to the lung-bud. Closure is assisted by adhesion of the surfaces of the pleural passage. The opening is at first caudal to the common cardinal vein, but, with the descent of the heart and septum transversum, it later lies dorsal. In post-natal anatomy its site is between the superior vena cava and the root of the lung. As the phrenic nerve lies alongside the vein, it also is ventral to the opening. Failure of the right opening to close is unknown in Man, due presumably to the persistence of the right superior vena cava, but the left opening occasionally remains widely open; in fact, it may be so dilated that the whole left side of the heart is in contact with the lung.

UROGENITAL SYSTEM

By Cecil P. Martin, M.A., M.B., Sc.D.

Professor of Anatomy, McGill University, Montreal

The **Urogenital System** is divided into:—(*a*) the *urinary organs* proper, which are concerned with the secretion, temporary storage, and discharge of the urine; and (*b*) the *reproductive* or *genital organs*, which arise from the same embryonic tissues as the urinary organs and retain an intimate relationship to them.

URINARY ORGANS

The urinary organs are:—the **kidneys**, where the urine is elaborated from the blood, the **ureters**, which convey the urine from the kidneys to the urinary bladder, the **urinary bladder**, where the urine is temporarily stored, and the **urethra**, by which it is voided.

KIDNEYS

Form and Size.—The kidneys are a pair of bean-shaped organs, brownish-red when fresh, and of a glistening appearance due to the fact that each of them is covered with a delicate fibrous capsule which is close-fitting though easily stripped off. They are approximately symmetrical in size and shape. Each kidney is about $4\frac{1}{2}$ inches (11 cm.) long, 2 inches (5 cm.) wide, and about $1\frac{1}{4}$ inches (3 cm.) thick; and it weighs about $4\frac{1}{2}$ ounces. It possesses an *upper* and a *lower end* or pole (of which the upper is generally the more bulky), an *anterior* and a *posterior surface*, and a *medial* and a *lateral border*. The lateral border is uniformly convex from the upper to the lower pole; the medial border is convex above and below but in the middle it forms a deep concavity which leads into a hollow that extends almost half-way through the kidney. This hollow is known as the **sinus** of the kidney; and the entrance into the sinus is called the **hilum**. The renal artery enters the sinus through the hilum; the renal vein and the upper, expanded part of the ureter leave the sinus by the same route.

Position.—Each kidney lies against the medial and posterior walls of a deep depression on the posterior wall of the abdomen near the vertebral column. In this region the vertebral column, partly covered by the psoas major muscle, projects forwards into the abdominal cavity leaving a deep gutter on each side. As these gutters pass downwards, they slope slightly forwards and laterally because the posterior abdominal wall itself slopes forwards and the psoas major muscles increase in bulk from above downwards. The gutters therefore are deep and fairly close together above but are shallow and farther apart below (Figs. 612 and 615). Consequently, the long axis of each kidney is not quite vertical but slopes laterally and slightly forwards from above downwards. Moreover, as the kidneys lie against the medial walls as well as the posterior walls of the gutters, they are slightly rotated on their long axes; their anterior surfaces are directed, therefore, laterally as well as forwards and their posterior surfaces medially as well as backwards. Likewise, the medial border of each kidney really faces medially and forwards, and the lateral border faces laterally and backwards (Fig. 612).

The two kidneys are not quite symmetrical in position; almost always the left is about half an inch higher than the right; and it is therefore slightly more medial, on account of the slope of the gutters in which they lie (Fig. 615). The

level of each kidney, however, varies slightly both with the respiratory movements and with posture, but the range of this normal physiological movement does not exceed an inch. During quiet respiration in the recumbent attitude, the hilum of the left kidney is approximately in the transpyloric plane about $1\frac{1}{2}$ inches from the median plane of the body, or about a finger's breadth medial to the tip of the ninth costal cartilage, and the hilum of the right kidney is about half an inch below this point. The lower pole of the kidney is about 2 inches from the median plane—the left in the subcostal plane and the right half an inch below this plane.

With reference to the posterior surface of the body the hilum of the left kidney is at the level of the spine of the first lumbar vertebra, or at the level of the line where the lateral border of the sacro-spinalis muscle meets the twelfth rib, and the lower pole is 2 inches or less above the highest point of the iliac crest (Fig. 614). Corresponding points on the right kidney are about half an inch lower.

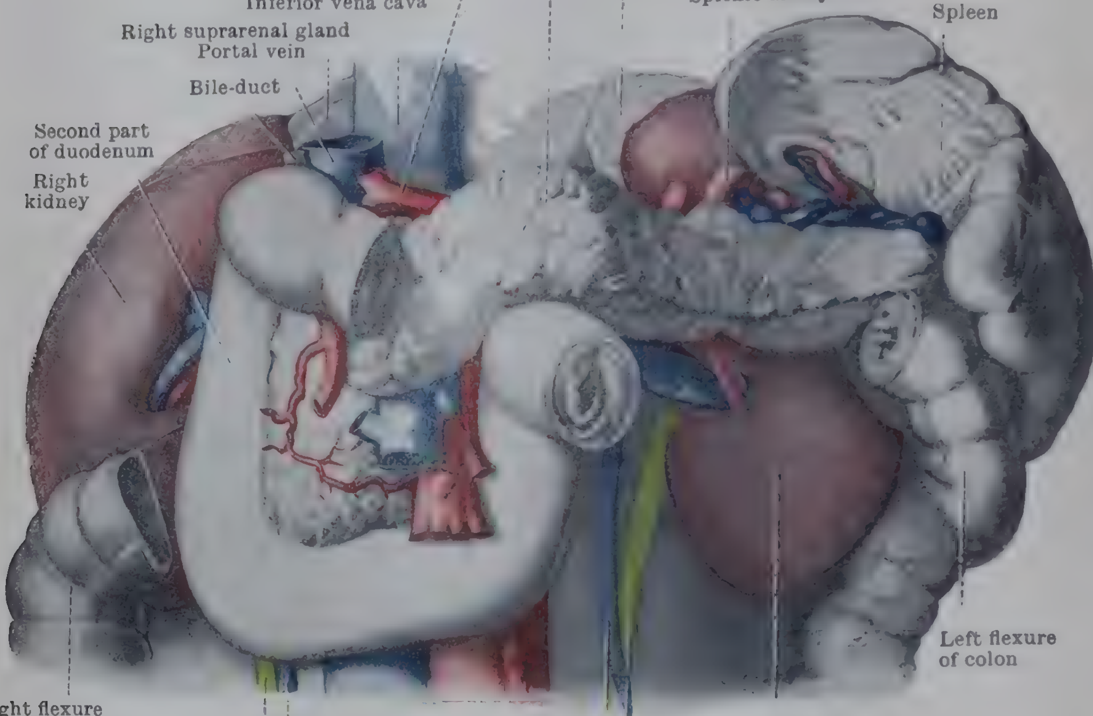

FIG. 611.—DISSECTION TO SHOW THE RELATIONS OF THE KIDNEYS. The greater part of the stomach has been removed by an incision made close to the pylorus. The transverse colon has been taken away, and the small intestine has been cut across close to the duodeno-jejunal flexure. (From a model by Birmingham.)

Renal Fascia and Fat.—Each kidney has a peculiarly intimate relationship to the corresponding suprarenal gland and is enclosed with it in a common investment of weak fascia, known as the **renal fascia**, one layer of which covers the front and the other the back of the enclosed organs. Outside this investing fascia and between it and the kidney (surmounted by the suprarenal gland) there is a variable amount of fat called the **renal fat**. The fat outside the renal fascia is known as *pararenal fat*; it is most abundant behind the lower end of the kidney. The fat within the fascia is called *perirenal fat* and is most abundant at the margins of the organ; it is traversed by weak fibrous strands which connect the renal fascia with the capsule of the kidney.

The two layers of the renal fascia fuse together a short distance above the suprarenal gland and join the fascia on the under surface of the diaphragm; lateral to the kidney also they fuse together and join the transversalis fascia. Below the kidney the two layers remain separate, the anterior gradually fading into retroperitoneal areolar tissue and the posterior joining the fascia over the iliacus muscle. The posterior layer, passing over the quadratus lumborum, is attached medially to the fascia of the psoas major at its posterior border. As it approaches the medial border of the kidney it then splits into two laminae: one turns laterally into the hilum of the kidney and is attached to the back

of the pelvis of the ureter; the other lamina blends with the psoas fascia and thereby gains an attachment to the bodies of the vertebræ just in front of the muscle. The anterior layer of the renal fascia extends across the aorta and inferior vena cava as a thin layer as far up as the origin of the superior mesenteric artery; above this level it loses itself in the connective tissue around the coeliac axis. From the anterior layer a distinct lamina also passes backwards medial to the kidney and blends with the anterior lamina of the posterior layer. This lamina is pierced by the renal vessels and the ureter (Martin, 1942); and its presence accounts for the limitation of perirenal effusions to one side of the body and for the explanation given by Mitchell (1939) that the anterior layer as well as the posterior is attached to the bodies of the vertebræ. See also the description in the Surface and Surgical Section (p. 1508), based on Mitchell (1950), and compare Figs. 612 and 1224.

Posterior Relations of Kidneys (Figs. 612-615).—If the kidney, together with the corresponding suprarenal gland and surrounding fascia and fat, is removed from the posterior abdominal wall, the boundaries of the gutter in

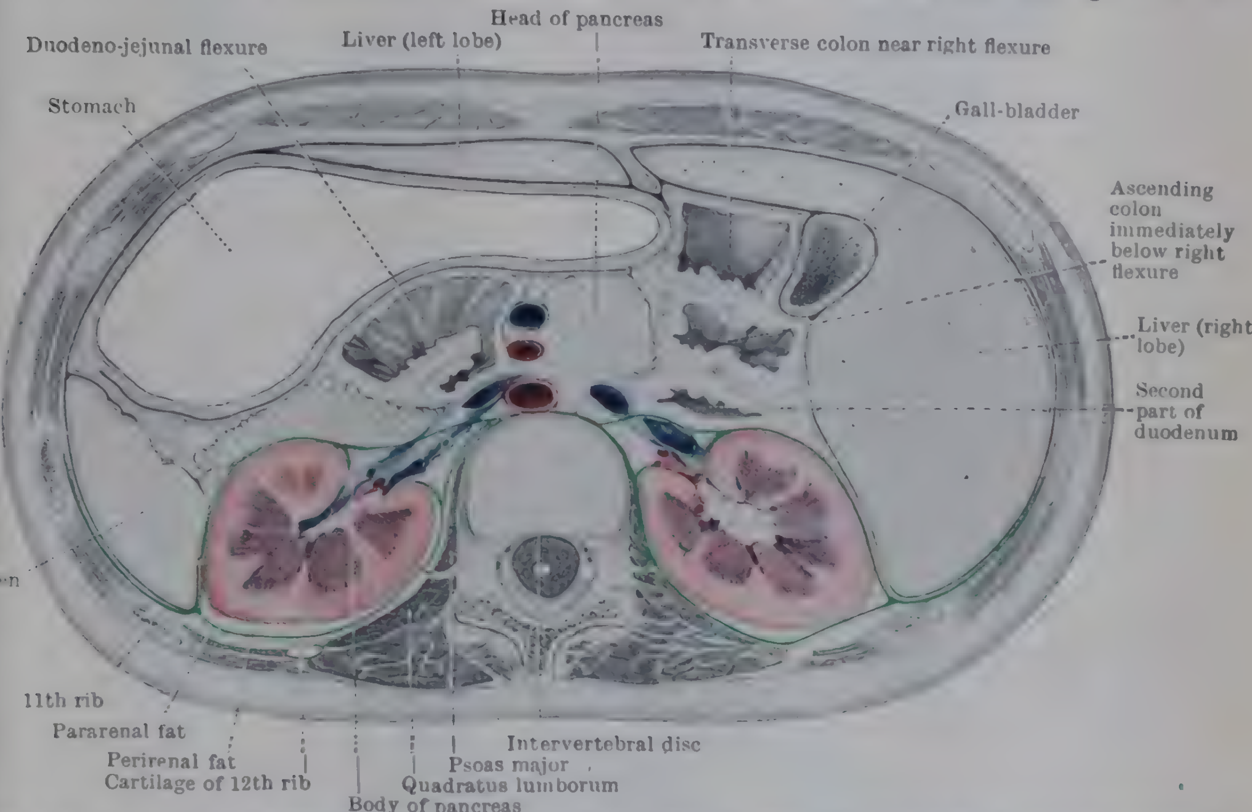

FIG. 612.—TRANSVERSE SECTION THROUGH ABDOMEN OF A CHILD. The position and the general relations of the kidneys are well seen, and the arrangement of the renal fascia is indicated. Cf. Fig. 1224, p. 1507. The fascia is coloured green.

which it lay can be seen. The medial boundary is formed by the psoas major muscle; and the medial part of the kidney overlaps the lateral side of this muscle. Lateral to this, and forming the posterior relation of most of the kidney, lies the quadratus lumborum muscle, and lateral to this again the aponeurosis of the transversus abdominis muscle, on to which the lateral part of the kidney extends for a short distance. But towards the upper end of the gutter the medial and lateral arcuate ligaments cross the psoas major and quadratus lumborum respectively, and above this line the diaphragm, arising from the ligaments, forms the uppermost part of the walls of the gutter. The supero-lateral third of the kidney therefore lies in front of the diaphragm.

Emerging from under the lower border of the lateral arcuate ligament and running downwards and laterally across the front of the quadratus lumborum muscle is the subcostal nerve accompanied by its vessels; and a little lower down the ilio-hypogastric and, below it, the ilio-inguinal nerve both emerge from the lateral side of the psoas major and run a parallel course. The subcostal and ilio-hypogastric nerves pierce the aponeurosis of the transversus abdominis a short distance lateral to the quadratus lumborum, and the ilio-inguinal nerve pierces it a little farther forwards (Fig. 615).

In this region, some bony structures can easily be felt through the diaphragm

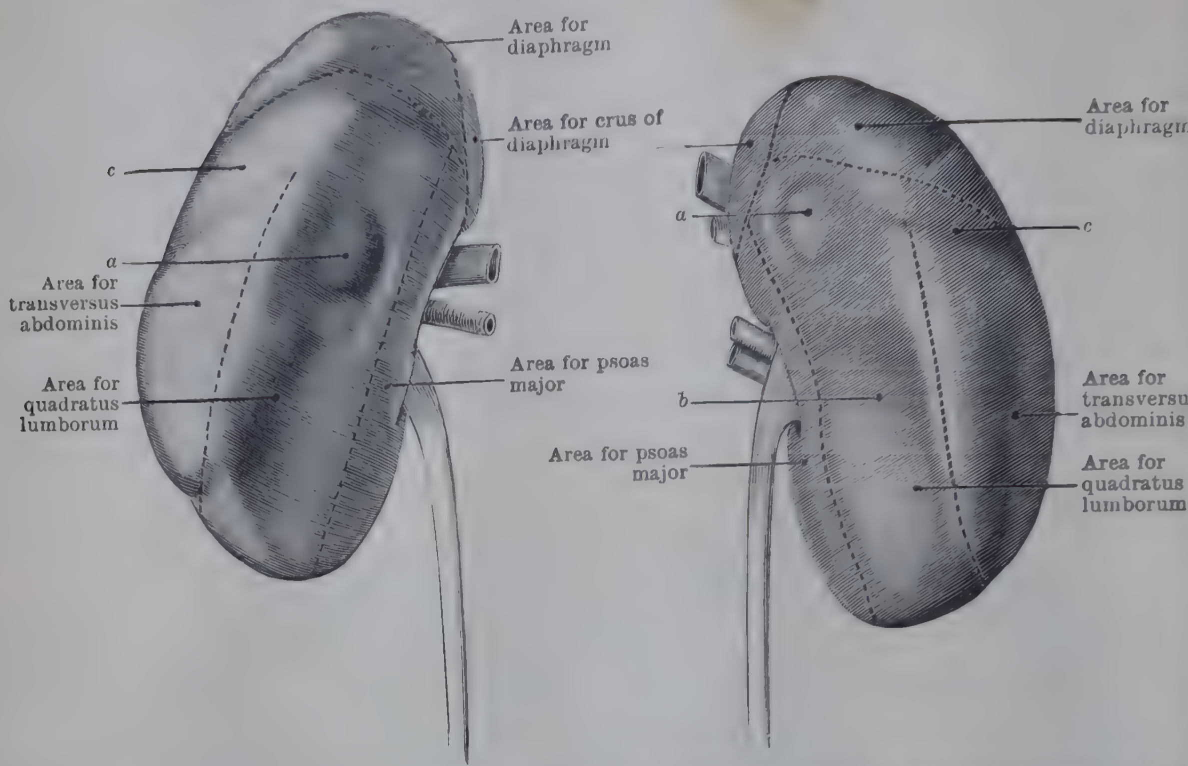

Fig. 613.—Posterior Surfaces of the Kidneys. The dotted lines mark out the areas in contact with muscles of the posterior abdominal wall.

a and *b*. Depressions corresponding to transverse processes of first and second lumbar vertebræ.
c. Depression corresponding to the twelfth rib.

and quadratus lumborum. The twelfth rib runs downwards and laterally behind the diaphragm, and its lateral part passes for a variable distance into the abdominal

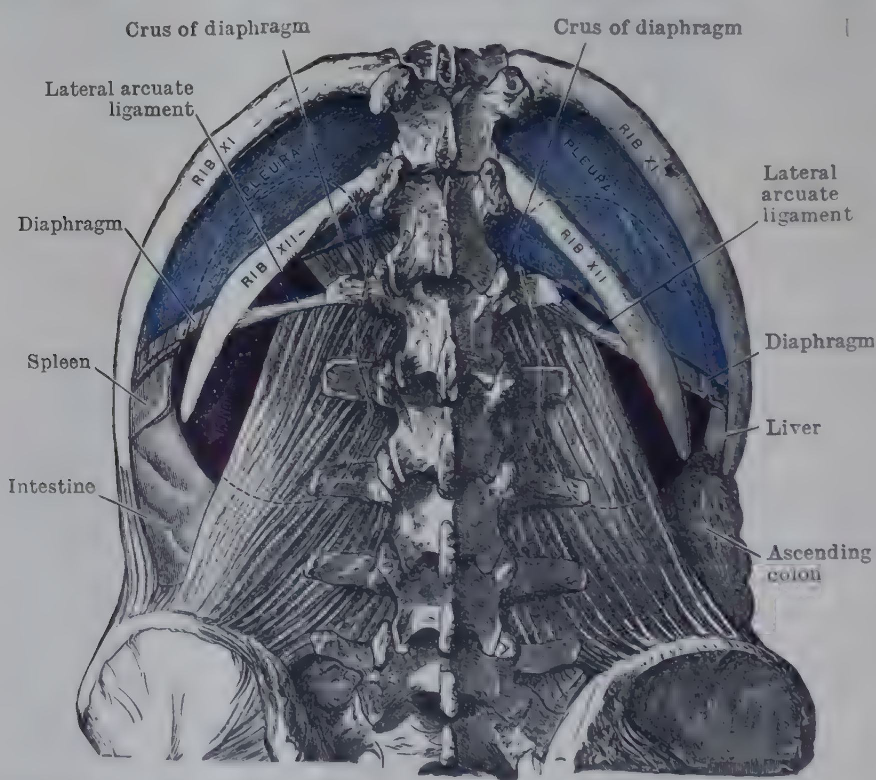

Fig. 614.—Dissection from Behind to show the Relation of the Two Pleural Sacs to the Kidneys. The outline of the concealed portions of the kidneys (which are more alike in level than usual) is indicated by dotted lines.

wall just lateral to the upper end of quadratus lumborum: the transverse process of the first lumbar vertebra lies at the level of the junction of the medial and

lateral arcuate ligaments, and those of the other vertebræ at correspondingly lower levels—their tips being behind the medial edge of the quadratus lumborum. If the kidneys have been hardened *in situ* shortly after death in a thin subject, their posterior surfaces are generally moulded by the muscles and bony structures against which they lay (Fig. 613), but stress should not be laid on this fact, for it is merely a post-mortem phenomenon and can easily suggest that the kidneys are less mobile than they are. Moreover, it is of the utmost importance to realize that the part of the twelfth rib which lies behind the diaphragm is separated from the diaphragm by the costo-diaphragmatic recess of the pleura, which extends down as far as a line drawn from the middle of the twelfth rib to a point midway between

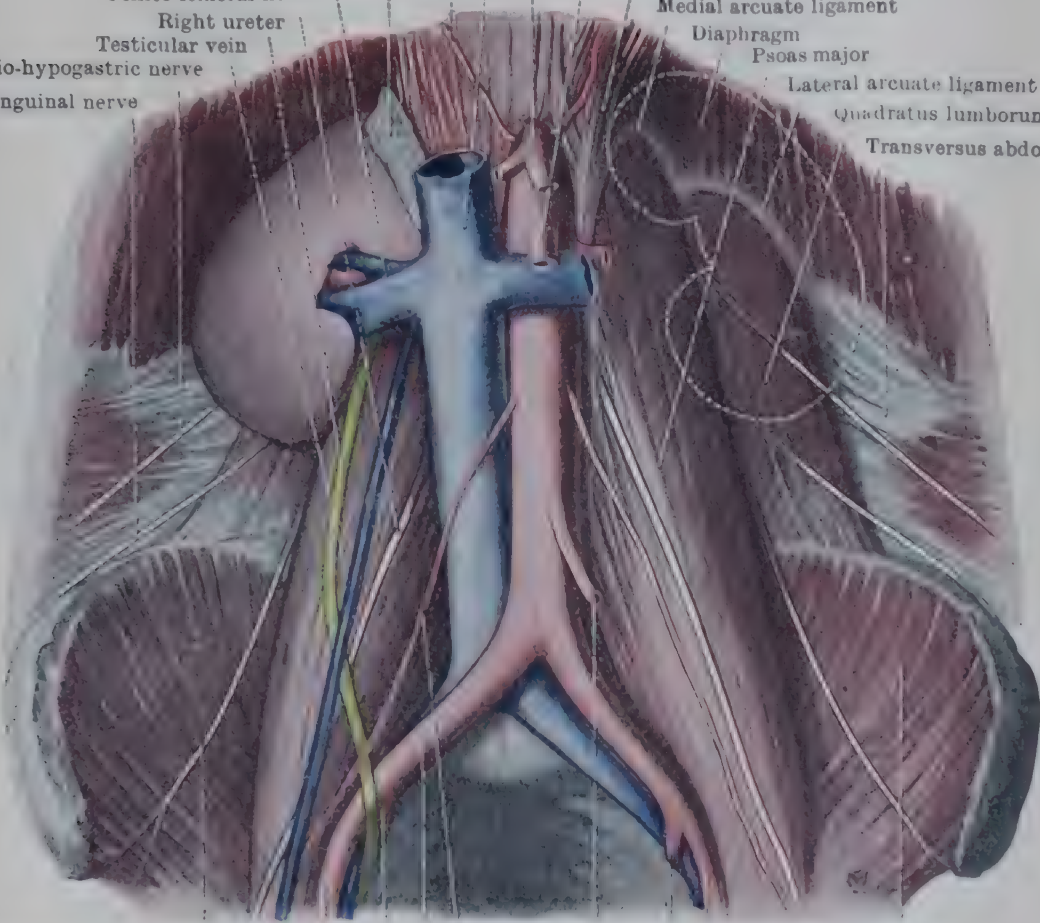

FIG. 615.—DISSECTION TO SHOW THE RELATION OF KIDNEY AND URETER TO THE POSTERIOR ABDOMINAL WALL. The dotted outline indicates the position of the left kidney

the head of the twelfth rib and the transverse process of the first lumbar vertebra (Fig. 614). The pararenal fat behind the upper part of the kidney is therefore separated from the pleura by only a very thin sheet of diaphragm; and as this part of the diaphragm is often partly deficient in the vertebro-costal trigone, especially on the left side of the body, the pararenal fat and the pleura may be in direct contact.

More remote posterior relations of the kidneys are as follows:—The middle layer of the lumbar fascia extends medially behind the quadratus lumborum as far as the tips of the transverse processes of the lumbar vertebræ; the upper three lumbar arteries run laterally behind the quadratus lumborum and then pierce the aponeurosis of transversus abdominis (the fourth lumbar artery usually passes in front of the quadratus lumborum but at a level that is below the position of the dead and immobile kidney found in dissecting-room material). Farther back

still, the sacro-spinalis muscle covers the transverse processes of the lumbar vertebræ and overlaps the quadratus lumborum; and it in its turn is covered behind by the posterior layer of the lumbar fascia giving origin to the serratus posterior inferior and the latissimus dorsi muscles.

Anterior Relations of Kidneys (Figs. 611 and 616).—A small portion of each kidney, near the upper pole, is covered by the corresponding suprarenal gland, part of which lies on its anterior aspect and extends downwards for a short distance along its medial border, the left generally to a slightly greater extent than the right. The other anterior relationships of the two kidneys are quite different; and, as already pointed out, all other organs in front of the kidney have a less intimate relationship to it, for they all lie outside the renal fascia, whereas the suprarenal gland is enclosed along with the kidney inside this fascia.

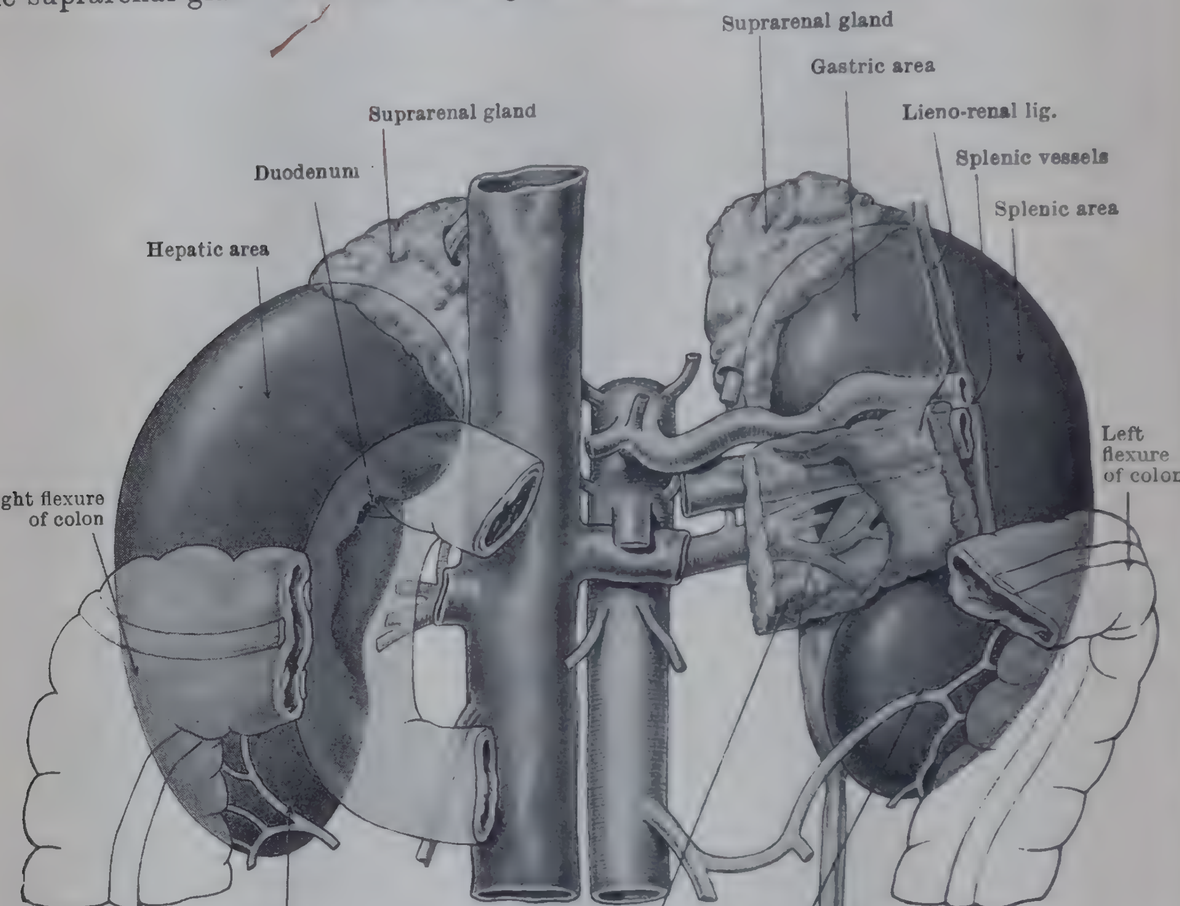

FIG. 616.—DIAGRAM OF ANTERIOR RELATIONS OF KIDNEYS.
The pancreas and certain other parts are shown as if transparent.

Anterior Relations of Right Kidney.—Below the area covered by the suprarenal gland, the anterior surface of the right kidney for about two-thirds of its extent is in relation with the back of the right lobe of the liver. The uppermost part of this hepatic area is usually related to the bare area of the liver, from which it is separated by some loose areolar tissue, but most of the hepatic area is covered by peritoneum of the greater sac which is reflected from the back of the liver on to the front of the kidney. Below the hepatic area, the region adjacent to the lower pole is in relation with the right flexure of the colon, and the region adjoining the hilum is covered to a variable extent by the second part of the duodenum, both these organs being separated from the kidney by loose areolar tissue. Below and medially, the peritoneum is reflected forwards from the hepatic area to cover the colon and the second part of the duodenum. At the extreme lower end of the kidney there is sometimes a small gap between the colic and duodenal areas, and, when this is present, it is covered with peritoneum of the greater sac that passes up from the posterior abdominal wall on to the front of the kidney and separates this small area from coils of small intestine.

Anterior Relations of Left Kidney.—Below and lateral to the area covered by the suprarenal gland there is a small triangular region covered with peritoneum of the lesser sac which passes down from the front of the suprarenal gland, and this region is separated from the posterior surface of the stomach by the lesser sac of the peritoneum. Below, this gastric area is bounded by the body of the pancreas, which lies across the middle of the kidney; and laterally the area is bounded by the line of attachment of the lieno-renal ligament, which runs approximately from the upper pole of the kidney to the junction of the middle and lower thirds of its lateral border. The peritoneum which covers the gastric area passes downwards on to the front of the body of the pancreas; from the pancreas it passes downwards and forwards as the anterior layer of the transverse mesocolon, while laterally it is reflected forwards as the medial layer of the lieno-renal ligament. The body of the pancreas is separated from the kidney by loose areolar tissue in which the splenic vein runs medially, while the artery runs its tortuous course along the upper border of the pancreas. The area lateral to the line of attachment of the lieno-renal ligament is separated from the spleen by the peritoneum of the greater sac which passes on to it from the posterior abdominal wall and is then reflected forwards as the lateral layer of the lieno-renal ligament. Below the pancreatic area, the lateral part is covered by the left flexure of the colon and the upper part of the descending colon—separated by loose areolar tissue—and the medial part by the peritoneum of the greater sac which passes up from the posterior abdominal wall to be reflected forwards and downwards as the posterior layer of the transverse mesocolon and to pass laterally on to the left flexure and the descending colon. This medial area is in relation to coils of jejunum in front of the peritoneum and to the ascending branch of the superior left colic artery, which crosses it behind the peritoneum. The obliquity of the anterior surface of the kidney has already been pointed out; and, if this is borne in mind, it will be realized that though the spleen and left flexure of the colon are described as anterior relations of the left kidney, they are really more lateral than anterior.

Medial Relations of Kidneys (Figs. 612 and 615).—Medial to each kidney is the corresponding psoas major muscle and psoas minor (if present); and along the medial margin of the psoas lies the abdominal part of the sympathetic trunk. On a more anterior plane, each kidney is related medially to the corresponding suprarenal and renal vessels, ovarian or testicular vein, and upper end of ureter. More anteriorly still there is the inferior vena cava on the right side and the abdominal aorta on the left.

Sinus of Kidney (Figs. 617 and 619).—The sinus is the hollow within the kidney, and its long axis corresponds to that of the kidney itself. Its walls are thick, being formed by the substance of the kidney, and, except where they are covered by the calyces of the ureter, they are lined with a continuation of the capsule of the kidney, which is reflected into the sinus over the lips of the hilum. The floor of the sinus is not even but presents a series of small conical elevations, called **renal papillæ**, which vary from six to fifteen in number. Radiating from each papilla there are several small ridges of kidney substance separated by depressed areas. The blood-vessels and nerves enter and leave the kidney by piercing the depressed areas. On the summit of each renal papilla there are many minute openings, which are the terminal apertures of the secretory tubules of which the kidney is mainly composed; the urine escapes through these foramina into the calyces of the ureter. The cavity of the sinus is filled with fat, embedded in which lie the calyces of the ureter, branches of the renal artery and tributaries of the renal vein. The artery usually branches and the tributaries of the vein unite a short distance outside the hilum; and, within the sinus, the tributaries of the vein are most anterior, while farther back are the calyces of the ureter, with branches of the artery both in front and behind.

Fixation of Kidneys.—The kidneys are held in position partly by the renal vessels and the surrounding fat and fascia, but mainly by the tension of the muscles of the anterior abdominal wall transmitted through the other abdominal viscera and acting against the inclined plane formed by the posterior abdominal wall.

Kidney in Section.—Sections through the kidney (Figs. 617 and 619) show that it is composed to a large extent of a number of conical masses—known as **renal pyramids**. The pyramids constitute, collectively, the **medulla** of the kidney, and are arranged with their bases directed towards the surface and their apices projecting into the lesser calyces of the pelvis of the ureter in the renal sinus, where they form the renal papillæ. The pyramids are more numerous than the papillæ, two or three usually ending in each papilla in the middle part of the kidney, and sometimes as many as six or more in each papilla near its ends. The bases of the pyramids are separated from the surface by a layer called the **cortex** of the kidney. The cortex not only covers over the bases of the pyramids, but also sends in prolongations, known as **renal columns**, between the pyramids, towards the sinus. In section, both parts have a striated appearance, but the cortex is less markedly striated and is usually different in colour. The **basal part** of each pyramid appears to be composed of alternate dark and light streaks, while the **papillary part** is often of a lighter colour, and is very faintly striated.

The larger blood-vessels are seen between the pyramids; and some of their main branches are visible passing across the bases of the pyramids.

In the fœtus and young child, and sometimes, though much less distinctly, in the adult, the surface of the kidney is marked by a number of grooves that divide it into polygonal areas (Fig. 679, p. 802) The areas represent the **lobes** or **reniculi** of which the kidney is originally composed, and each corresponds to one papilla with its pyramids and surrounding cortex.

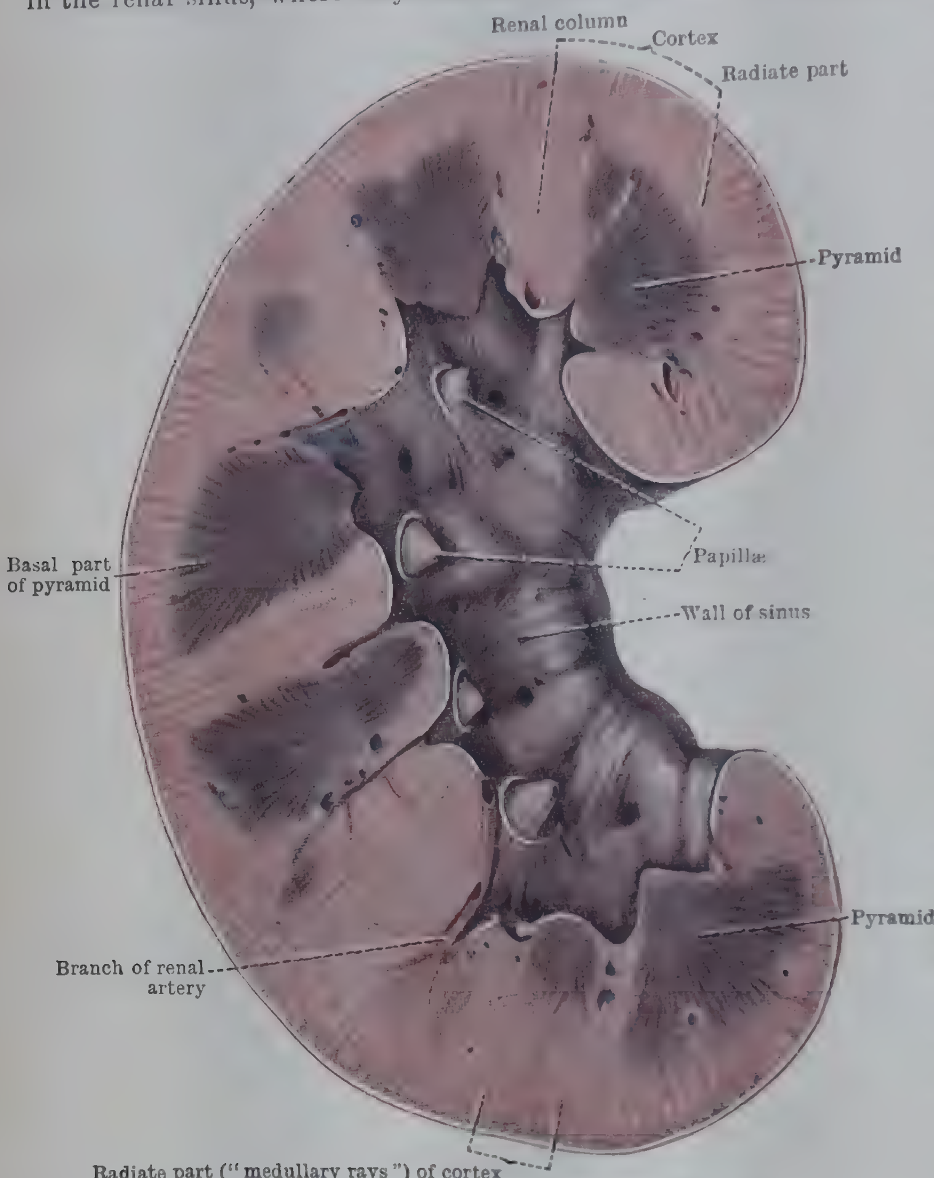

FIG. 617.—LONGITUDINAL SECTION THROUGH THE KIDNEY.

The vessels and fat have been removed to show the wall of the sinus of the kidney. The points where the vessels enter the substance of the kidney are seen as holes in the wall of the sinus.

An examination with an ordinary pocket lens shows that it is the lighter striæ of the bases of the pyramids which are continued into the cortex. As they pass through the cortex towards the surface of the kidney the striæ become less distinct, and appear, when cut longitudinally, as separate ray-like prolongations carried outwards from the bases of the pyramids. The parts of the cortex which seem in this way to be continuations of the medulla are called "medullary rays" or the **radiate part** of the cortex. The part of the cortex which intervenes between them is darker in colour and forms what is known as the **convoluted part** or "labyrinth". The appearance presented by the cortex in section varies much according to the plane in which the section has been taken. If the section is parallel to the axis of a pyramid, the medullary rays will appear as isolated streaks directed from the base of the pyramid towards the surface of the kidney, and separated from one another by narrow strips of the convoluted part. In sections made at right angles to the axis of a pyramid, or cutting this axis obliquely, the convoluted part presents the appearance of a continuous net the meshes of which are occupied by the rays, and the rays now exhibit circular or oval outlines. In a similar manner sections through the bases of the pyramids differ much in appearance according to the plane in which they are cut.

Kidney-Tubules.—The glandular substance of the kidney is composed of a vast number of minute **renal tubules**, each of which has an exceedingly complicated course (Fig. 618). The wall

of each tubule consists throughout of a basement membrane and of an epithelial lining, but the lumen of the tubule and the character of the epithelium vary much in its different parts. Every tubule begins in a thin-walled spherical dilatation, known as a **glomerular capsule**, into which a complicated loop of capillary blood-vessels or **glomerulus**, covered by a reflexion of the delicate wall of the capsule, is invaginated (Fig. 618). The capsules with their enclosed capillaries are called **renal corpuscles**, and they are all placed in the convoluted portion of the cortex, where they may be recognized as minute red points just visible to the unaided eye and best marked when the renal vessels are congested. The part of the tubule that leads from the capsule—*first convoluted tubule*—is very tortuous and lies within the convoluted part of the cortex. Passing from the convoluted part, the tubule enters a medullary ray, in which its course becomes less complicated, and here it receives the name of *spiral tubule*. Leaving the medullary ray, the tubule enters the basal portion of the pyramid, and, diminishing in diameter, it pursues a straight course towards the apex of the pyramid, forming the so-called *descending limb of Henle's loop*. Within the apical portion of the pyramid the tubule suddenly bends upon itself, forming the *loop of Henle*, and, reversing its direction, it passes back again through the base of the pyramid into a medullary ray of the cortex as the *ascending limb of Henle's loop*. The ascending limb exhibits a slight spiral twisting. Leaving the medullary ray again, the tubule once more enters the convoluted part of the cortex, where its outline becomes so uneven that the name *irregular* or zigzag *tubule* is applied to it. While still within the convoluted part, its contour having acquired a more uniform appearance, the tubule receives the name of *second convoluted tubule*; this tubule finally ends in a short *junctional tubule*, which passes back into a medullary ray and joins a *collecting tube*. Each collecting tube receives numerous renal tubules, and pursues a straight course through a medullary ray of the cortex and the pyramid. Finally, several collecting tubes, uniting together, form an *excretory tube*, which opens on the summit of a renal papilla into a calyx of the ureter by one of the minute foramina already described. In microscopic sections the various portions of the renal tubule may be distinguished by the position which they occupy and by the character of the lining epithelium.

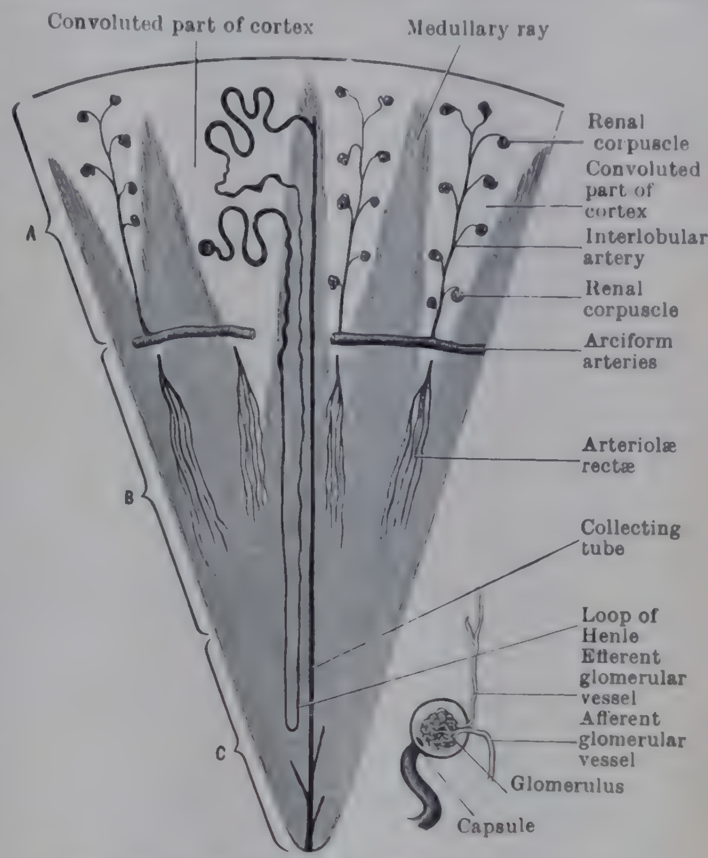

Fig. 618.—Diagrammatic Representation of the Structures forming a Kidney-Lobe.

In the middle part of the figure the course of one of the renal tubules is indicated, and, on each side of that, the disposition of the larger arteries. A, Cortex; B, Basal portion, and C, Papillary portion of pyramid.
The small diagram illustrates the connexions of the structures that compose a renal corpuscle.

Supporting Tissue of Kidney.—The tubules and the blood-vessels are all united together by a very small amount of areolar tissue which completely surrounds each tubule and blood-vessel and binds it to its neighbours. It has been found possible to obtain an accurate idea of the arrangement of this areolar tissue by submitting thin sections of the kidney to the action of certain digestive fluids. When that is done the tubules and blood-vessels are removed, and the areolar tissue stroma is left behind. The areolar tissue thus revealed is seen to form a continuous network, the spaces in which faithfully reproduce the outlines and the arrangement of the renal tubules. The network of the stroma is continuous with the capsule of the kidney.

Vessels and Nerves of Kidney.—The **renal arteries**, one on each side, arise directly from the aorta. The left is usually slightly higher than the right and they are both large vessels relative to the size of the kidneys. Each artery lies behind the corresponding renal vein, and at or just outside the hilum of the kidney it divides into three or four branches, one of which passes behind the upper, expanded part of the ureter while the others lie in front of the ureter, between it and the renal vein. Within the sinus each branch divides further. Having entered the substance of the kidney, the larger arteries lie in the intervals between the pyramids and are called **interlobar arteries**. These vessels divide and form a series of incomplete arterial arches—the **arciform arteries**—which pass across the bases of the pyramids. Although we speak of arterial arches, it must be understood that no anastomosis between the branches of the interlobar arteries actually takes place, but that each artery which enters the wall of the kidney-sinus is an 'end-artery' with an isolated distribution. The arterial arches give off a number of vessels which pass through the convoluted part of the cortex towards the surface

of the kidney; they are known as the **interlobular arteries**, and they lie at very regular intervals. From them a number of short branches arise, termed **vasa afferentia**, each of which proceeds to the dilated extremity, or capsule, of a renal tubule. There, the vas afferens breaks up into a much-convoluted capillary mass, called a *glomerulus*, which is contained within the invagination of the capsule. The little vessel—**vas efferens**—which issues from the glomerulus, instead of running directly into a larger vein, breaks up, after the manner of an artery, into capillaries which supply the convoluted tubules of the labyrinth and the longitudinal tubules of the medullary rays. At the bases of the pyramids, where the longitudinal tubules pass into the pyramids, the efferent vessels of some of the glomeruli do not break up immediately into capillaries but pass as fine arterioles into the pyramids and then break up into a capillary network around the tubules of the pyramid. These fine arterioles, known as the **arteriolæ rectæ**, are just visible to the naked eye, and they give the bases of the pyramids their striated appearance (Fig. 618). It has recently been shown that near the base of the pyramids there are some large glomeruli in which the afferent and efferent vessels are of equal calibre. These glomeruli are apparently non-functional and from their efferent vessels the arteriolæ rectæ arise. In certain conditions the renal blood-flow can be shunted through the vessels of these non-functional glomeruli and the arteriolæ rectæ directly from the renal artery into the renal veins without passing through the functional glomeruli of the cortex proper (Trueta *et al.*, 1947). Franklin (1949) gives an account of the history of research on the renal circulation.

The fibrous capsule of the kidney receives minute branches from the interlobular arteries, some of which pierce the capsule and communicate by capillaries with the vessels of the renal fat.

Veins corresponding to the interlobular arteries and arteriolæ rectæ collect the blood from the capillaries around the tubules and unite to form a series of complete arches across the bases of the pyramids. From the venous arcades, vessels arise which traverse the intervals between the pyramids and reach the sinus of the kidney, where they unite to form the tributaries of the renal vein. Some small veins in the superficial part of the cortex communicate through the fibrous capsule with minute veins in the renal fat. The main tributaries issue from the sinus and unite to form the **renal vein**, which runs a direct course to end in the inferior vena cava.

Variations in the renal vessels are common. Supernumerary arteries and veins or supernumerary branches of the renal artery and vein are frequent. The abnormal vessel may enter or leave the kidney within the sinus or at some other point. Small accessory renal veins from the lower pole of the kidney are especially common.

The **lymph-vessels** of the kidney end in the aortic lymph-glands (p. 1416).

The **nerves** of the kidney are derived from the renal plexus and accompany the branches of the artery. Their branches form regular plexuses on the walls of the arteries and renal tubules, and the terminations of the nerves among the epithelial cells of the tubules have been demonstrated.

From clinical evidence it would appear that the afferent nerve-fibres which supply the kidney are connected with the tenth, eleventh, and twelfth thoracic nerves.

Variations.—A marked difference in the size of the two kidneys is sometimes observed, a small kidney on one side of the body being usually compensated for by a large kidney on the opposite side. Congenital absence of one or other kidney is recorded. A few cases are on record in which an extra kidney was found on one or other side.

Traces of the superficial lobulation of the kidney, present in the fœtus and young child, are often retained in the adult.

Horseshoe-kidney is a not infrequent abnormality. In such cases the two kidneys are united at their lower ends across the median plane by a connecting piece of kidney-substance. The amount of fusion between the two kidneys varies much; it is sometimes very complete, while in other cases it is but slight, the connexion being composed chiefly of fibrous tissue. The hilum of each kidney looks forwards, and the ureters always pass in front of the connecting piece.

Very rarely the kidney appears to be almost entirely surrounded by peritoneum and to be attached to the abdominal wall by a kind of mesentery which encloses the vessels and nerves passing to the hilum. The condition is believed to be congenital.

One or both kidneys may be at a much lower level than usual—in the iliac fossa or even in the pelvic cavity. When congenital, this is associated with an arrest in the normal change in position, relative to surrounding structures, which the kidney experiences during development. In such cases the kidney does not receive its blood-supply from the usual source but from vessels which arise from the lower end of the aorta, or from an iliac artery, or the middle sacral artery. Such congenital abnormally situated kidneys do not usually possess the typical outline of the normal organ but vary much in shape, and the hilum is often malformed and misplaced.

In some mammalian animals, such as the bear, the kidneys are composed of a number of completely isolated lobes, each of which corresponds to one papilla with its pyramids and surrounding cortex; while in others, such as the horse, the fusion of the lobes is more complete than in the human kidney, and a single mass represents the united papillæ.

URETERS

The **ureters** are the ducts that lead from the kidneys to the urinary bladder. Each ureter begins above in a thin-walled, funnel-shaped expansion, called the **pelvis of the ureter**, which is placed partly inside and partly outside the sinus

of the kidney. Towards the lower end of the kidney the part of the pelvis which lies outside the sinus diminishes in calibre, and forms a tube-like duct which conveys the urine to the bladder.

Pelvis of Ureter.—Within the sinus of the kidney the pelvis lies among the larger renal vessels (Fig. 619). It is formed by the junction of two (or, more rarely, three) thin-walled tubes—the **greater calyces**—each of which has a number of branches. The branches, called **lesser calyces**, are short, and increase in diameter as they approach the wall of the sinus, to which they are attached. Their wide, funnel-like ends enclose the renal papillæ and receive the urine. The lesser calyces are usually about eight in number, one calyx sometimes surrounding two or even three papillæ. The portion of the pelvis that lies outside the kidney has in front of it, in addition to the renal vessels, on the *right side*, the second part of the duodenum, and on the *left side*, a part of the pancreas and the peritoneum of the posterior abdominal wall (Figs. 611, 616) or, sometimes, the duodeno-jejunal flexure.

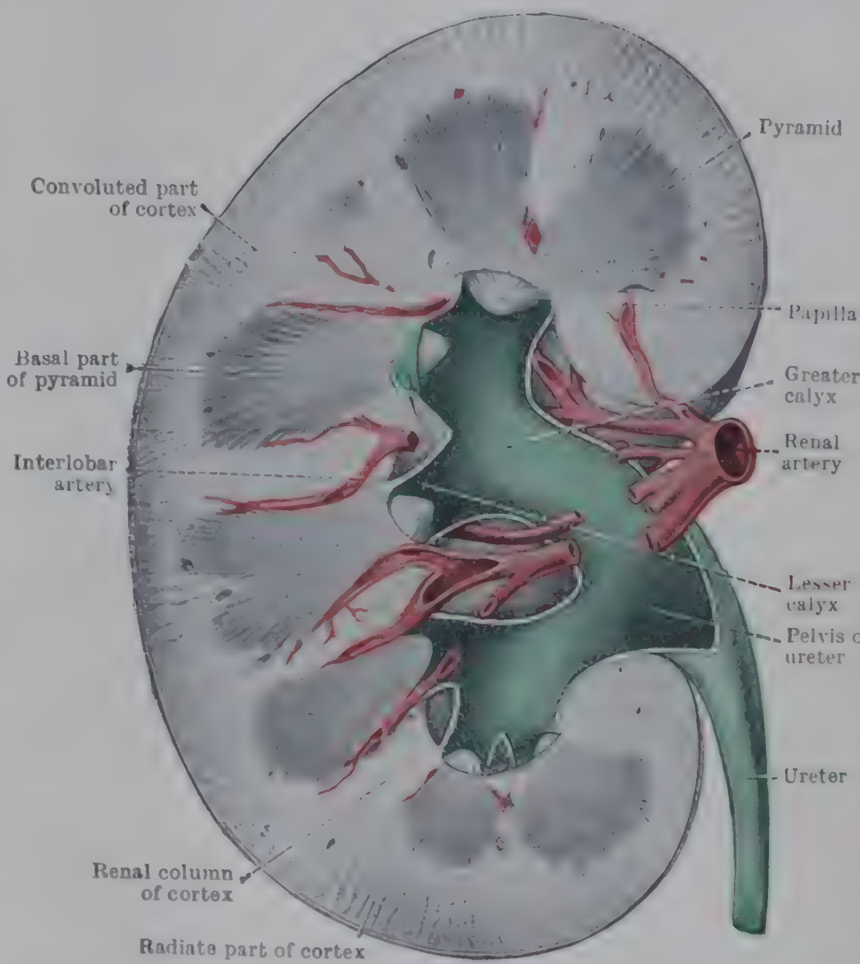

Fig. 619.—Longitudinal Section of Kidney and Pelvis of Ureter to show the Relations of the Calyces to the Renal Papillæ.

Ureter Proper.—The ureter proper is a pale-coloured, thick-walled duct with a small lumen. When *in situ* it has a total length of about ten inches, and lies throughout its whole course in the extra peritoneal tissue behind the peritoneum, to which it is closely adherent. The upper part of the ureter lies in the abdominal cavity, and the lower part in the true pelvis (Figs. 611 and 620).

The **abdominal portion** of the ureter, about five inches in length, is directed downwards and slightly medially, and lies on the psoas major muscle (Fig. 615). Certain structures are related to the ureters in a similar manner on both sides of the body; for instance, the abdominal portion of each ureter is crossed very obliquely, in front, by the testicular or ovarian vessels, and behind each ureter the genito-femoral nerve passes downwards and laterally. Other structures are related to the duct of the right or left side alone. On the *right side*, the second part of the duodenum lies in front of the upper part of the ureter, and the line of attachment of the mesentery crosses it lower down, shortly before the ureter enters the true pelvis. The right colic and ileo-colic arteries also are anterior relations. On the *left side*, the left colic vessels and the line of attachment of the pelvic mesocolon cross the ureter.

Crossing the common iliac or the external iliac artery, the ureter enters the true pelvis. Usually the left ureter crosses the common iliac artery, and the right ureter the external iliac; but that arrangement is by no means constant.

The **pelvic portion** of the ureter is about five inches in length; it passes backwards and downwards on the side-wall of the pelvis under cover of the

peritoneum, describing a curve which is convex backwards and laterally (Fig. 639), the most convex point being close to the deepest part of the greater sciatic notch.

In its course within the pelvis the ureter lies below and in front of the internal iliac artery, and crosses the medial side of the obturator nerve and vessels and of the umbilical artery. About the level of the ischial spine, the ureter is crossed from before backwards by the vas deferens, and from that point onwards it is not so intimately related to the peritoneum. It then bends slightly medially and forwards to reach the lateral angle of the bladder, and comes into relationship with the upper end of the seminal vesicle, in front of which it lies (Fig. 626). The vas deferens having crossed the ureter also turns medially, and as it does so it lies on a plane posterior to the ureter. The lower end of the ureter is surrounded by a dense plexus of veins which brings the vesical plexus into communication with the internal iliac vein. The largest of the nerve-cords which connect the hypogastric plexus with the pelvic plexus divides to pass on each side of the ureter in the region where the ureter is crossed by the vas deferens (Fig. 639).

When the right and left ureters reach the bladder they are a little more than two inches apart. They pierce the wall of the bladder very obliquely, and are embedded within its muscular tissue for nearly three-quarters of an inch. Finally, they open into the bladder by a pair of minute, slit-like apertures which are of a valvular nature and prevent a backward passage of fluid from the bladder. It is probable, however, that an exaggerated idea of the valvular nature of the openings of the ureters into the bladder is obtained by an examination of the parts in the dead subject. When the bladder is empty the openings of the ureters are placed about one inch apart, but when the bladder is distended they may be two inches apart, or more. As the ureter pierces the wall of the bladder the muscular fibres of the bladder and ureter remain quite distinct, and so the ureter, remaining a thick-walled tubular structure, appears to pass through a gap in the muscular wall of the bladder. The mucous coat of the ureter becomes continuous with that of the bladder.

The lumen of the ureter proper is not uniform throughout; it is slightly constricted near its pelvis and where it crosses the iliac artery; and it is narrowest where it passes through the bladder-wall.

In the female, the ureter, near its termination, passes below the root of the broad ligament of the uterus, and lies about three-quarters of an inch lateral to the cervix uteri above the lateral fornix of the vagina, and finally inclines medially to lie in front of the lateral margin of the vagina (Fig. 661). The upper end of the vagina usually deviates to one side, more often the left, and hence much more of one ureter than of the other may come to lie in front of the vagina (Brash, 1922). Its lower part is accompanied by the uterine artery, which crosses above and in front of it not far from its termination. Higher up it lies in the peritoneal ridge which forms the posterior boundary of the fossa ovarica (Fig. 653).

Structure of Ureter.—The wall of the ureter proper, which is thick and of a whitish colour, is composed of mucous, muscular, and fibrous coats. The **mucous coat** is covered with an epithelium composed of many layers of cells, those nearest the lumen being of large size. When the canal is empty the mucous coat is thrown into numerous longitudinal folds, and so its lumen has a stellate outline in transverse section. The submucous tissue varies much in thickness in different parts of the ureter, and contains some elastic fibres. The **muscular coat** consists of plain muscle-fibres collected into bundles which are separated by a considerable amount of fibro-areolar tissue, and are arranged, some longitudinally, some circularly. In the upper part of the ureter a relatively large amount of fibro-areolar tissue is present deep to and among the bundles of muscle-fibres, which are arranged in three distinct strata—an inner longitudinal, middle circular, and an outer longitudinal. In the middle part of the tube the same layers may be recognized, but the circularly disposed bundles of fibres are more numerous than higher up. In the lower part of the ureter the fibro-areolar tissue is relatively scanty and the inner longitudinal fibres lie close to the mucous coat; in this region also the longitudinal folds of the mucous coat become fewer and less marked. A short distance above the bladder, a number of coarse bundles of longitudinally arranged muscle-fibres are applied to the outer surface of the muscular coat. These form the so-called "sheath of the ureter", and are continuous with the superficial part of the muscular wall of the bladder. In the portion of the ureter which traverses the wall of the bladder nearly all the fibres of the muscular coat are disposed longitudinally. The muscle-fibres lie immediately outside the epithelium, and end just where the mucous coats of the bladder and ureter become continuous. The outer, **adventitious coat** of fibrous tissue varies in thickness at different levels, and in its lower part blends with the fibro-areolar tissue which lies among the muscle-fibres of the sheath of the ureter just mentioned.

The mucous coat of the calyces and of the pelvis of the ureter has an epithelium like that of the ureter proper. Where each renal papilla projects into one of the calyces a deep, circular recess is formed between the wall of the calyx and the papilla; at the bottom of this recess the epithelium of the calyx becomes continuous with that covering the papilla. At the apex of the papilla the epithelium joins that of the renal tubules. The muscular fibres in the wall of the calyces and of the pelvis are collected into loosely arranged bundles separated by wide intervals occupied by fibrous tissue. As in the ureter proper, the outermost and innermost fibres are longitudinal, and the middle ones are circular. The circular fibres alone form a distinct layer.

Vessels and Nerves of Ureter.—The abdominal part of the ureter receives its **blood-supply** from the renal and the testicular or ovarian arteries; the pelvic portion is supplied by the vesical and middle rectal vessels, and it may receive a direct branch from the common iliac or the internal iliac artery.

The **nerves** of the ureter are derived from the renal, testicular or ovarian, and hypogastric plexuses. The afferent fibres reach the spinal cord through the eleventh and twelfth thoracic and first lumbar nerves.

Variations.—The ureter is sometimes represented by two tubes in its upper portion. In rarer cases it is double throughout the greater part of its extent, or even in its whole length with two openings into the bladder. Asymmetry in such abnormalities is very common.

Variations in the form of the pelvis of the ureter are of frequent occurrence. Most usually the pelvis divides into two greater calyces—an upper and a lower. In some cases the two calyces spring directly from the ureter without the intervention of a pelvis, or a marked subdivision may lead to the formation of two pelves.

Methods of Clinical Anatomical Examination.—A kidney of normal size and occupying its normal position cannot be palpated in the living subject, but, if the organ is much enlarged or abnormally mobile, it can usually be felt at the end of a deep inspiration. To search for a palpable kidney, place the patient on his back, pass one hand behind him and press forward below the last rib and with the other hand press backwards on the anterior abdominal wall opposite the fingers of the first hand. If the kidney is palpable it can be felt slipping between the opposed fingers when the patient takes a deep breath. The outline of the kidney cannot be defined by percussion as the organ is deeply placed and adjacent to other organs of a similar consistency to itself.

In the angle between the lateral border of the sacro-spinalis muscle and the lower border of the twelfth rib, the kidney lies fairly close to the posterior surface of the body, for there it is separated from the surface only by relatively thin structures—the quadratus lumborum, the layers of the lumbar fascia, the serratus posterior inferior, and the latissimus dorsi. Lesions, *e.g.*, an abscess in the region of the kidney, can cause tenderness and swelling in this area. The close relationship of the psoas major muscle and the kidney is important as, owing to it, extension of the thigh may increase pain due to lesions in the kidney region.

Radiographic Examination of Kidney and Ureter.—The outline of the **kidney** can usually be seen faintly in ordinary radiographs, and it can be made obvious by preliminary injection of air or oxygen into the perirenal fat (Pl. LXIX, p. 744). The position of the kidney may be determined also by the use of the opaque media that are employed in X-ray examination of the ureter.

There are two methods of examining the **ureter**. (1) In *descending pyelography* ("excretion urography") an organic compound of iodine is given intravenously. This substance is opaque to X-rays, is rapidly excreted by the kidneys, and it outlines the pelvis and ureter as it passes down to the bladder. The kidney itself is increased in density during the period of excretion (Pl. LXXI, Fig. 1, p. 745). (2) In ascending or *retrograde pyelography* a solution of sodium iodide is injected directly by means of a catheter introduced into the ureter from the bladder with the aid of a cystoscope. Sodium iodide, in the concentration employed, is more opaque to X-rays than the organic compounds used in descending pyelography; and the whole length of the ureter, including the pelvis and calyces, is rendered clearly visible by its use. The catheter itself may be radio-opaque and may be recognized on the film even after the injection of sodium iodide (Pl. LXX, p. 744).

In radiographs taken after these procedures the pelvis of the ureter is usually seen lying immediately below the shadow of the twelfth rib, and the shadow cast by the ureter proper is seen to fall on the tips of the transverse processes of the lower lumbar vertebræ and on the sacro-iliac joint. In retrograde pyelography the catheter may cause some displacement of the ureter from its normal position (Pl. LXX).

URINARY BLADDER

Position.—The urinary bladder is a hollow muscular organ situated below the peritoneum on the anterior part of the pelvic floor above and behind the pubic symphysis. The space in which it lies is three-sided. On each side, it is bounded

above by the obturator internus and lower down by the levator ani muscles; and these two side-walls meet in front at the pubic symphysis. As the two levator ani muscles slope downwards, backwards and medially they form the walls of a gully which is deeper behind than in front owing to the slope of its floor; this floor is defective in front because of the slight gap that exists between the two levator ani muscles, but the deficiency is bridged over by the medial pubo-prostatic ligaments (pubo-vesical in the female) and partly compensated for at a lower level by the fascia on the sphincter urethræ muscle. The space is bounded behind by the fascial tissue which stretches across the back of the bladder and is

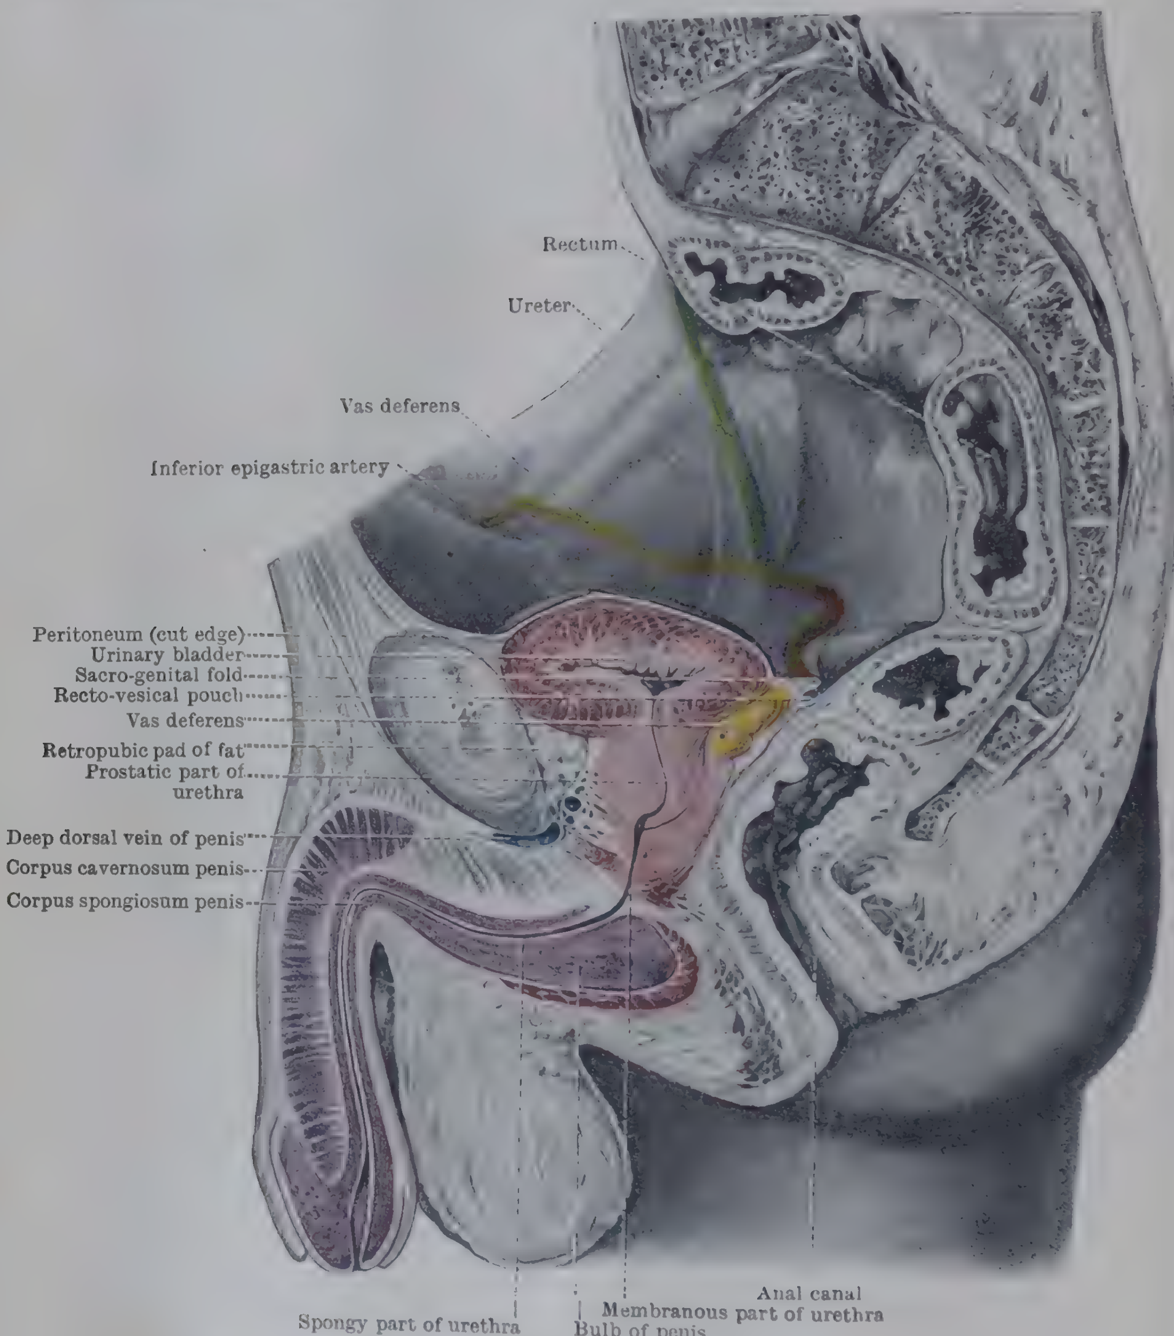

FIG. 620.—MEDIAN SECTION OF PELVIS OF ADULT MALE SUBJECT.
The urinary bladder is empty and firmly contracted; compare with Fig. 621.

thickened and condensed as it passes from the bladder to be connected with the fascia of the levator ani on each side.

Shape and Parts (Fig. 624).—The empty adult bladder lies completely or almost completely within the above-mentioned space, and in dissecting-room fixed specimens it is usually moulded by the walls of the space and by the pressure of overlying viscera. It is therefore usual to describe the empty adult bladder as possessing four surfaces:—a *superior surface* looking straight upwards, a pair of *infero-lateral surfaces* facing downwards, laterally, and forwards, and a *posterior*

surface directed backwards and slightly downwards. The posterior surface is called **the base**; the anterior end of the bladder, where the superior and the two infero-lateral surfaces meet, is known as the **apex**; and the lowest part of the organ, where the base and the two infero-lateral surfaces come together, is termed the **neck**. But deductions made from an examination of such dead and relaxed bladders appear to be inapplicable to the living organ. The bladder almost always

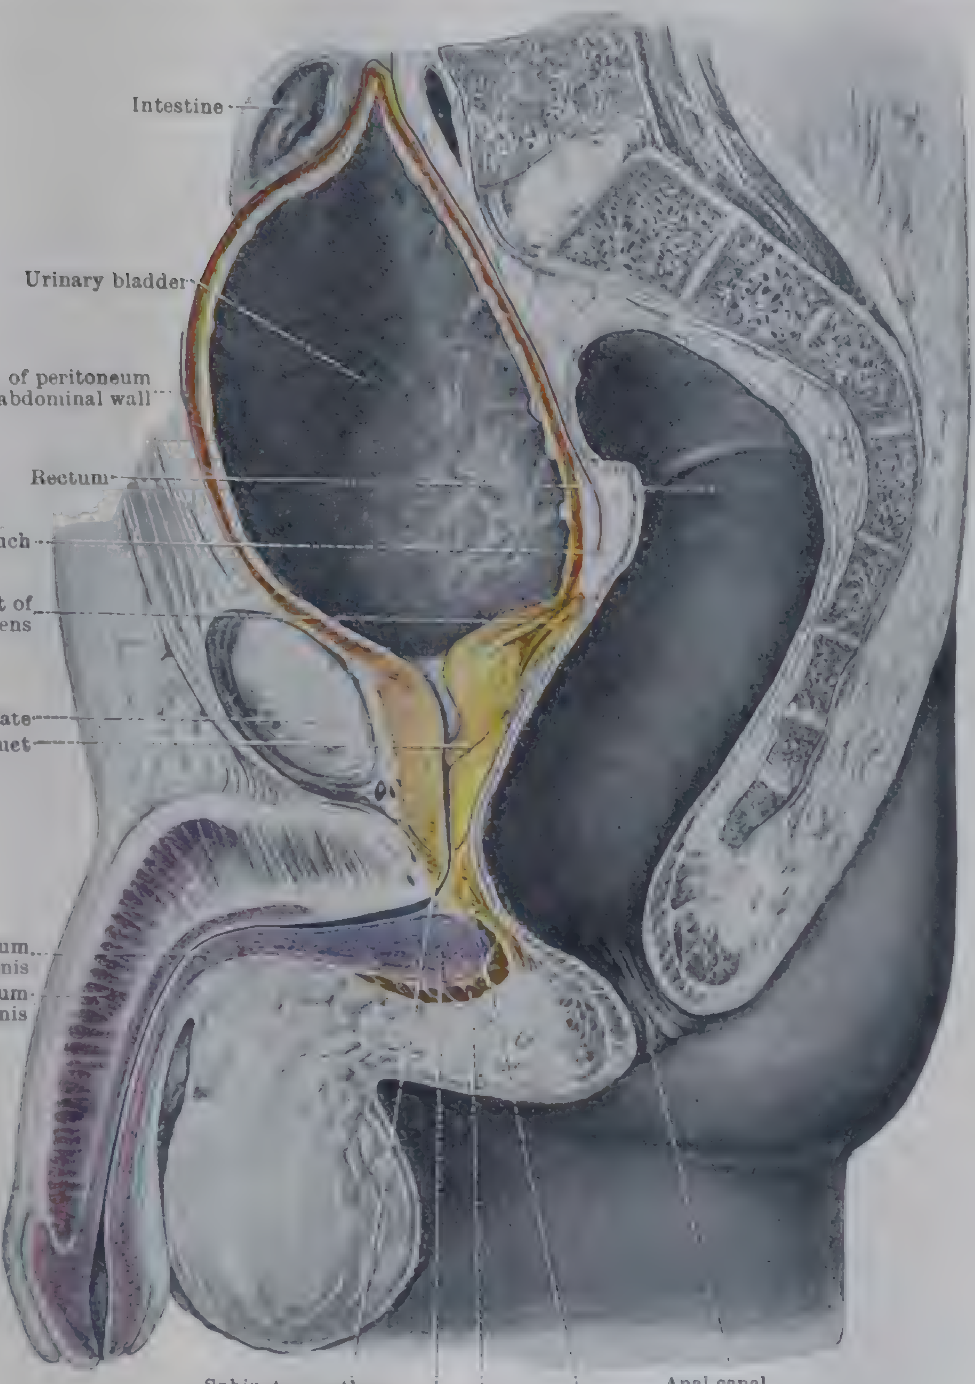

FIG. 621.—MEDIAN SECTION OF PELVIS OF ADULT MALE SUBJECT.
The urinary bladder and rectum are both distended. Compare with Fig. 620.

contains a little fluid and is physiologically closed except at intermittent intervals; and its walls are always in some degree of tonic contraction. These facts alone ensure that the living bladder is always more or less rounded, though its spherical shape may be slightly altered either by pressure of surrounding organs or by its attachment to surrounding structures. Hence, radiographs of the bladder in living subjects show it as a rounded organ, with its upper aspect frequently flattened by the weight of overlying viscera, or even slightly depressed by a heavy overlying viscus, *e.g.*, a gravid uterus. It would therefore probably be more correct to speak of the various *aspects* of the bladder than of its *surfaces*; for its true shape appears

to be that of a sphere or a spheroid, though this conformation may be temporarily modified by pressure of surrounding structures.

The distended bladder rises above the three-sided space already described and projects upwards into the true abdominal cavity.

Attachments.—In both sexes the **neck** is the most firmly fixed part of the bladder. In the male it is held in place chiefly by the pubo-prostatic ligaments and by its firm connexion with the prostate, with which it is structurally continuous. Each side of the neck gives attachment to the *lateral pubo-prostatic ligament*, which is merely the fascia on the anterior part of the levator ani muscle. The *medial pubo-prostatic ligaments* are a pair of thick, short, strong bands that lie side by side over the anterior part of the gap between the two levatores ani in front of the neck of the bladder and attach it firmly to the back of the pubic bones; these ligaments contain bundles of plain muscle-fibres which are continuous with the muscular coat of the bladder and are named, therefore, the *pubo-vesical muscle.* The prostate lies in the posterior part of the gap between the two levator ani muscles and is itself enclosed in a strong fibrous sheath which also is firmly connected with the pubo-prostatic ligaments and is attached inferiorly to the fascia on the sphincter urethræ muscle. In the female the neck of the bladder and upper part of the urethra are connected with the pubis and the levator ani by similar fascial bands which, in the absence of a prostate, are named *pubo-vesical* ligaments; and these parts are also directly connected with the fascia which covers the sphincter urethræ.

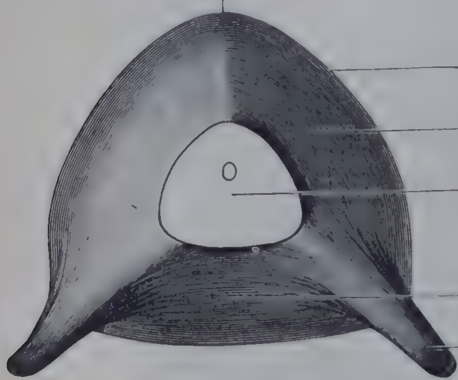

FIG. 622.—INFERIOR ASPECT OF EMPTY MALE URINARY BLADDER. From a subject in which the viscera had been hardened *in situ.*

The **apex** of the bladder is continuous with the median umbilical ligament, which extends up on the posterior surface of the anterior abdominal wall to the umbilicus. This ligament is the fibrous remnant of the *urachus*—the passage which in the embryo connects the developing bladder with the allantois.

The **base** of the bladder is attached by means of the condensation of fascia which, on each side, blends with the fascia on the levator ani muscle. The whole condensation is really a collection of fibrous tissue around the internal iliac artery and its branches, and it passes medially to be attached to the base of the bladder and seminal vesicles in the male, and the base of the bladder and the sides of the vagina and cervix uteri in the female.

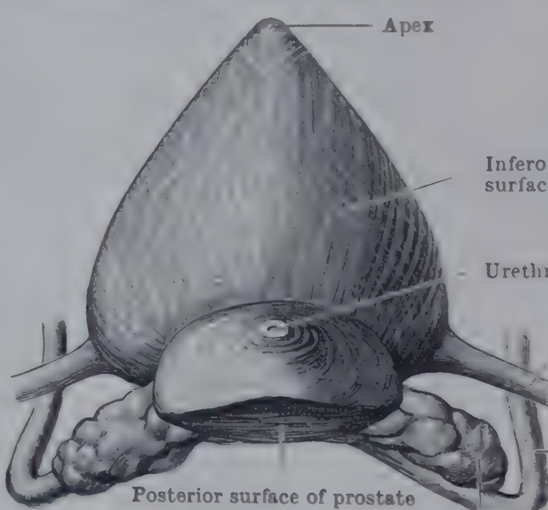

FIG. 623.—URINARY BLADDER, PROSTATE, AND SEMINAL VESICLES, VIEWED FROM BELOW.

Taken from a subject in which the viscera were hardened *in situ.* Same specimen as Fig. 624, A. The bladder contained a very small amount of fluid.

In addition to these connexions, the base is attached by areolar tissue loosely to the anterior wall of the vagina in the female, but firmly to the seminal vesicles and ampullæ of the vasa deferentia in the male.

The ureters enter the bladder at the upper and lateral aspects of the base, the points of entrance being about two inches apart; and the urethra leaves the bladder at its lowest point—that is the neck.

In dissecting-room specimens, once the median umbilical ligament has been

cut, the whole anterior part of the bladder is very mobile but the base and neck remain fixed.

Relations of Male Bladder.—The **superior surface** of the bladder (Figs. 620 and 625) is covered with peritoneum, which separates it from coils of small intestine or from the pelvic colon. The peritoneum passes from the upper surface of the bladder forwards on to the posterior surface of the anterior abdominal wall at the level of the pubic crest; laterally it passes slightly downwards and then upwards on to the side-wall of the pelvis, thus forming a shallow *paravesical fossa* on each side of the bladder; and posteriorly it passes backwards for about half an inch forming a prominent shelf-like fold—the *sacro-genital fold*—and then turns abruptly downwards for about an inch to be reflected on to the front of the rectum, thus forming the recto-vesical pouch (Fig. 625). As the peritoneum turns downwards it may, in the median plane, cover a small portion of the base of the bladder but more laterally it is separated from the base by the vas deferens and the upper end of the seminal vesicle. When the bladder is completely empty, the peritoneum on its upper aspect may be thrown into a transverse fold—the *plica vesicalis transversa*.

The two **infero-lateral surfaces** and the border between them are separated

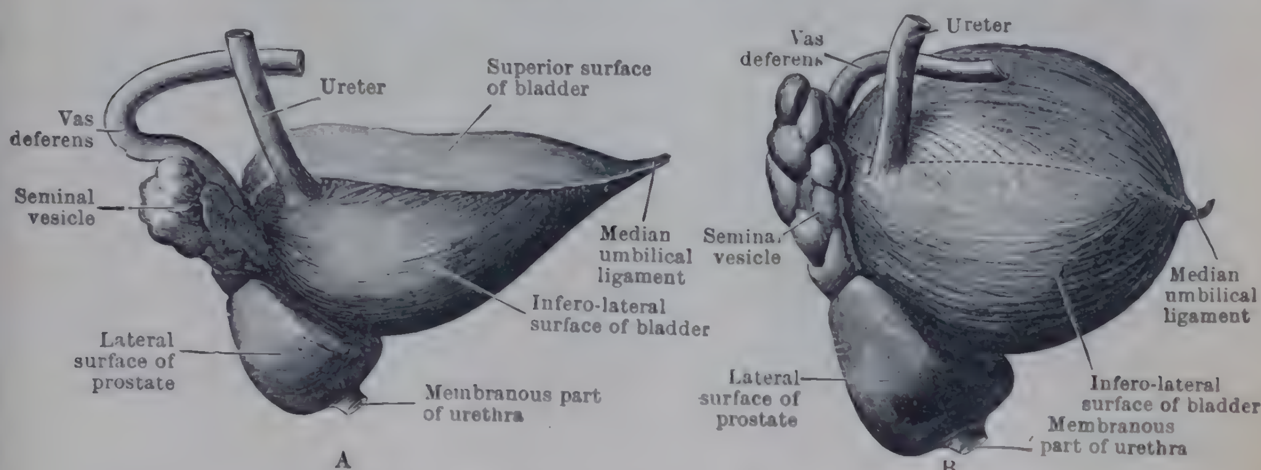

FIG. 624.—URINARY BLADDER, PROSTATE, AND SEMINAL VESICLE VIEWED FROM THE RIGHT SIDE.

Drawn from specimens in which the viscera were hardened *in situ*. In A the bladder contained a very small quantity of fluid; in B the quantity was a little greater. In A the peritoneum is shown covering the superior surface of the bladder, and its cut edge is seen where it is reflected along the lateral border. In B the level of the peritoneal reflexion is indicated by a dotted line.

from the surrounding firm structures by a space—the *retropubic space*—which is filled with loose areolar tissue, fat and a plexus of veins (Fig. 620). This mass of tissue, adapted as a packing to fill the gaps between the bladder and the neighbouring, rather rigid, pelvic walls, is known as the *retropubic pad of fat*. The retropubic space is bounded in front by the back of the pubis, at each side by the levator ani muscle below and the obturator internus muscle above, inferiorly by the pubo-prostatic ligaments, and posteriorly by the fascial condensation which passes from the base of the bladder to the side-walls of the pelvis. Superiorly, it is bounded by the peritoneum which passes from the upper surface of the bladder to the anterior wall of the abdomen and the side-walls of the pelvis. As the bladder fills and expands, it lifts the peritoneum upwards as far as the line of the lateral umbilical ligaments (obliterated umbilical arteries), and the retropubic space therefore potentially extends upwards on to the back of the anterior abdominal wall and on to the side-walls of the pelvis as far as these ligaments. The obturator nerve and vessels extend into the posterior and upper part of the side-wall of the retropubic space even when the space is unexpanded; and as the bladder fills and the space enlarges the vas deferens also may be included. The plexus of veins in the retropubic pad of fat is especially rich in the neighbourhood of the neck of the bladder.

The **base** of the bladder faces backwards and slightly downwards (Figs. 620 and 624). Its infero-lateral parts are in contact with the seminal vesicles, which diverge from each other at rather more than a right angle as they pass laterally

and upwards from the back of the neck; medial to each seminal vesicle, the base

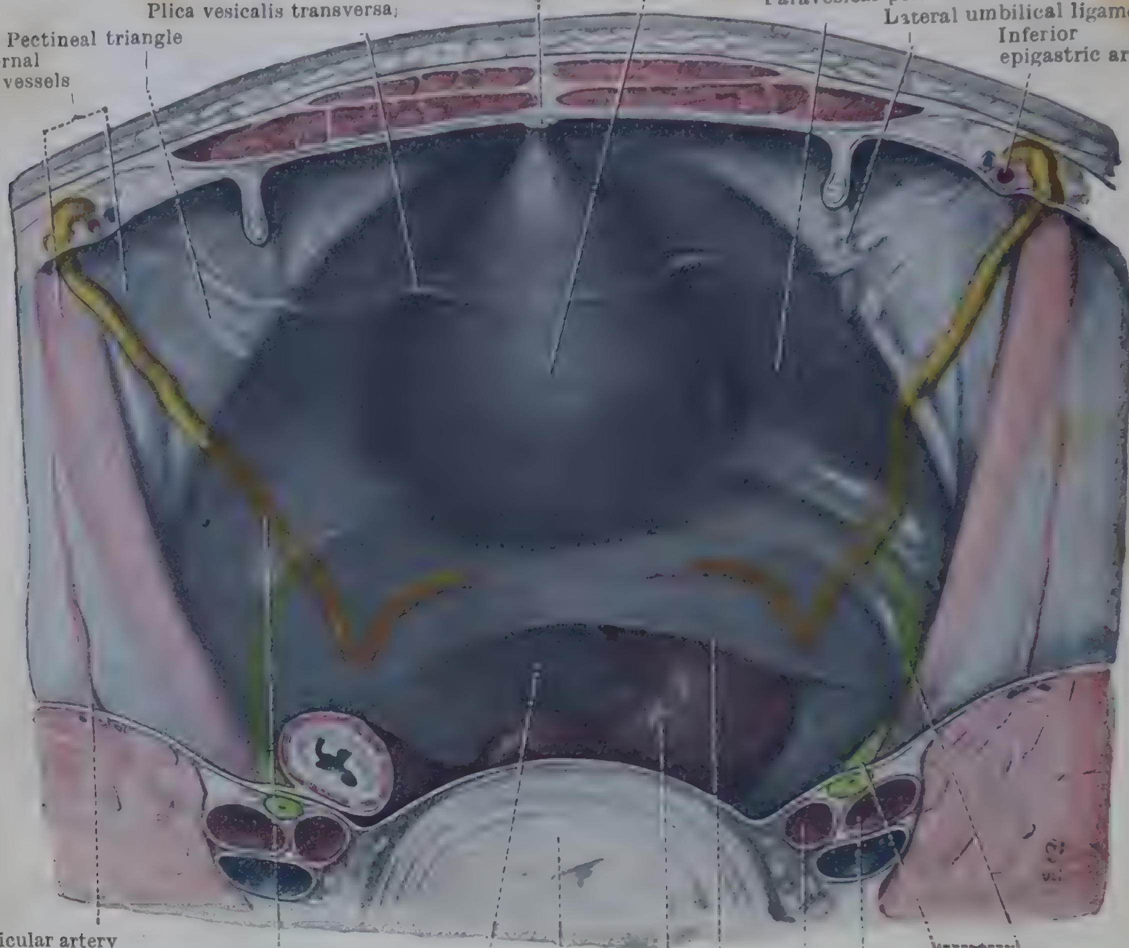

FIG. 625.—CAVITY OF MALE PELVIS SEEN FROM ABOVE AND BEHIND.

From a specimen in which the bladder was firmly contracted and contained but a small amount of fluid. The peritoneal pouch in front of the rectum is bounded on each side by the sacro-genital folds, which meet together in the median plane some distance behind the posterior border of the bladder.

is in contact with the ampulla of the vas deferens of the same side; between the two vasa it is separated by some loose areolar tissue from the front of the rectum, but the uppermost part of that interval may be covered with peritoneum.

The **neck** is firmly attached to the prostate, or, rather, structurally continuous with it; and a well-marked groove runs round the junction of the two organs.

Relations of Female Bladder (Figs. 627, 657, and 659).—The bladder occupies a slightly lower position than in the male. The **superior surface** is covered with peritoneum, which, as in the male, passes forwards on to the back of the anterior abdominal wall, and also laterally to the side-wall of the pelvis, forming, as

Note the outlining of the Fornix of the Vagina and the escape of the injection into the peritoneal cavity in droplets. See pp. 783, 1558.

it does so, a shallow *paravesical fossa*. Posteriorly the peritoneum passes from the superior surface of the bladder upwards to be attached to the uterus at the junction of the cervix and body of that organ, and then passes forwards on the antero-inferior surface of the body of the uterus. In the female, therefore, the body of the uterus lies above the bladder and the peritoneal recess between the two organs is known as the *utero-vesical pouch*. This pouch is usually slit-like, but in some cases coils of small intestine pass into it and partly separate the bladder and uterus.

The base of the bladder in the female is attached by areolar tissue to the

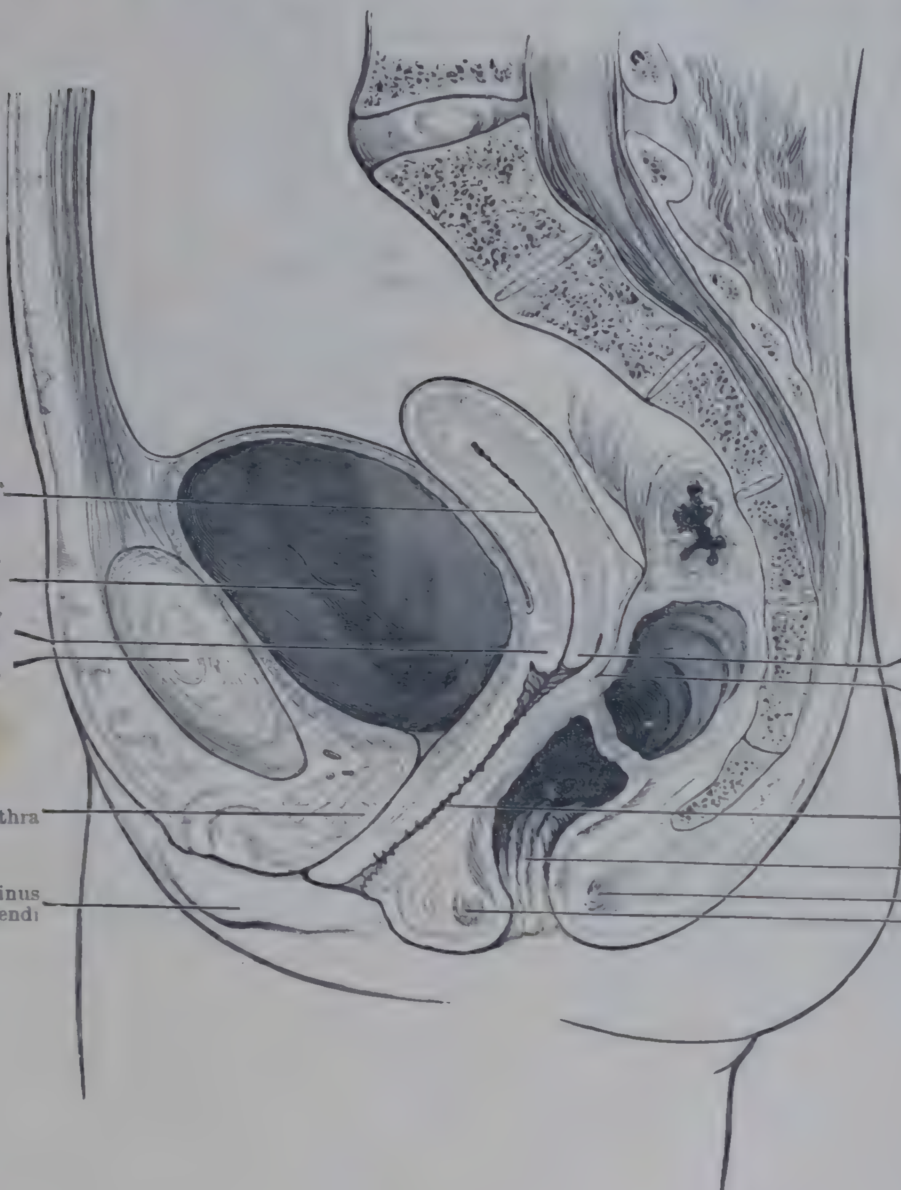

FIG. 627.—MEDIAN SECTION OF PELVIS OF ADULT FEMALE.
The cavity of the uterus is indicated diagrammatically.

anterior wall of the vagina so loosely that a line of cleavage between the two organs can be easily opened up. The upper end of the base, just as it passes into the superior surface of the organ, is separated from the front of the supravaginal part of the cervix uteri by loose areolar tissue: and laterally on each side the uterine vessels are about an inch distant (Fig. 656).

The **infero-lateral surfaces** and the **apex** have the same general relations in the female as in the male.

The **neck**, in the absence of the prostate, is continuous only with the urethra, and the fascial bands connected with it are called the pubo-vesical ligaments.

Bladder in New-Born Child and Infant.—At birth the empty bladder is spindle- or torpedo-shaped; its long axis extends from the apex to the internal urethral orifice, and is directed downwards and backwards (Fig. 628). The

lateral and posterior borders seen in the adult organ cannot be recognized at birth, nor is there any part of the bladder-wall directed backwards and downwards, as is the base of the adult organ. In the fœtus and young child the bladder occupies a much higher level than it does in the adult, and, even when empty, it extends upwards into the abdominal cavity. Its anterior surface is in contact with the back of the anterior abdominal wall. At birth the peritoneum forming the recto-vesical pouch covers the whole of the posterior surface of the bladder, and reaches as low as the upper limit of the prostate. The internal urethral orifice is placed at a high level, and sinks gradually after birth (Fig. 629). In the new-born child the opening is on a level with the upper margin of the pubic symphysis and the openings of the ureters are almost in the plane of the pelvic brim. The umbilical arteries are more intimately related to the bladder in the child than in the adult, and lie close against its sides as they pass upwards on the back of the anterior abdominal wall towards the umbilicus (Fig. 643).

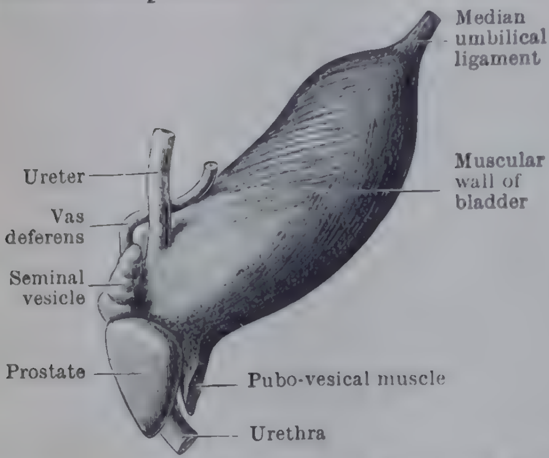

Fig. 628.—Urinary Bladder of New-Born Male Child, viewed from Right Side.
The drawing is from a specimen which had been hardened *in situ*. (Compare with Fig. 624, A.)

Interior of Bladder (Figs. 630, 631, 632, and 656).—The mucous membrane which lines the bladder is loosely connected to the muscular coat, and when the bladder is contracted the mucous lining is thrown into a number of prominent wrinkles or folds. At one place only is the mucous membrane firmly connected to the muscular coat, and the inner surface of that part of the bladder-wall is smooth and free from wrinkles. This smooth area corresponds to a triangular surface above and behind the urethral orifice, called the **trigone of the bladder**, and to the part of the bladder-wall which immediately surrounds the opening. The apex of the triangle is at the beginning of the urethra, and the base is a line drawn between the openings of the ureters. Immediately above and behind the urethral opening the bladder-wall in the male sometimes bulges slightly into the cavity owing to the presence of the median lobe of the prostate, which lies outside the mucous coat in that position. When well-marked, as it often is in old men, the bulging is termed the **uvula of the bladder**. Stretching across between the openings of the ureters there is usually a smooth **inter-ureteric ridge**, due to the presence of a transverse bundle of muscle-fibres. It may be deficient near the median plane, and it is curved so as to be convex downwards and forwards. Lateral to the openings of the ureters there is a pair of ridges, called the **ureteric folds**, produced by the terminal parts of the ureters as they traverse the bladder-wall and lie outside of the mucous coat of the bladder. In old people the region above and behind the trigone often bulges backwards and forms a shallow *retro-ureteric fossa*. A less distinct depression may sometimes be observed on each side of the trigone. Around the urethral orifice there is a number of minute radially disposed folds which, disappearing into the urethra, become continuous with the longitudinal folds of the mucous membrane of the upper part of that canal. The ureter pierces the bladder-wall very obliquely, and so the ureteral orifice has an elliptical outline. The lateral boundary of each opening is a thin, crescentic fold which, when the bladder is artificially distended in the dead subject, acts as a valve in preventing water or air from entering the ureter. In the empty bladder the urethral orifice and the openings of the two ureters lie at the angles of an approximately equilateral triangle the sides of which are about an inch in length. When the bladder is distended, the distance between the openings may be increased to two inches or more.

Position of Internal Urethral Orifice.—During the various changes in shape and size which the bladder undergoes, the region of the internal urethral orifice remains almost fixed in position. In the male the urethral orifice is immediately

above the prostate, and behind and slightly below the level of the upper margin of the pubic symphysis, from which it is distant about two to two and a half inches. It can be reached by a finger introduced into the bladder through the abdominal wall above the pubic symphysis. It is usually half an inch to one inch above the level of a plane which passes through the lower margin of the symphysis and the lower end of the sacrum, but in some cases it is slightly lower. The comparatively small variations in the level of the internal urethral orifice which do occur depend partly upon the quantity of fluid in the bladder and partly upon the amount of distension of the lower portion of the rectum. When the bladder is very much distended the orifice is at a slightly lower level than when the organ is empty; on the other hand, distension of the lower part of the rectum raises the level of the urethral orifice to some extent. In the female the internal urethral orifice is normally at a lower level than in the male (compare Figs. 620 and 627).

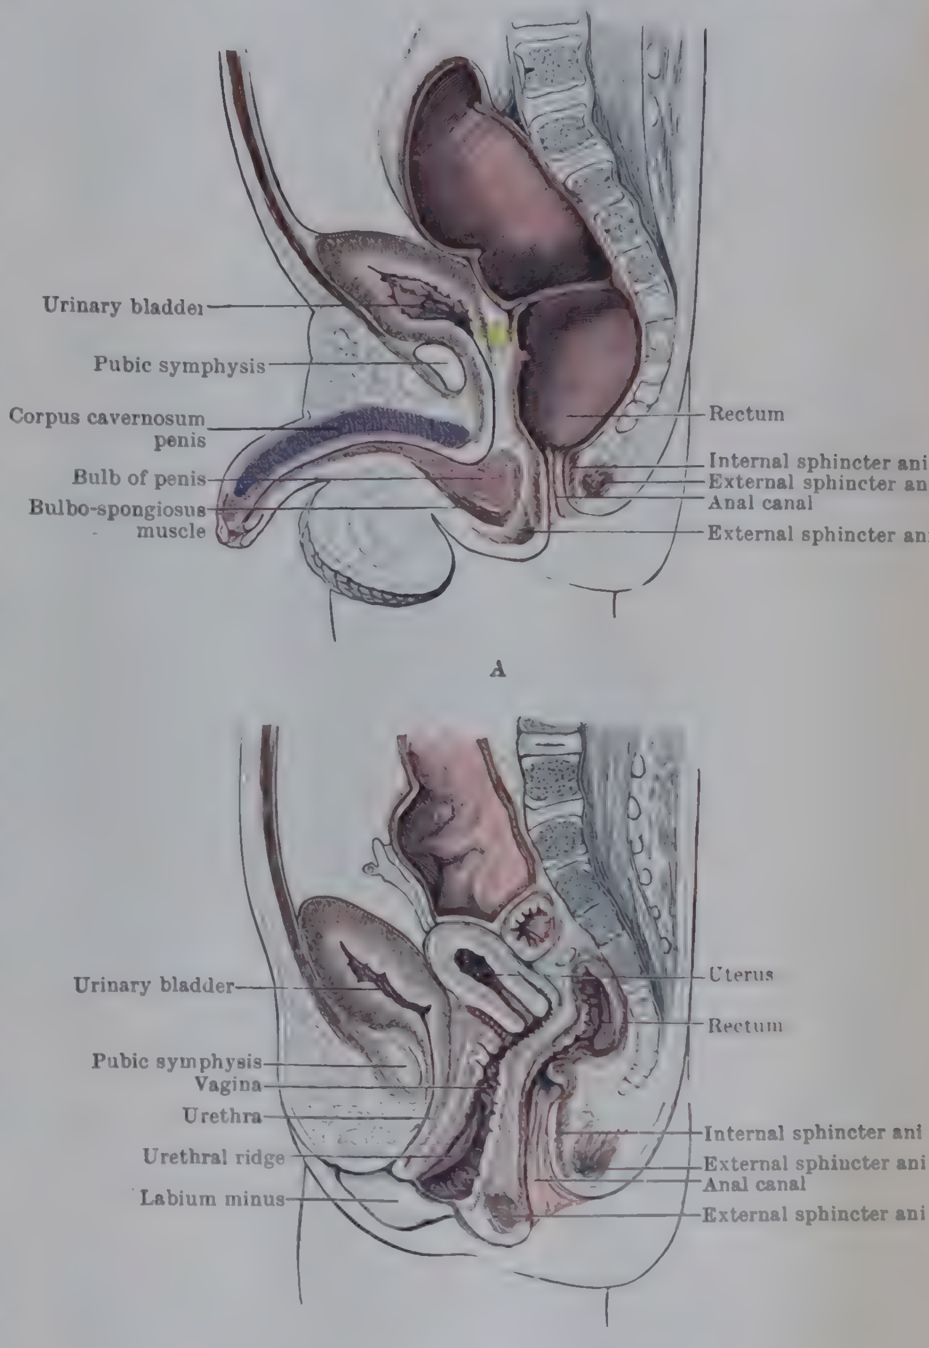

FIG. 629.—MEDIAN SECTIONS OF PELVES OF NEW-BORN CHILDREN.
A, Male; B, Female.

Capacity of Bladder.—The bladder in normal distension may contain nearly a pint; but in most cases the organ is emptied when its contents reach from six to ten ounces (Thompson, 1919). If its contents amount to three-quarters of a pint, the bladder is in contact with the back of the anterior abdominal wall for a distance of about three inches above the pubic crest and the peritoneal reflexion from its upper surface on to the abdominal wall has been raised above this level.

Structure of Bladder.—The wall of the bladder from without inwards is composed of a serous, a muscular, a submucous, and a mucous coat. The **serous coat** is the peritoneum, and covers only the upper part of the bladder (Figs. 620, 627).

A considerable amount of loose fibro-areolar tissue surrounds the **muscular coat**, and, penetrating it, divides it into numerous coarse bundles of muscle-fibres. All the muscle-fibres are of the plain variety, and the bundles which they form are arranged in three very imperfectly separated strata called external, middle, and internal. The **external stratum** is for the most part made up of fibres which are directed longitudinally, and it is best marked near the median plane on the upper and under aspects of the bladder. Farther from the median plane, on the

sides of the bladder, the fibres composing the external stratum run more obliquely, and frequently cross one another. In the male many of the fibres of the external stratum pass into the prostate in front of and behind the urethral opening, and in the female the corresponding fibres join the dense tissue which in this sex forms the upper part of the wall of the urethra. Other fibres of this stratum on each side of the median plane join the lower part of the pubic symphysis and constitute the **pubo-vesical muscle**, which follows the course of the pubo-prostatic ligaments. Lastly, some fibres of the external stratum blend posteriorly with the front of the rectum and receive the name of **recto-vesical muscle.** In both sexes many muscular fibres of the bladder are continued along the course of the ureter to form the sheath of the ureter already mentioned (p. 738). The **middle stratum** is composed of fibres which for the most part run circularly, and form the greater part of the thickness of the muscular coat. In the region of, and behind, the urethral orifice the bundles of fibres are finer and more densely arranged, and surround the opening in a plane which is directed obliquely downwards and forwards. This part

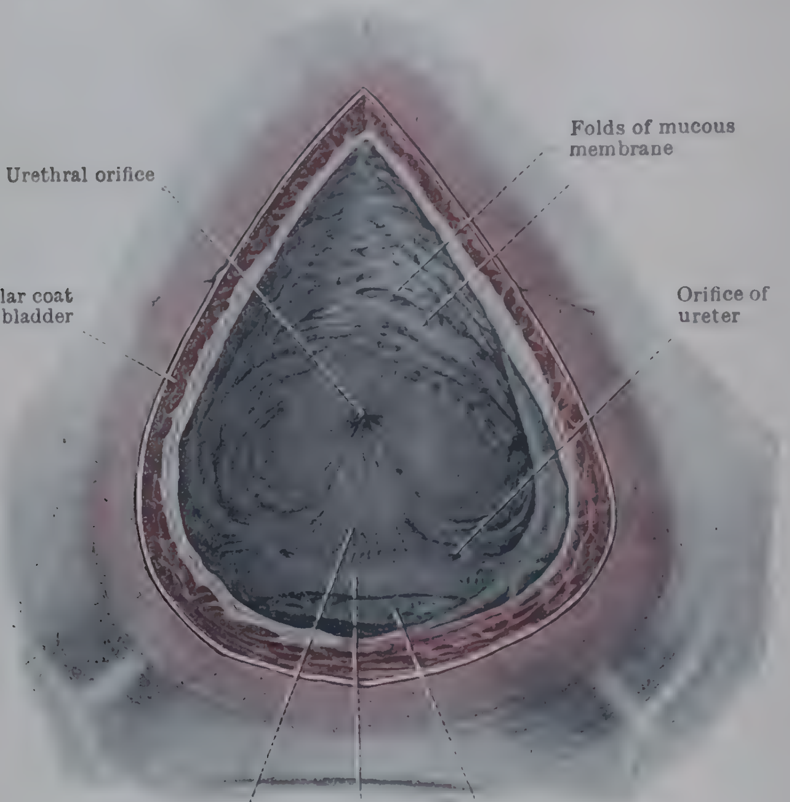

Fig. 630.—Empty and Contracted Urinary Bladder, opened by Removal of its Upper Wall.

The peritoneum is seen spreading out from the lateral and posterior borders of the organ. Compare with Fig. 625.

of the middle stratum is often spoken of as the *sphincter vesicæ.* Inferiorly the fibres of the sphincter vesicæ are continuous with the muscular tissue of the prostate in the male, and with the muscular wall of the urethra in the female. In other parts of the bladder the bundles of the middle stratum are coarser and separated by intervals filled with fibro-areolar tissue. The **internal stratum** is composed of a thin layer of muscle-fibres directed for the most part longitudinally.

The **submucous coat** is composed of areolar tissue which contains numerous fine elastic fibres.

The **mucous coat** is attached by the submucous layer to the muscular coat loosely except in the region of the trigone. There, the muscular fibres are firmly adherent to the mucous coat. Over the trigone the mucous coat is always smooth and flat; elsewhere it is thrown into folds when the bladder is empty. The mucous coat of the bladder is continuous with that of the ureters and urethra. Its epithelial covering is of the variety known as transitional epithelium; it varies much in appearance as the organ expands and contracts. The appearance of the mucous coat is described on p. 746.

When as a result of urethral obstruction the muscular coat of the bladder becomes hypertrophied, strong strands of muscular tissue become raised up and project into the cavity of the bladder. The resulting net-like arrangement of ridges resembles the trabeculæ carneæ of the ventricles of the heart.

Vessels and Nerves of Bladder.—The **arteries** on each side are the *superior* and *inferior vesical arteries.* The largest **veins** are found above the prostate and in the region where the ureter reaches the bladder. They form a dense plexus which pours its blood into tributaries of the internal iliac vein, and communicates below with the prostatic venous plexus.

The **lymph-vessels** from the bladder join the iliac groups of lymph-glands (p. 1411).

The **nerve-supply** of the bladder is derived on each side from the *vesical plexus*, the fibres of which come from two sources, namely, (1) from the *upper lumbar nerves* through the hypogastric plexus (sympathetic), and (2) from the *pelvic splanchnic nerves* (parasympathetic), which spring from the *second* and *third* or the *third* and *fourth sacral nerves*. These splanchnic nerves join the vesical plexus directly

Methods of Clinical Anatomical Examination.—The normal bladder cannot be palpated. The outlines of the normal empty bladder cannot be determined by percussion; but, as the organ fills and rises into contact with the anterior abdominal wall, its upper outline can be mapped out by percussion. The base of the female bladder can be palpated by a vaginal examination.

The interior of the bladder can be inspected by means of a cystoscope: and the outline of its cavity may be seen radiographically (Pl. LXXI, Fig. 2, p. 745) after the use of one of the opaque media employed in X-ray examination of the ureter (p. 739).

URETHRA

The **urethra** is the channel which conveys the urine from the bladder to the exterior. In the *male* its proximal part, less than one inch in length, extends from the bladder into the prostate where the ducts of the reproductive glands join the canal; a much longer distal portion serves as a common passage for the urine and the semen. The *female* urethra represents only the proximal part of the male canal. It is a short passage that leads from the bladder to the external urethral orifice—an aperture placed within the pudendal cleft immediately in front of the opening of the vagina.

Male Urethra.—The **male urethra** (Figs. 631 and 632) is a channel of about eight inches in length and leads from the bladder to the external urethral orifice at the end of the glans penis. The canal not only serves for the passage of urine; it affords an exit also for the seminal products, which enter it by the ejaculatory ducts, and for the secretion of the prostatic and bulbo-urethral glands; in addition, numerous minute **urethral mucous glands** pour their secretion into the urethra.

As it passes from the internal urethral orifice to its external opening the urethra describes an ∽-shaped course, and it is customary to divide it into three sections. The first part is within the true pelvis, and has a nearly vertical course as it traverses the prostate. Turning more forwards, the urethra passes below the pubic symphysis and pierces the fibrous layers which form the pelvic wall in that region. Leaving the pelvis, the canal enters the bulb of the penis and throughout the rest of its course it lies in the erectile tissue of the corpus spongiosum and of the glans penis. The part of the urethra which is embedded in the prostate is called the **prostatic part**; the short part which pierces the pelvic wall is called the **membranous part**; and the part surrounded by the corpus spongiosum is the **spongy part**. Of the three sections the spongy portion is much the longest, and the membranous is the shortest.

The **prostatic part** descends through the prostate from the base towards the apex, describing a slight curve which is concave forwards. It is about one inch in length, and is narrower above and below than in its middle portion, which is, indeed, the widest part of the whole urethral canal. Except while fluid is passing, the canal is contracted, and the mucous membrane of the anterior and posterior walls is in contact and thrown into a series of longitudinal folds. When distended, the middle, or widest part of the canal, may normally have a diameter of about one-third of an inch. The posterior wall, often termed the "floor", of the prostatic urethra presents a distinct median ridge called the **urethral crest** (Fig. 632). The crest projects forwards into the urethra to such an extent that the canal in transverse section presents a crescentic outline (Fig. 651). The groove on each side of the crest is known as the **prostatic sinus**, and into it the numerous ducts of the prostatic glands open by minute apertures. Some few ducts from the middle part open nearer the median plane, on the sides of the urethral crest. The highest point of the urethral crest is half-way down, and on it there is a small, slit-like opening which leads backwards and upwards for a distance of about a quarter of an inch, as a blind pouch, in the substance of the prostate. That little diverticulum is known as the **prostatic utricle**, and it represents

the fused caudal ends of the para-mesonephric ducts, from which the uterus and vagina are developed. On each side of the mouth of the utricle there is the much more minute opening of the ejaculatory duct (see p. 759). When traced upwards, the urethral crest diminishes in height and becomes indistinct, but it can often be traced as a slight median ridge as far as the uvula of the bladder. In the opposite direction the ridge becomes less marked, but it can be followed into the

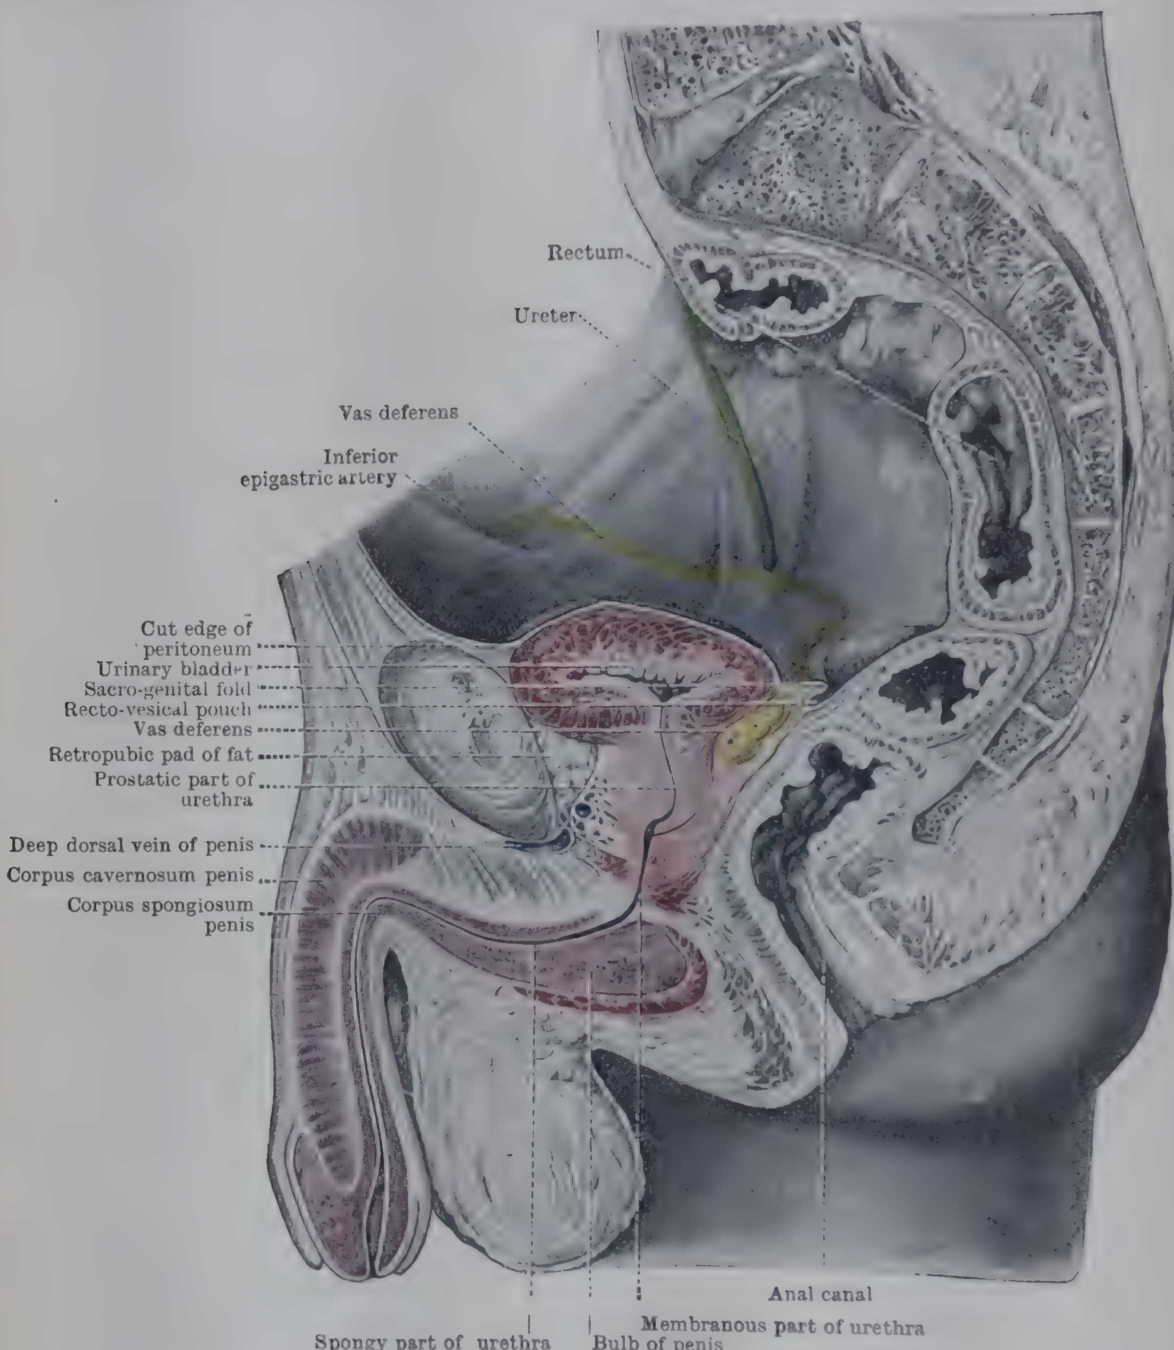

Fig. 631.—Median Section of Adult Male Pelvis.

The urinary bladder is empty and firmly contracted. The urethra is opened up in its entire length.

membranous portion of the canal, where it divides into a pair of inconspicuous elevations which gradually fade out (Fig. 632).

The curvature and, to a less degree, the length of the prostatic urethra depend upon the amount of distension of the bladder and of the rectum (compare Figs. 620 and 621).

The **membranous part** of the urethra leads downwards and forwards from the apex of the prostate to the bulb of the penis, and is the shortest of the three divisions of the canal—its length being slightly less than half an inch. It is also, with the exception of the external orifice, the least dilatable part of the urethra. It begins at the layer of fascia which lies above the sphincter urethræ muscle,

where it is continuous with the prostatic portion of the urethra. It ends about a quarter of an inch below the perineal membrane by becoming continuous with the spongy portion of the urethra. It lies about one inch behind and below the inferior pubic ligament and is surrounded by fibres of the sphincter urethræ muscle: and behind it, on each side of the median plane, lies a bulbo-urethral gland. The posterior part of the bulb of the penis projects backwards and overlaps the posterior wall of the membranous part of the urethra to a considerable extent (Fig. 650).

Besides the folds continued down from the urethral crest there are other longitudinal folds of mucous membrane seen when the canal is empty, and the lumen of the empty tube is therefore stellate in transverse section.

Although the membranous part of the urethra appears to be firmly held, it is not strongly attached to the surrounding fascia, and in the living body it is so mobile that it can be drawn upwards for a distance of about 4 cm. above the perineal membrane (Souttar, 1947). This is of some importance in the operation of "retropubic prostatectomy" (p. 1514).

It is important to note also that the lower part of the membranous portion of the urethra, where it is overlapped by the bulb, lies below the perineal membrane. It is considerably wider than the upper part, and is very thin-walled. It is the part of the canal which is most liable to rupture (Figs. 631 and 632).

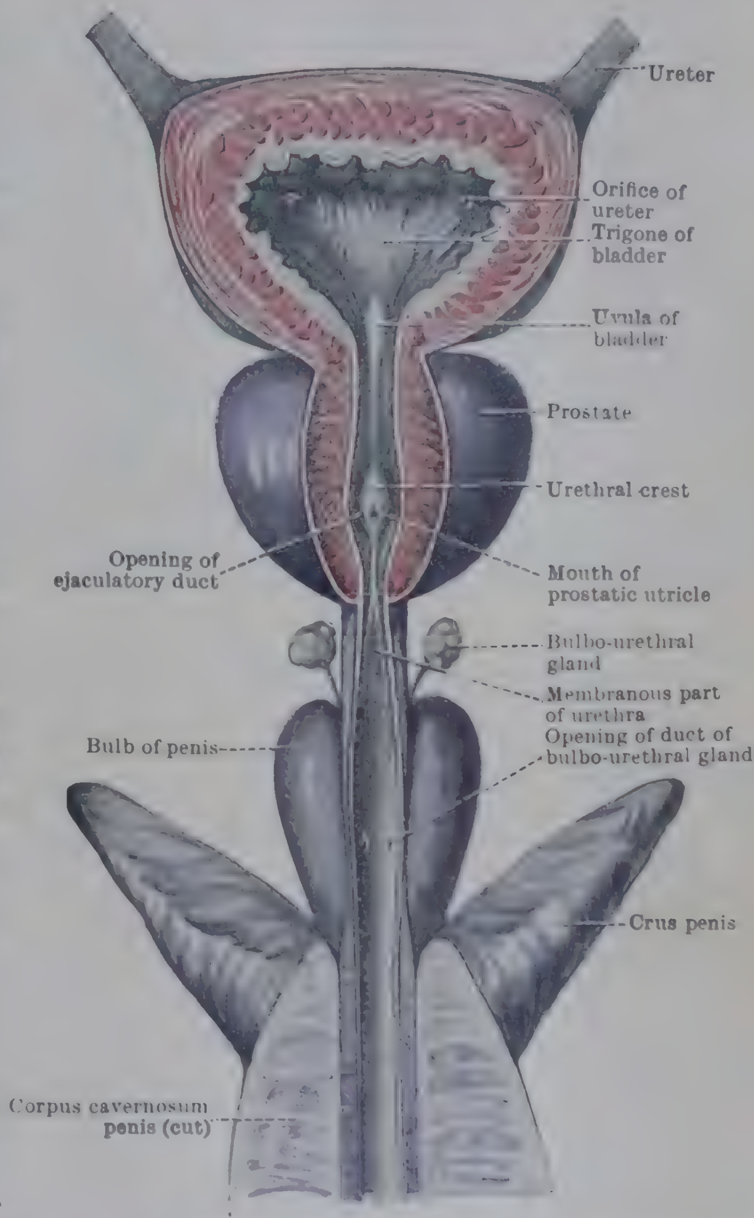

FIG. 632.—DISSECTION SHOWING TRIGONE OF BLADDER AND FLOOR OF THE URETHRA IN ITS PROSTATIC, MEMBRANOUS, AND PROXIMAL SPONGY PARTS.

The **spongy part** of the urethra is about six inches in length and is much the longest of the three divisions. It begins at a point about half an inch in front of the posterior end of the bulb of the penis, and it ends at the external urethral orifice. Its proximal or perineal portion has a fixed position and direction, while its distal part varies with the position of the penis. It traverses the corpus spongiosum, including the bulb and the glans, and is therefore entirely surrounded by erectile tissue in the whole of its length. Directed at first forwards through the bulb, it turns downwards and forwards at the point where it comes to lie in front of the lower part of the pubic symphysis (Fig. 631). The bend in the canal corresponds approximately to the place of attachment of the suspensory ligament to the dorsum of the penis. When the penis is drawn upwards towards the front of the abdomen, the direction of the terminal half of the canal is, of course, changed, and at the same time the whole spongy urethra becomes more uniformly curved.

Immediately after the urethra has pierced the perineal membrane its under-surface is overlapped by the erectile tissue of the bulb, but the upper wall remains uncovered for a distance of about a quarter of an inch (Fig. 631). The

wall of the urethra is there very thin, and the passage is more readily dilatable than in other parts. In this region the urethral wall may readily be torn if undue force is used in passing an instrument or if the handle of the instrument is depressed too soon, when an attempt is being made to pass it into the narrower, more fixed part of the canal. The urethra lies at first in the upper part of the erectile tissue, but as it passes forwards it sinks deeper and comes to occupy the middle part of the corpus spongiosum. In the glans, on the other hand, the erectile tissue lies mainly on the dorsal and lateral aspects of the urethra (Fig. 648). Like the other parts of the urethra, the spongy portion is closed except during the passage of fluid, the closure being effected by the apposition of its dorsal and ventral walls except in the glans penis, where the side-walls of the canal are in contact. Thus, the lumen of the first part of the canal, when empty, is represented in cross-section by a transverse slit (Fig. 647), and that of the terminal part by a vertical slit. The spongy part of the urethra does not present a uniform calibre throughout; it is wider in the bulb and glans than in the corpus spongiosum. In the bulb the urethra expands downwards, forming a little bulging called the **intrabulbar fossa.** The terminal dilated part is named the **fossa terminalis** and opens on the surface by the slit-like **external urethral orifice**, which is the narrowest and least dilatable point of the whole urethra.

The ducts of the bulbo-urethral glands open by very minute apertures in the inferior wall of the proximal part of the spongy part of the urethra (Fig. 632). Before opening into the canal, they lie for some distance immediately outside its mucous membrane. A number of little pit-like recesses, called the **urethral lacunæ**, also open into the spongy part of the urethra, and their openings lead for the most part obliquely into the canal in the direction of its external orifice.

A valve-like fold of the mucous membrane is sometimes found in the upper wall of the urethra in the region of the fossa terminalis. Its free edge is directed towards the external orifice, and it may engage the point of a fine instrument introduced into the urethra.

Structure.—The mucous membrane of the urethra contains numerous elastic fibres and varies in thickness in different parts of the canal. In many positions it shows distinct longitudinal folds and also minute depressions or pits—the *urethral lacunæ* already mentioned. The lining epithelium is composed of many layers of cells, and it is continuous through the internal urethral orifice with the epithelium of the bladder, which at first it closely resembles. In the region of the fossa terminalis the lining cells, which throughout the spongy portion of the canal are of a columnar type, become flat and scaly.

Numerous minute mucous glands—**urethral glands**—open into the urethra. They are most plentiful in the upper wall, but they occur in smaller numbers also in the floor and the side-walls. They are most numerous in the membranous part and in the anterior half of the spongy part.

The larger glands are deeply placed outside the mucous coat, and they communicate with the urethra by long, slender, obliquely placed, branched ducts. The smaller glands lie in the mucous coat and form flask-like depressions with very short ducts. The ducts of some of the glands open into the lacunæ; but many lacunæ have no connexion with the urethral glands.

Frequently two or more elongated ducts belonging to some of the larger glands open into the urethra quite close to its termination. They are spoken of as **para-urethral ducts**, and may be traced backwards for some distance outside the mucous membrane of the roof of the urethra. Morphologically they do not correspond to the ducts in the female which have received the same name.

The muscular wall in the upper part of the urethra consists of plain muscle-fibres directed for the most part longitudinally, but some circular fibres also are present. Throughout the greater part of the spongy urethra the muscular coat is either absent or exceedingly thin.

Around the beginning of the urethra there is an obliquely placed band of circularly arranged plain muscle-fibres which is continued downwards and forwards from below the anterior part of the trigone of the bladder. The lower and anterior fibres of this band lie in the anterior wall of the upper part of the prostatic urethra. The band is sometimes spoken of as the **sphincter vesicæ internus.** At a lower level, in front of the prostatic urethra, there is a band of striated muscular fibres which is continuous inferiorly with the inner circularly disposed part of the sphincter urethræ. Like the latter, it is probably to be regarded as a part of a primitive voluntary urogenital sphincter muscle, such as is represented also in the female subject.

Female Urethra.—The **female urethra** (Fig. 657) is a canal about an inch and a half in length which follows a slightly curved direction downwards and forwards, below and behind the lower border of the pubic symphysis. Except during the passage of urine the canal is closed by the apposition of its anterior and posterior walls. The **external urethral orifice** is placed between the labia minora, immediately in front of the opening of the vagina, about one inch below

and behind the clitoris (Fig. 663). The opening is slit-like, and is bounded by slightly marked lips. The mucous lining of the canal is raised into a number of slightly marked longitudinal folds, one of which, more distinct than the others and placed on the posterior wall of the passage, receives the name of **urethral crest.**

The upper part of the urethra is separated from the front of the vagina by a *vesico-vaginal space* filled with loose connective tissue. Lower down, however, it becomes very intimately connected with the vagina, so that, as it approaches the external urethral orifice, it appears to be embedded in the anterior vaginal wall. This is due to the fact that the lower part of the urethra is bound to the front of the vagina by the fusion of their fasciae into a single dense layer —the " post-urethral ligament " (Shaw, 1947).

Structure.—The muscular coat of the female urethra is continuous above with that of the bladder, and is composed of layers of obliquely disposed plain muscle-fibres, together with a few bundles which are longitudinally directed. In the lower part, some of the fibres do not completely surround the urethra but are attached to the anterior wall of the vagina. Within the muscular coat the wall of the urethra is very vascular, and the canal itself is lined with a pale mucous membrane which is thrown into the longitudinal folds mentioned above. The epithelium of the canal, in its upper part, is of the transitional variety, like that of the bladder; in its lower part it becomes scaly. Numerous minute **urethral glands** and pit-like **urethral lacunæ** open into the urethra. One group of these glands on each side possesses a minute common duct, known as the **para-urethral duct**, which opens into the pudendal cleft by the side of the external urethral orifice. These glands represent the prostatic glands of the male. The vascular layer which lies between the muscular coat and the mucous membrane contains elastic fibres, and in appearance resembles erectile tissue. Striated muscle-fibres are present on the outer surface of the muscular coat of the urethra. In the upper part of the canal these fibres form a complete ring-like sphincter, so that the urethra is encircled by both plain and striated fibres. Lower down, some of the striated fibres are attached to the anterior vaginal wall, and in the lower third, where they are specially developed, they pass backwards on the outer surface of the vagina to enclose that passage together with the urethra in a single loop of muscle-tissue. The lower fibres, therefore, form a urogenital sphincter associated with the **sphincter urethrae muscle.**

MALE GENITAL ORGANS

The male reproductive organs are (1) the testes together with (2) their coverings and (3) their ducts, (4) the prostate, (5) the bulbo-urethral glands, (6) the external genital organs, and (7) the male urethra.

The **testes** are the essential reproductive glands of the male, and are a pair of nearly symmetrical oval bodies situated in the scrotum. The duct of each testis is at first much twisted and contorted to form a structure known as the **epididymis**, which is applied against the back of the testis; the duct emerges from the epididymis as the **vas deferens**, which passes upwards towards the lower part of the anterior abdominal wall and pierces it obliquely to enter the abdominal cavity. There, each vas deferens is covered with the peritoneum, and, crossing the pelvic brim almost at once, enters the true pelvis. The duct now runs on the side-wall of the pelvis towards the base of the bladder, where it comes into relation with a branched tubular structure termed the **seminal vesicle.** Joined by the duct of the seminal vesicle, the vas deferens forms a short canal, called the **ejaculatory duct**, which terminates by opening into the prostatic part of the **urethra**. The **prostate** and the **bulbo-urethral glands** are accessory organs connected with the male reproductive system. The ducts of the bulbo-urethral glands and those of the prostate, like the ejaculatory ducts, open into the **urethra**, which thus serves not only as a passage for urine, but also for the generative products. The external genital organs are the **penis and scrotum**.

TESTES

The **testes** are a pair of oval, slightly flattened bodies of a whitish colour, measuring about an inch and a half in length, one inch from before backwards, and rather less in thickness. Each testis is placed within the cavity of the scrotum in such a manner that its long axis is directed upwards and slightly forwards and laterally. Usually the left gland is a little lower than the right. The testis (Fig. 635) has two slightly flattened surfaces: a *lateral surface*, which looks backwards as well as laterally, and a *medial surface*, which looks forwards as well as medially, and is usually the more flattened. The two surfaces are separated

by rounded **anterior** and **posterior borders**. The anterior border is the more convex and is free. By the posterior border the testis is suspended within the scrotum. The **epididymis** and the lowest portion of the **spermatic cord** are attached to the posterior border of the testis (Figs. 634, 635).

Epididymis.—The epididymis is a comma-shaped structure that clasps the posterior border of the testis and to some extent overlaps the posterior part of its lateral surface (Fig. 633). The upper, swollen part is called the **head of the epididymis** and overhangs the upper end of the testis, to which it is directly connected by numerous emerging ducts, by fibro-areolar tissue, and by the serous covering of the organ. The inferior and smaller end is termed the **tail of the epididymis**; it is attached by loose areolar tissue and by the serous covering to the lower part of the testis. The intervening part, or **body of the epididymis**, is applied against the posterior part of the lateral surface of the testis but is separated from it by an involution of the serous covering of the organ which forms an intervening pocket termed the **sinus of the epididymis**.

The main mass of the epididymis is composed of an irregularly twisted tube, called the **canal of the epididymis**, which forms the first part of the duct of the testis (Figs. 636, 637).

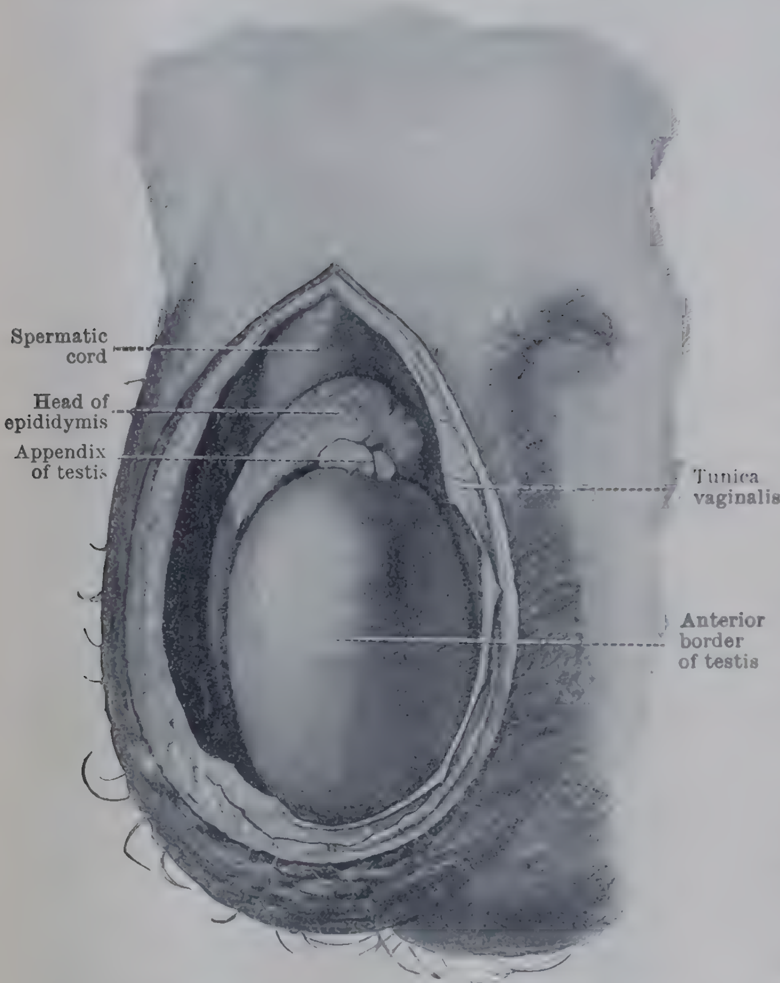

FIG. 633.—RIGHT TESTIS AND EPIDIDYMIS, EXPOSED BY REMOVAL OF ANTERIOR WALL OF SCROTUM.

Minute sessile or pedunculated bodies are often found attached to the head of the epididymis and to the upper end of the testis. They are called appendices of the epididymis and testis, and have a developmental interest. The **appendix of the testis** is a minute body which lies on the upper end of the testis and represents the free end of the para-mesonephric duct of the embryo and the fimbriated end of the uterine tube of the female; it is usually sessile. The **appendix of the epididymis** is attached to the head of the epididymis and is believed to represent a remnant of the mesonephros. Another small vestigial body called the **paradidymis**, also believed to be a remnant of the mesonephros, is sometimes found above the head of the epididymis in front of the lower part of the spermatic cord. It is best marked in young children and is seldom found in the adult.

Tunica Vaginalis.—The walls of the cavity within which the testis and epididymis are placed are lined with a serous membrane—the **tunica vaginalis**—which resembles in appearance and structure the peritoneum, from which it was originally derived. The cavity is considerably larger than the contained structures, and extends to both a higher and a lower level than the testis. The cavity tapers as it is traced upwards. The tunica vaginalis is an invaginated membrane doubled in on itself from behind, for, after lining the scrotal chamber, it is reflected forwards from the posterior wall to cover the testis, epididymis, and lower part of the spermatic cord. The inner layer is known as the visceral layer and is closely applied to the enclosed organs; the outer or parietal layer is fairly strongly attached to the wall of the scrotum; and between the two layers there is a closed

cavity that contains a little serous fluid. The visceral layer dips into the narrow interval between the body of the epididymis and the lateral surface of the testis to form a slit-like recess called the **sinus of the epididymis** (Figs. 634 and 635). In three positions the surface of the testis receives no covering from the tunica vaginalis—above, where the head of the epididymis is attached; below, where the tail is in contact; and posteriorly, where the blood-vessels and nerves enter the organ from the spermatic cord.

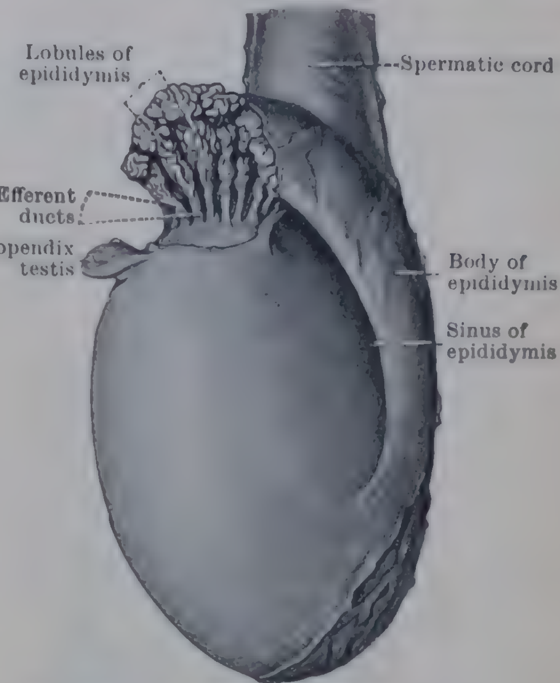

FIG. 634.—LEFT TESTIS AND EPIDIDYMIS.

Part of the tunica vaginalis has been removed in order to show the efferent ducts and the lobules of the epididymis.

Structure of Testis.—Under cover of the tunica vaginalis the testis is invested by an external coat of dense, white, inelastic fibrous tissue called the **tunica albuginea**, from the deep surface of which a number of thin fibrous **septa** dip into the gland. These septa imperfectly divide the organ into a number of wedge-shaped parts called **lobes of the testis** (Fig. 635). All the septa end posteriorly in a mass of fibrous tissue called the **mediastinum testis**, which is directly continuous with the tunica albuginea and projects forwards into the testis along its posterior border. It is traversed by an exceedingly complicated network of fine canals called the **rete testis**; the minute tubules that compose the substance proper of the testis open into the rete. The mediastinum is pierced also by the arteries, veins, and lymph-vessels of the testis; they enter the posterior border of the organ, traverse the mediastinum, and spread out on the fibrous septa. In this way a delicate network

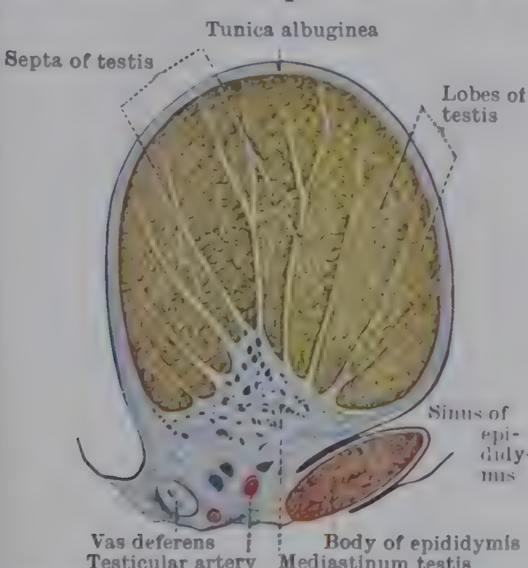

FIG. 635.—TRANSVERSE SECTION OF TESTIS AND EPIDIDYMIS.

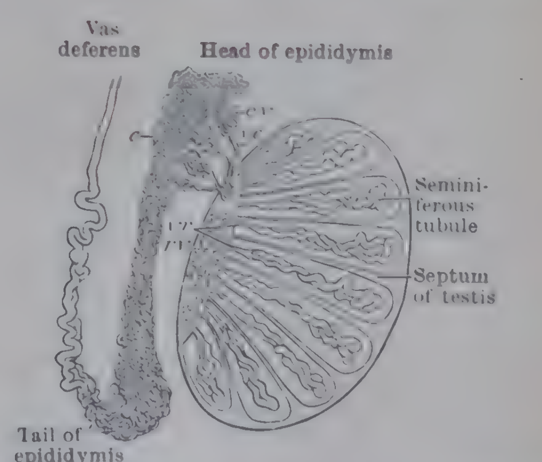

FIG. 636.—DIAGRAM TO ILLUSTRATE STRUCTURE OF TESTIS AND EPIDIDYMIS.

c. Canal of epididymis. c.v. Lobules of epididymis. r.v. Rete testis. v.e. Efferent ductules of testis. v.r. Straight seminiferous tubules.

of vessels—the *tunica vasculosa*—is formed on the deep surface of the tunica albuginea and on the sides of the septa.

The mediastinum, the septa, and the tunica albuginea form a framework enclosing a number of imperfectly isolated spaces which are filled by a substance of a light brown colour called the **parenchyma testis**. The parenchyma is composed of enormous numbers of **convoluted seminiferous tubules**. These minute tubules look like fine threads to the unaided eye, and they are but loosely held together by a small amount of areolar tissue. Usually two or four tubules are found in each lobe of the gland, and the total number in the testis has been

estimated at more than 800. The convoluted tubules pass towards the mediastinum testis and unite at acute angles to form a smaller number of slender tubes which run a straight course and are called the **straight seminiferous tubules**; and they open into the rete testis (Fig. 636). The tubules are much more twisted and convoluted near the tunica vaginalis than in the region of the mediastinum.

Microscopic sections show that the walls of the seminiferous tubules are composed of a basement membrane and of an epithelial lining formed of several layers of cells. Certain cells of the epithelium (*spermatogonia and spermatocytes*, p. 28) are, in the adult, constantly undergoing transformation into **spermatozoa**, and the appearance of the tubules in section varies much, according to age and to the greater or less activity of the epithelial cells.

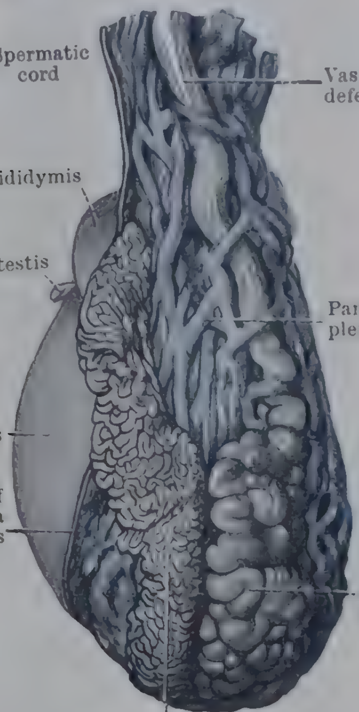

FIG. 637. — LEFT TESTIS AND EPIDIDYMIS VIEWED FROM BEHIND, SHOWING CANAL OF EPIDIDYMIS AND FIRST PART OF VAS DEFERENS.

Structure of Epididymis.—The secretion of the convoluted seminiferous tubules is carried through the straight tubules into the rete testis, and it leaves the rete, to reach the canal of the epididymis, through from fifteen to twenty minute tubules called the **efferent ductules of the testis.** These efferent ductules pierce the tunica albuginea and enter the head of the epididymis. Each ductule is at first straight, but soon becomes much convoluted, and forms a little conical mass called a **lobule of the epididymis**. Within the head of the epididymis the little twisted canals open into the single, much-convoluted tube which constitutes the chief bulk of the epididymis, and is called the **canal of the epididymis**. This canal, which is about 20 feet in length, may be said to begin in the head of the epididymis, and to end, after an extraordinarily tortuous course, at the tail by becoming the **vas deferens** (Figs. 636, 637).

In most cases one or more slender convoluted diverticula from the canal of the epididymis may be found near its lower end; they receive the name of **aberrant ductules**, and one of them which is very constantly present often measures a foot or more in length.

The canal of the epididymis and the efferent ductules of the testis are lined with a ciliated epithelium, the cilia of which maintain a constant current towards the vas deferens. The canal has a muscular coat composed of an inner stratum of circular fibres and an outer stratum of longitudinally directed fibres. The wall, at first thin, becomes much thicker as the canal approaches the vas deferens.

Vessels and Nerves of Testis.—The testis is supplied by the **testicular artery**, a branch of the aorta. It is a slender vessel which, after a long course, reaches the posterior border of the testis, where it breaks up into branches. According to Harrison & Barclay (1948), there are commonly two main branches which pass forwards in the tunica albuginea, one on each side of the organ, to ramify on its deep surface in variable patterns. From these arteries—which vary in number and arrangement—the principal terminal branches pass backwards into the substance of the testis in the tunica vasculosa of the septa and converge on the mediastinum. Only very fine branches, as a rule, pass into the testis directly through the mediastinum. For the relation of the *artery of the vas deferens* and the *cremasteric artery* to the blood-supply of the testis through anastomoses with the testicular artery, see Harrison (1949).

The **veins** issue from the posterior border of the testis and form a dense plexus, called the **pampiniform plexus**, which finally pours its blood through the testicular vein, *on the right side*, into the inferior vena cava, and, *on the left side*, into the left renal vein.

The **lymph-vessels** of the testis pass upwards in the spermatic cord and end in the lymph-glands at the sides of the aorta and inferior vena cava below the renal veins (p. 1415).

The **nerves** for the testis and epididymis accompany the artery, and are derived through the *aortic* and *renal plexuses* from the tenth thoracic segment of the spinal cord. The arteries and nerves of the testis communicate with those on the lower part of the vas deferens, namely, with the artery of the vas deferens and with nerve-bundles from the hypogastric plexus.

VAS DEFERENS AND SPERMATIC CORD

The **vas deferens** is the direct continuation of the canal of the epididymis. It begins at the lower end of the epididymis and ends, after a course of nearly 18 inches, by joining the duct of the seminal vesicle to form the ejaculatory duct, which opens into the prostatic part of the urethra; in parts of its course it is slightly convoluted, and the actual distance traversed is not more than 12 inches. It first ascends to the superficial inguinal ring; it next runs laterally in the inguinal canal to the deep ring; and then, having entered the abdomen, it bends medially and backwards to reach the true pelvis, where it ends behind the neck of the bladder.

At first it lies in the scrotum, where it ascends over the back of the testis along the medial side of the epididymis, and it is here that it is most convoluted (Fig. 637). At the upper end of the testis it falls in with the vessels and nerves of the testis and epididymis, and it is bound together with them by areolar tissue in a loose bundle called the spermatic cord.

FIG. 638.—TRANSVERSE SECTION OF SPERMATIC CORD IMMEDIATELY BELOW SUPERFICIAL INGUINAL RING.

The **spermatic cord** is therefore made up of (1) the vas deferens and its own artery, (2) the testicular artery and the pampiniform plexus of veins, (3) the lymph-vessels and nerves of the testis and epididymis, and (4) remnants of the processus vaginalis—the plexus of veins being by far the bulkiest of these constituents. The cord extends from the testis to the deep inguinal ring, and it is enclosed in three tubular sheaths or **coats**—the external spermatic fascia, the cremasteric muscle and fascia, and the internal spermatic fascia (Fig. 638). When these coats reach the scrotum they expand and take a share in the formation of the wall of the scrotum; and the cremasteric coat carries with it its blood-supply and nerve-supply—*the artery and nerve to the cremaster*.

Between the scrotum and the superficial inguinal ring, the cord lies on the deep fascia of the muscles that spring from the pubis, and it is crossed by the superficial external pudendal vessels. In this part of the course the vas is in the posterior part of the cord, and is easily distinguished from the other constituents (even in the undissected body), by its hard, firm feel when the cord is gripped between finger and thumb. When the cord enters the inguinal canal it lies on the inferior crus of the superficial ring immediately lateral to the pubic tubercle; and here it loses its external spermatic coat, which blends with the external oblique aponeurosis at the margins of the ring (Fig. 645).

During its passage through the inguinal canal, the vas lies in the lower part of the cord on the grooved, upper surfaces of the inguinal ligament and its pectineal part; the external oblique aponeurosis and the lower fleshy fibres of the internal oblique are in front; and the conjoint tendon and the transversalis fascia are behind. Half way along the canal the cord loses its cremasteric coat, for that coat is derived from the lower border of the internal oblique muscle, which arches over the cord.

Less than half an inch above the mid-inguinal point, at the lateral side of the inferior epigastric artery, the cord reaches the deep inguinal ring. Here, the cord loses its internal spermatic coat, which blends with the transversalis fascia at the margins of the ring. Here also, the cord ends, for at this point the vas deferens parts company with the vessels and nerves.

The vas deferens now curves medially across the external iliac artery behind the root of the inferior epigastric artery, and then, changing its direction, it runs for a short distance backwards, medially, and, upwards, outside the peritoneum, to a point $1\frac{1}{2}$ or 2 inches from the pubic tubercle, where it crosses the pectineal line and enters the true pelvis. In that part of its course the vas usually

lies at first in front of the external iliac vessels, and then in the floor of a little triangular fossa—the *pectineal triangle*—which lies between the external iliac

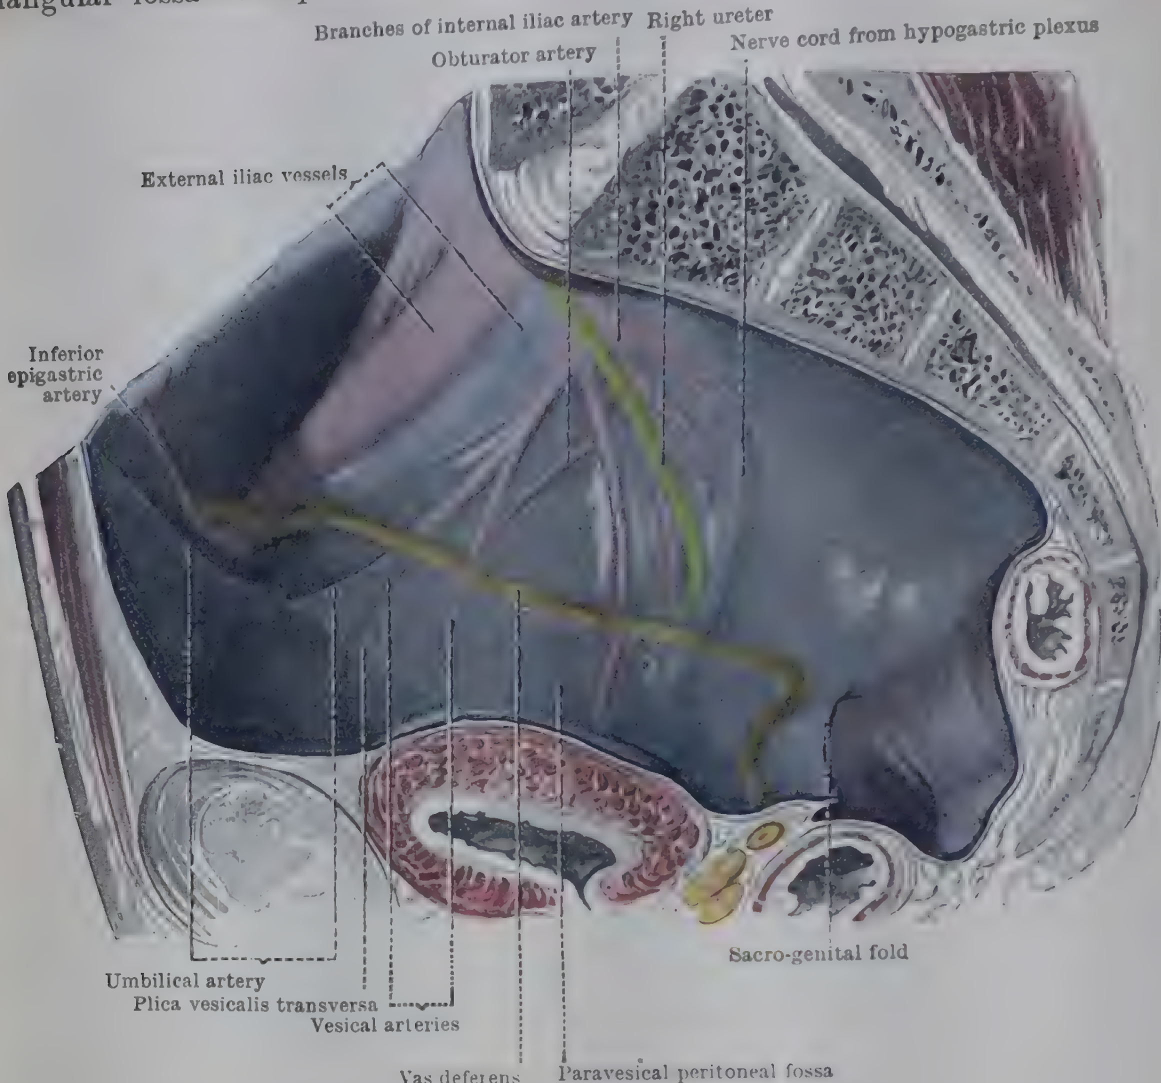

FIG. 639.—MEDIAN SECTION OF ADULT MALE PELVIS TO SHOW COURSE OF VAS DEFERENS ON SIDE-WALL OF PELVIC CAVITY.

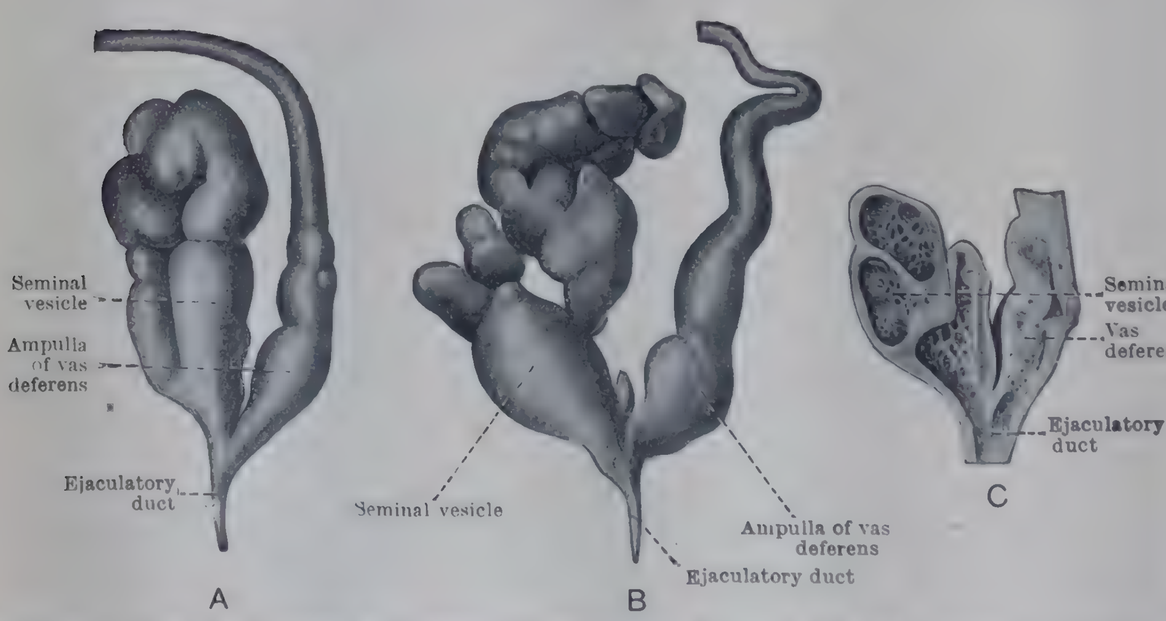

FIG. 640.—A and B. DRAWINGS OF SEMINAL VESICLE AND AMPULLA OF VAS DEFERENS TAKEN FROM DIFFERENT SUBJECTS. C. SEMINAL VESICLE AND AMPULLA OF VAS DEFERENS CUT TO SHOW THE PITTED STRUCTURE OF THEIR WALLS.

vessels and the pelvic brim (Fig. 625). On the side-wall of the pelvis the vas is continued backwards, and a little downwards and medially, in the direction of the ischial spine, and lies immediately external to the peritoneum, through which it

can usually be seen. In the pelvic part of its course the vas crosses the medial side of (1) the umbilical artery, (2) the obturator nerve and vessels, (3) the vesical **vessels**, and (4) the **ureter** (Fig. 639).

Beyond the ureter the vas deferens takes a sudden bend and passes downwards and medially outside the peritoneum of the pelvic floor. There, the vas lies a short distance behind the terminal part of the ureter and immediately in front of the sacro-genital fold of peritoneum (Figs. 625, 639). Reaching the interval between the base of the bladder in front and the rectum behind, the two vasa deferentia occupy the angle between the right and left seminal vesicles (Fig. 642). As they approach each other each vas becomes slightly tortuous, sacculated, and dilated, and assumes a general resemblance in structure to a portion of the seminal vesicle. The dilated part of the vas is termed its **ampulla**. Immediately above the base of the prostate the vas deferens becomes once more a slender tube and is joined by the duct of the corresponding seminal vesicle to form the **ejaculatory duct** (Fig. 640).

In some cases the vas deferens crosses the umbilical artery before it enters the cavity of the true pelvis; it normally does so in the fœtus (Fig. 643).

Ejaculatory Duct.—This is the very slender tube formed by the union of the vas deferens with the duct of the corresponding seminal vesicle (Fig. 640). It is less than an inch in length, and lies very close to its fellow of the opposite side as it passes downwards and forwards through the prostate behind its median lobe. The ducts open by slit-like apertures into the first part of the urethra, one on each side of the mouth of the **prostatic utricule**. They are well seen in sections through the upper part of the prostate (Fig. 651, A).

The mucous membrane of the duct is thrown into numerous complicated folds, and in connexion with it there is a number of remarkable minute diverticula which are enclosed within the muscular coat of the duct. Ancel (1920) states that the ejaculatory duct is absent on one or both sides in 18 per cent of adults and that the vas deferens and duct of the seminal vesicle then open separately either into the utricle or on the urethral crest.

SEMINAL VESICLES

The **seminal vesicles** are a pair of hollow sacculated structures placed on the base of the bladder in front of the rectum (Figs. 624, 642). Each vesicle is about two inches in length, and has its long axis directed downwards, medially, and slightly forwards. The upper end of the vesicle, which is partly covered with peritoneum, is large and rounded, and lies at a considerable distance from the median plane, behind the lower end of the ureter, and is separated from the rectum by the peritoneum of the recto-vesical pouch. Below the level of the peritoneal cavity the seminal vesicle and rectum are more intimately related. The vesicle tapers towards its lower end, which is placed not far from the median plane immediately above the prostate. In this position the vesicle becomes constricted to form a short duct which joins the lateral side of the corresponding vas deferens at an acute angle. The common duct thus formed is the **ejaculatory duct**. The medial side of each vesicle is related to the vas deferens, and the lateral side, when the bladder is empty, lies

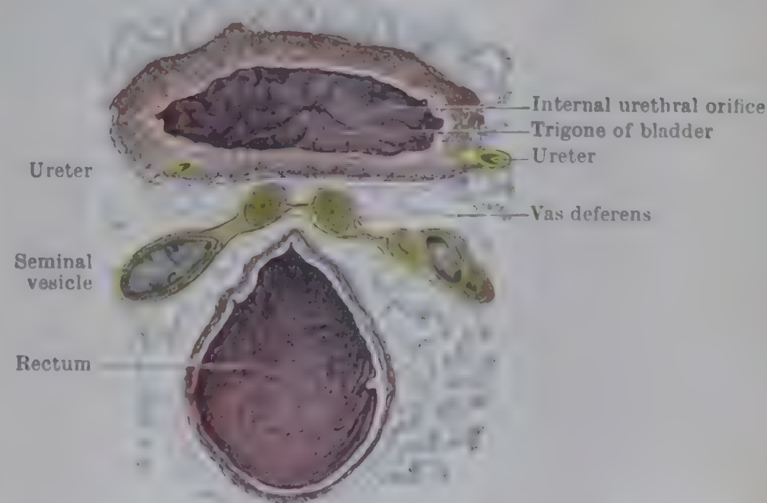

FIG. 641.—HORIZONTAL SECTION THROUGH RECTUM AND URINARY BLADDER AT THE LEVEL AT WHICH THE URETERS PIERCE THE BLADDER-WALL.

From a specimen in the Surgical Museum, Trinity College, Dublin.

close to the levator ani. The seminal vesicles are more intimately related to the wall of the bladder than to that of the rectum. Their upper ends are separated from the rectum by a portion of the recto-vesical pouch, and, lower down, the partition of plain muscle-fibres and of fascia which intervenes between the seminal vesicles and the rectum is thicker than that which separates them from the bladder.

The seminal vesicle assumes a more vertical position when the bladder is distended, and a more horizontal direction when the bladder is empty. Its upper end is sometimes curved backwards against the side of the rectum. In some cases the seminal vesicles are much smaller than usual, and may be less than one inch in length. Frequently they are asymmetrical in size and shape.

Each seminal vesicle is in reality a tube bent in a tortuous manner on itself; if the dense

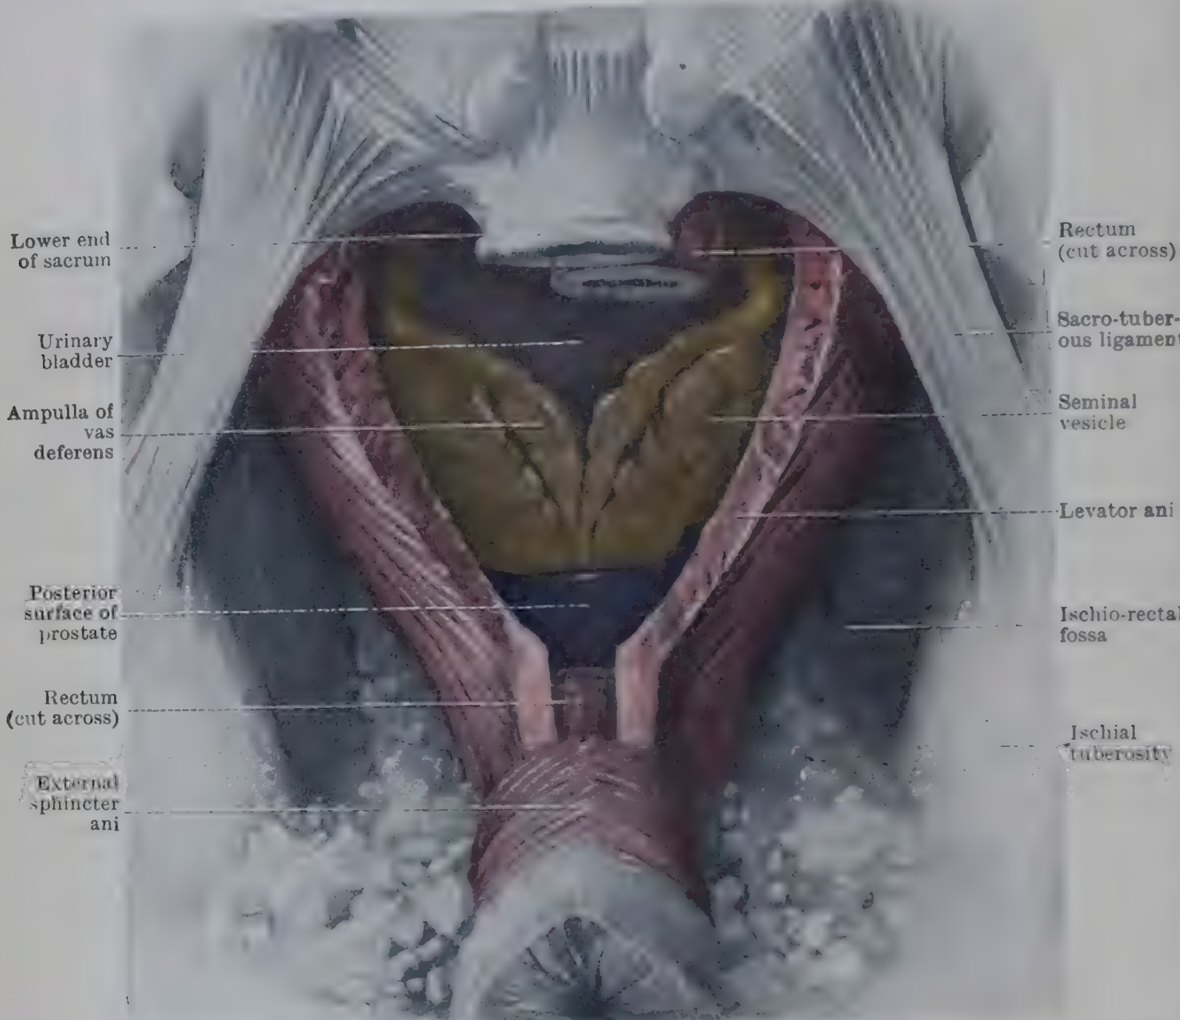

FIG. 642.—DISSECTION FROM BEHIND TO DISPLAY THE SEMINAL VESICLES, THE AMPULLÆ OF THE VASA DEFERENTIA, AND THE PROSTATE.

tissue which envelops it is taken away, the length of the tube when untwisted may be found to be as much as five inches. The tube is closed above, and a variable number of short tortuous branches arise from it at different levels. The blind end of the tube usually lies at the upper end of the vesicle, but in some cases the tubular structure is so bent upon itself that the blind terminal part lies against the side of the issuing duct. Their mode of development shows that the seminal vesicles are diverticula of the vasa deferentia, from which they originally arise as small, pouched outgrowths.

The seminal vesicles are not present in all mammals, and in those in which they do occur their relative size and form vary much. The carnivora and marsupials, for instance, have no seminal vesicles; in some other animals, *e.g.*, hedgehog, they are relatively of enormous size.

The dense tissue in which the seminal vesicles are embedded contains much plain muscle-tissue which sweeps round in the side-wall of the recto-vesical pouch. Inferiorly this tissue is attached to the capsule of the prostate. The large veins coming from the prostatic and vesical plexuses are closely related to the seminal vesicles.

Structure of Vas Deferens and Seminal Vesicle.—Except at the ampulla, the vas deferens is a thick-walled tube with relatively a very small lumen. The hard cord-like sensation which it conveys to the touch is due to the thickness and denseness of its wall. The wall of the vas is composed of three layers—an outer **adventitious coat** of fibrous tissue, a middle **muscular coat**, and an inner **mucous coat**. The thickness of the wall is due to the great

development of its coat of plain muscle, which is arranged in three layers: an outer and an inner of longitudinal fibres, and a middle layer—by far the thickest—of circular fibres. The mucous membrane of the vas exhibits a number of slight longitudinal folds and is covered with a ciliated epithelium. The ampulla has a much thinner wall, and, as the surface of its mucous membrane has a number of ridges separating depressed areas, the lining of this part of the tube presents a honeycomb appearance. The wall of the seminal vesicle resembles that of the ampulla in being thin, and in having a mucous lining with uneven, honeycomb-like ridges and depressions (Fig. 640, C). In it the same coats are to be recognized as in the vas deferens but the muscular layer is much thinner, and the strata composing it are less regularly arranged.

Vessels and Nerves of Vas Deferens and Seminal Vesicle.—The vas receives its main **artery** from the superior or the inferior vesical artery. This *artery to the vas* accompanies it as far as the testis, where it ends by anastomosing with branches of the testicular artery. The seminal vesicle is supplied by twigs from the *inferior vesical artery*. The **nerves** come from the hypogastric plexus. In lower animals the nerves for the seminal vesicles are derived from the nerve-roots of the second, third, and fourth lumbar nerves.

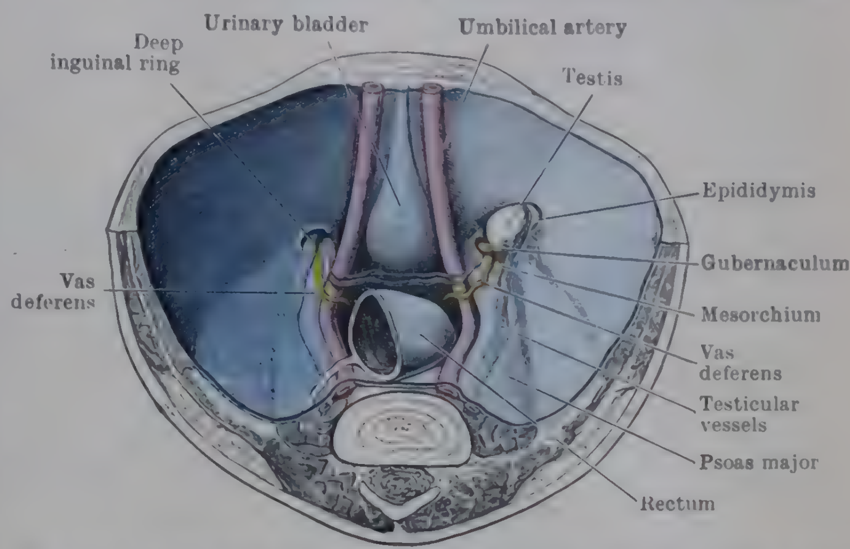

Fig. 643.—View from Above of Cavity of Pelvis and Lower Part of Abdomen in Male Fœtus about the Seventh Month.

On the left side, which represents a slightly more advanced condition than the right, the testis has entered the inguinal canal; on the right side the testis is still within the abdominal cavity.

Descent of Testis

The cause of the peculiar course pursued by the vas deferens in the adult, and the manner in which it is related to the anterior abdominal wall, are made clear by a study of the arrangement of the parts in the fœtus (Kirk, 1936; Wyndham, 1943). Until nearly the end of intra-uterine life the testes are in the abdominal cavity. The testis at first lay on the posterior abdominal wall at the level of the upper lumbar vertebræ. To its lower pole a ridge of tissue called the **gubernaculum testis** (John Hunter, 1786) was attached and this ridge extended down to the inguinal region. Both testis and gubernaculum were behind the primitive peritoneum but they pushed it forwards; the gubernaculum thus formed a ridge covered with peritoneum, and the testis—almost completely surrounded by peritoneum—was attached to the posterior abdominal wall by a peritoneal fold called the **mesorchium**. Meanwhile a blind tube of peritoneum called the **processus vaginalis** grew down through the layers of the developing abdominal wall in the inguinal region, and as it did so it pushed attenuated parts of these layers before it. These layers become the coats of the spermatic cord. As the processus vaginalis grew down, the gubernaculum grew down behind it, forming a peritoneum-covered ridge similar to that in the abdominal cavity, and then, by tension of the gubernaculum, the testis, still protruding forwards into a peritoneal invagination, slid down the posterior abdominal wall and the back of the processus vaginalis. By the third month of fœtal life the testis lies in the iliac fossa, and by the seventh it is near the deep inguinal ring (Figs. 643, 644).

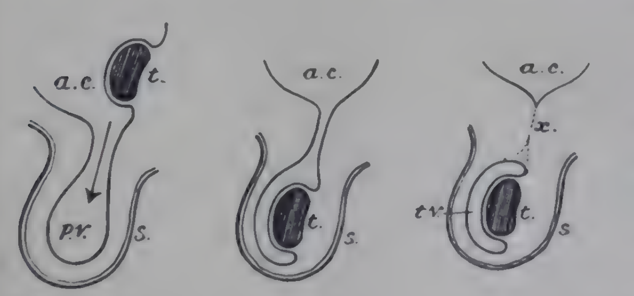

Fig. 644.—Diagram to illustrate Descent of the Testis and Origin of Tunica Vaginalis.

a.c. Abdominal cavity. *p.v.* Processus vaginalis. *t.* Testis. *s.* Scrotum. *t.v.* Tunica vaginalis. *x.* Vestige of processus vaginalis.

Often a small fibrous band may be found in the adult passing through the inguinal canal and joining the peritoneum superiorly in the region of the deep inguinal ring. Sometimes the band is connected below with the tunica vaginalis, but more often it cannot be traced so far downwards. When present it represents the obliterated portion of

the processus vaginalis, and is therefore known as the **vestige of the processus vaginalis.**

The processus vaginalis occasionally persists after birth as a channel freely open to the abdominal cavity above; or the passage, becoming closed at intervals, may give rise to one or more cysts within the coats of the spermatic cord.

It sometimes happens that the descent of the testis is arrested, and then it either remains on the posterior abdominal wall or protruding forwards into a persisting upper part of the processus vaginalis in the inguinal canal. The term "cryptorchism" is applied to such cases of undescended testis; and the organ is then usually functionless. On the other hand, the testis may be *ectopic* through irregular descent into the perineum or even into the upper part of the thigh.

As the testis enters the inguinal canal the gubernaculum atrophies, but at birth a short part of the gubernaculum may still be found passing downwards towards the lower part of the scrotum and lying below the level of the tunica vaginalis. It is considered by some anatomists that the movement downwards of the testis may be partly due to a pull caused by the shrinking of the gubernaculum as it atrophies. In its descent the testis takes with it its duct and vessels and nerves, and they form the *spermatic cord.*

In some mammals, such as the elephant, the testes remain permanently within the abdominal cavity; while in others, such as the rabbit and the hedgehog, the peritoneal pouches remain widely open throughout life, and the testes are periodically withdrawn into the abdomen. There is some evidence that the descent of the mammalian testes is related to the fact that temperature in the scrotum is lower than in the abdomen (Crew, 1922); but intra-abdominal pressure may also be a factor (Keith, 1948). (See also Wells, 1943.)

SCROTUM

The **scrotum** varies much in appearance in different subjects, and even in the same person at different times. As the result of cold or of exercise, the wall of the scrotum becomes contracted and firm, and its skin becomes wrinkled; at other times the wall may be relaxed and flaccid, the scrotum then assuming the appearance of a pendulous bag. The left side of the scrotum reaches a lower level than the right, in correspondence with the lower level of the left testis. The skin of the scrotum is of a darker colour than the general skin of the body and is covered sparsely with hair; it is marked in the median plane by a ridge called the **raphe scroti**, which is continued backwards towards the anus and forwards on to the urethral surface of the penis. The difference in the appearance of the scrotum at different times is due to the degree of contraction or relaxation of a layer of plain muscular fibres, constituting the **dartos**, situated in the superficial fascia. When that muscular layer is contracted, the scrotum becomes smaller, and the skin is thrown into folds or wrinkles; when it is relaxed, the scrotum is flaccid and pendulous, and the skin becomes more smooth and even. The layer of fascia which contains the muscle-fibres can be shown to be continuous superiorly with the superficial fascia of the penis, and with the deep layer of the superficial fascia of the abdomen, and to be attached laterally to the sides of the pubic arch. The muscle-fibres are arranged in a thick layer of interlacing bundles, and many of the deeper fibres are continued into the **septum of the scrotum**, which divides the scrotum into a pair of chambers, one for each testis. The wall of each chamber is formed by the corresponding tunica vaginalis, internal spermatic fascia, cremasteric muscle and fascia and external spermatic fascia, while the skin, the superficial fascia, and the dartos muscle form coverings which are common to the whole scrotum, and they enclose both chambers. The layer of tissue immediately internal to the dartos is made up of exceedingly loose and easily stretched areolar tissue, and in it, as throughout in the superficial fascia of the scrotum, there is an entire absence of fat.

The scrotum in the fœtus has no cavity, but, like the labia majora in the female, it is composed entirely of vascular and fatty areolar tissue.

Vessels and Nerves of Scrotum.—On each side the **arteries** are *scrotal branches* from the internal pudendal artery, which reach it from behind, and from the external pudendal arteries, which reach its upper and anterior part.

The **nerves** of the scrotum are derived on each side from the posterior scrotal branches of the pudendal nerve, from the perineal branch of the posterior cutaneous nerve of the thigh, and from the ilio-inguinal nerve. The branches from the pudendal and posterior cutaneous nerves reach the scrotum from behind, while the ilio-inguinal supplies its upper and anterior part.

PENIS

The **penis** (Figs. 620, 650) is composed chiefly of erectile tissue, and is traversed by the urethra. The surface nearest the urethra is called the **urethral surface**; the opposite and more extensive aspect is the **dorsum penis**. The erectile tissue is for the most part disposed in three longitudinal columns, which in the body of the organ are closely united, while at the root of the penis they separate from one another and become attached to the perineal membrane and the sides of the pubic arch. Two of the columns of erectile tissue are placed alongside the median plane; they form the dorsum and sides of the penis, and are called the **corpora cavernosa penis**. The third column is situated in the median plane near the urethral surface, and is called the **corpus spongiosum penis**. The corpus spongiosum is the part of the penis

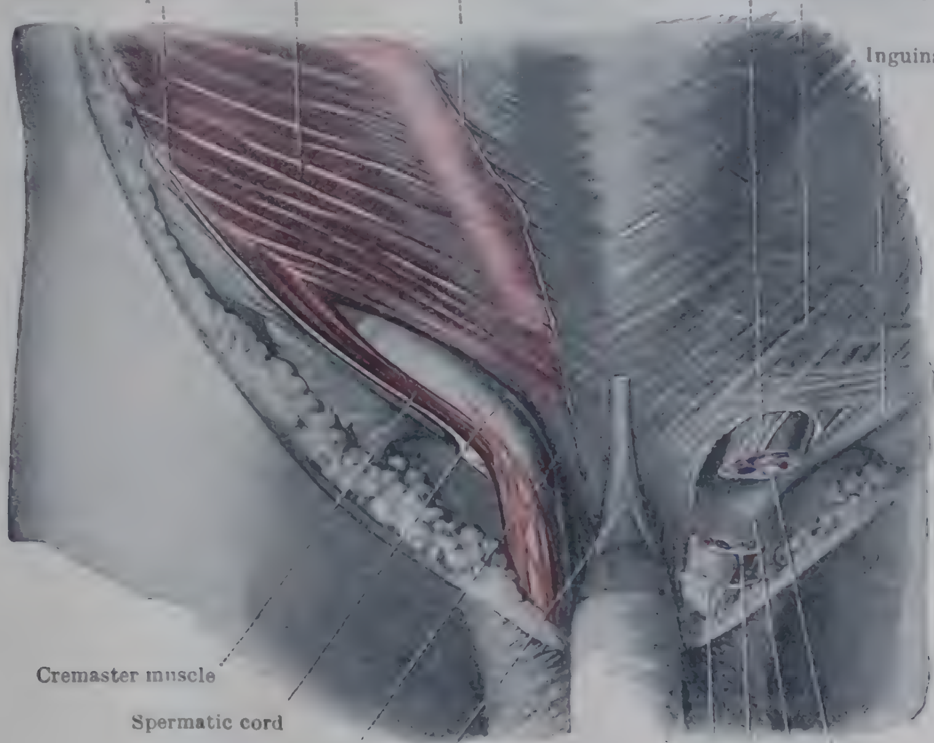

FIG. 645.—DISSECTION TO SHOW THE SPERMATIC CORD AS IT ISSUES FROM THE SUPERFICIAL INGUINAL RING. On the right side the external oblique muscle has been removed.

traversed by the urethra, and it is considerably smaller than the corpora cavernosa, which form the chief bulk of the organ (Figs. 646, 647).

In the **body of the penis** each corpus cavernosum presents a rounded surface, except where it is flattened by contact with its fellow of the opposite side. They are separated on the dorsal surface by a shallow groove, and on the urethral aspect by a deeper and wider furrow in which the corpus spongiosum lies (Fig. 646). Towards the distal end of the penis the corpus spongiosum expands, and, spreading towards the dorsal surface, forms a kind of conical cap—the **glans penis**—which covers over the blunt terminations of the corpora cavernosa (Fig. 648). The prominent margin of the glans, called the **corona glandis**, projects backwards and laterally beyond the ends of the corpora cavernosa. The glans is traversed by the terminal part of the urethra, which ends near the summit of the glans in a slit-like opening—the **external urethral orifice**. The united corpora cavernosa end in a blunt conical extremity, the apex of which is received into a hollow in the base of the glans. The skin of the body of the penis is thin, delicate, and freely movable, and, except near the pubis, is free from hairs; on the urethral aspect the skin is marked by a median raphe, continuous with the raphe of the scrotum. Traced towards the base of the glans, the skin forms

a free fold—the **prepuce** or foreskin—which overlaps the glans to a variable extent. From the deep surface of the prepuce the skin is reflected on to the terminal part of the penis along a line a little proximal to the corona glandis, and is continued over the entire glans to the external urethral orifice (Fig. 631). A small median fold—the **frenulum of the prepuce**—passes to the deep surface of the prepuce from a point immediately below the external urethral orifice. The skin of the glans is firmly attached to the underlying erectile tissue, and here, as well as on the deep surface of the prepuce, it has some resemblance to mucous membrane.

The secretion known as the **smegma præputii**, which tends to collect beneath the prepuce, has its source in the desquamated and broken-down epithelial cells derived from the surface of the glans and prepuce. A long, narrow prepuce, which cannot be retracted from the glans and may be adherent to it, may have to be removed by the operation of *circumcision.*

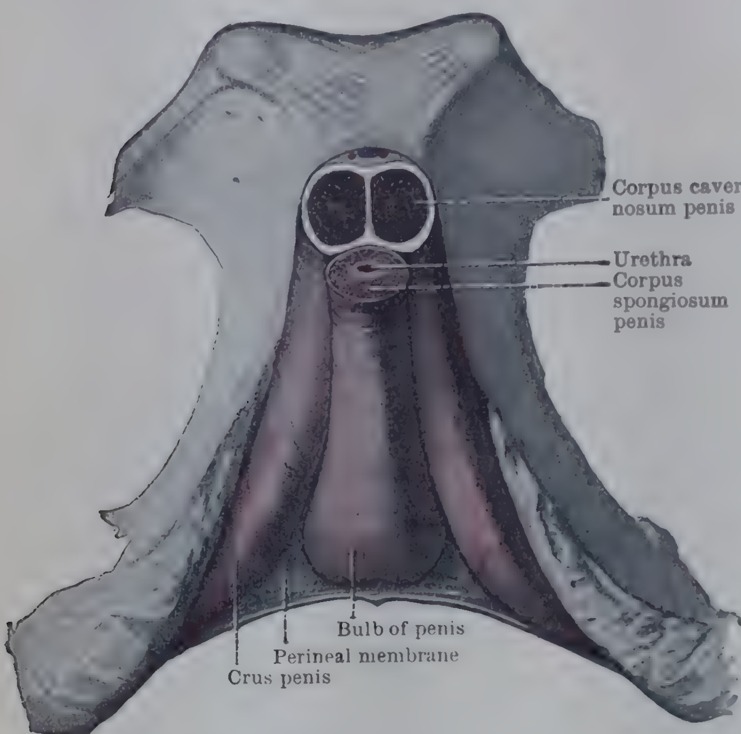

Fig. 646.—Root of Penis.
The body of the penis is seen in section.

At the **root of the penis** its three corpora separate from one another (Fig. 646). The corpora cavernosa, diverging sidewards, at first become slightly swollen, and then, gradually tapering, gain a firm, fibrous attachment to the periosteum on the medial surface of the sides of the pubic arch. These diverging parts of the corpora cavernosa are called the **crura penis** and each is covered by the corresponding ischio-cavernosus muscle. The corpus spongiosum, lying between the crura, becomes enlarged, and forms a globular mass which receives the name of the **bulb of the penis**. The bulb varies much in size in different subjects, and is attached to the under surface of the perineal membrane. The posterior part and under surface of the bulb usually show a median notch—an indication that the bulb is originally composed of two symmetrical portions which during development have become fused in the median plane. A slightly marked fibrous median septum indicates, at a deeper level, the plane along which fusion took place. The urethra, having pierced the perineal membrane, enters the bulb obliquely a short distance in front of its posterior end (Fig. 631). The superficial surface of the bulb is covered by the bulbo-spongiosus muscles.

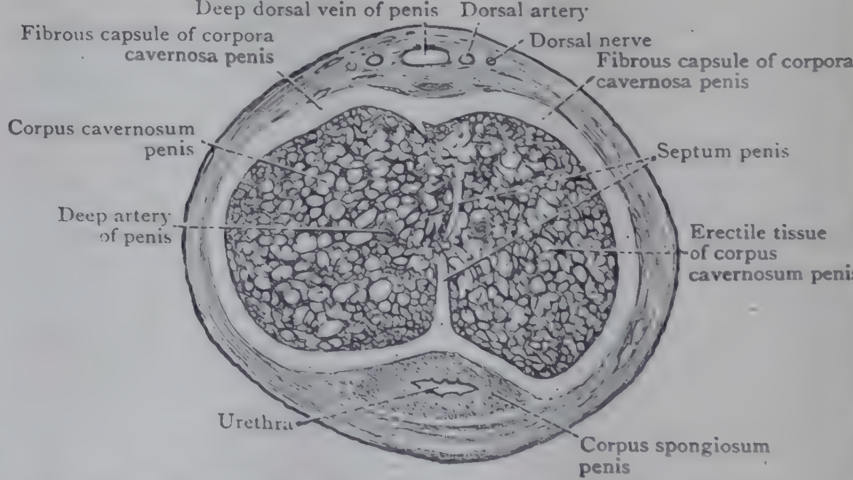

Fig. 647.—Transverse Section through Anterior Part of Body of Penis to show its Structure.

A triangular band of strong fibrous tissue, called the **suspensory ligament of the penis**, is attached to the front of the pubic symphysis and extends to the fascial sheath of the penis, with which it becomes continuous (Fig. 645).

Structure of Penis.—Each corpus cavernosum penis is enclosed in a dense, white fibrous coat which fuses with the corresponding coat of the opposite side to form the median **septum of the penis.** The septum is very incomplete, especially near the end of the penis, where it is interrupted by a number of nearly parallel slits (Figs. 647 and 648). Through these slits the erectile tissue of the two corpora cavernosa is continuous.

The fibrous coat contains some elastic fibres, and it is divided into an outer layer of longitudinal fibres and an inner layer of circular fibres, some of which latter are continued into the septum. Numerous fibrous strands proceed from the deep surface of the fibrous coat, and, stretching across the interior of the corpus cavernosum, form a fine sponge-like framework whose interspaces communicate freely with one another and are filled with blood. These spaces lead directly into the veins of the penis, and, like the veins, have a lining of flat endothelial cells. The size of the penis varies with the amount of blood in the erectile tissue. The structure of the corpus spongiosum resembles that of the corpora cavernosa, but the fibrous coat is much thinner and more elastic, and the spongework is finer (Fig. 647).

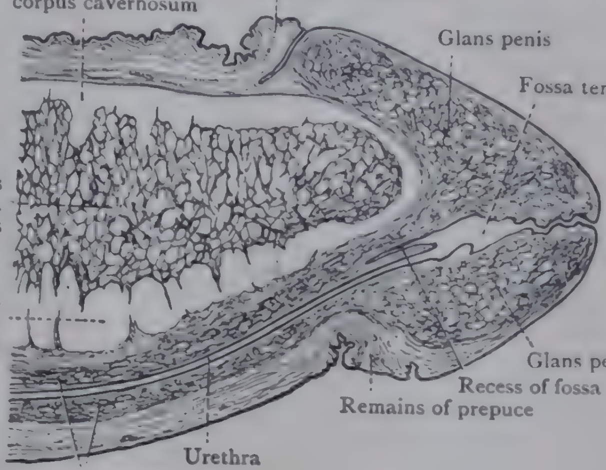

Fig. 648.—Median Section through Terminal Part of (circumcised) Penis to show its Structure.

The glans penis also is composed of erectile tissue which communicates by a rich venous plexus with the corpus spongiosum. No strongly marked fibrous coat is present, and the erectile tissue is bounded by the skin, which is exceedingly thin and firmly adherent. The urethra in this part of the penis is dilated and is compressed sideways into a slit-like passage called the *fossa terminalis*; the fossa is surrounded by a mass of fibro-elastic tissue which forms a kind of double median septum within the glans. This septum is continued backwards to join the fibrous coat of the conical end of the corpora cavernosa, and ventrally it gives attachment to the frenulum of the prepuce. It divides the erectile tissue of the glans imperfectly into right and left portions, which, however, freely communicate dorsally. From the septum, trabeculæ pass out in all directions into the tissue of the glans.

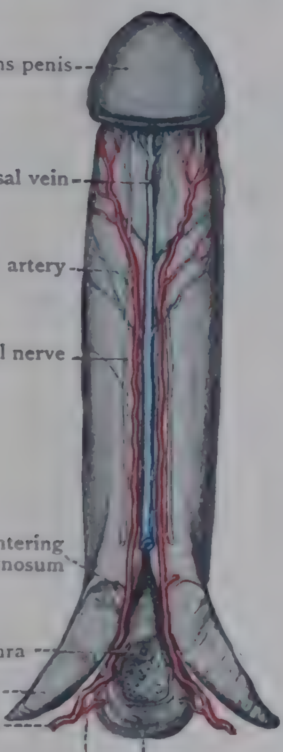

Fig. 649.—Dorsal Surface of Penis, showing the main Blood-Vessels and Nerves.

A fascial sheath, containing numerous elastic tissue fibres, forms a loose common envelope for the corpora cavernosa and the corpus spongiosum. It is termed the *fascia penis*, and reaches as far as the base of the glans, where it becomes fixed to the floor of the groove limited by the corona of the glans. In its proximal part the sheath gives insertion to many of the fibres of the bulbo-spongiosus and ischio-cavernosus muscles.

Superficial to the fascia penis there is a layer of extremely lax areolar tissue, and more superficial still is a prolongation of the dartos tunic of the scrotum, covered by the delicate skin of the penis. Numerous sebaceous glands are present in the skin, especially on the urethral surface of the penis.

In some mammals, such as the walrus, dog, bear, and baboon, a bone called the **os penis** is developed in the septum between the corpora cavernosa penis.

Vessels and Nerves of Penis.—The **arteries** are derived from the internal pudendal artery. The erectile tissue of the corpora cavernosa is supplied chiefly by the *deep arteries of the penis*, and that of the corpus spongiosum by the *arteries to the bulbs.* Branches of the *dorsal arteries* of the penis pierce the fibrous coat of the corpora cavernosa and furnish additional twigs to the erectile tissue. The glans receives its chief blood-supply from branches of the dorsal arteries. The small branches of the arteries run in the trabeculæ of the erectile tissue; and the capillaries, into which they lead, open directly into the cavernous venous spaces. As they lie in the finer trabeculæ the smaller branches often present a peculiar twisted appearance, and the name **helicine arteries** is therefore applied to them.

The **veins** with which the cavernous spaces communicate carry the blood, for the most part,

either directly into the *prostatic plexus*, or into the *deep dorsal vein* and so to that plexus. The deep dorsal vein of the penis begins in tributaries from the glans and prepuce, ascends in the groove between the corpora cavernosa, and passes beneath the inferior pubic ligament to join the prostatic plexus. On each side of it lies a dorsal artery, and, still farther from the median plane, a dorsal nerve (Figs. 647, 649).

The **lymph-vessels** of the penis are arranged in a deep and superficial series, and they end in the medial group of the *superficial inguinal lymph-glands*.

The **nerve-supply** of the penis is derived from the pudendal nerve (2nd, 3rd, and 4th sacral nerves), and from the pelvic sympathetic plexuses. The branches of the pudendal are the *dorsal nerve of the penis*, and branches from the *perineal nerves*. They supply the cutaneous structures of the penis, while the filaments from the *pelvic plexuses*, which reach the penis through the prostatic nerve-plexus, end in the erectile tissue.

PROSTATE

The **prostate** is a partly glandular, partly muscular organ of a dark brown-red colour which surrounds the beginning of the urethra in the male. It lies within the pelvis behind the pubic symphysis and is enclosed by a dense fascial sheath. Through the various connexions of this sheath the prostate is firmly fixed within the pelvic cavity. The ejaculatory ducts traverse the upper part of the prostate in their course to join the urethra. The size of the prostate varies considerably, but usually its greatest transverse diameter is $1\frac{1}{2}$ inches, its antero-posterior diameter $\frac{3}{4}$ of an inch, and its vertical diameter $1\frac{1}{4}$ inches. Superficially the prostate is separated from the bladder by deep, wide lateral grooves and by a narrow posterior groove (Figs. 624, 650).

The prostate has an apex which is directed downwards, a base looking upwards, a posterior surface, and a pair of lateral surfaces. The *base* is directed upwards against the inferior aspect of the bladder in the neighbourhood of its urethral opening. The greater part of the base is structurally continuous with the bladder wall; only a narrow portion remains free on each side and forms the lower limit of the deep groove which marks the separation of the bladder and prostate (Fig. 624). The *lateral surfaces* of the prostate are convex and prominent, especially in their posterior and upper portions, and rest against the fascia covering the levatores ani muscles. They are directed for the most part laterally, downwards, and slightly forwards, and meet together in front in a rounded anterior border, sometimes called the "anterior surface" of the prostate (Fig. 651). The *posterior surface*, is flat and triangular, and is directed backwards and very slightly downwards against the anterior wall of the rectum, through which it may be felt in the living subject. The apex points downwards and is in relation to the fascial covering of the sphincter urethræ muscle. From the apex, the anterior border passes upwards in the median plane behind the pubic symphysis and retropubic pad of fat; and it is interrupted in its lowest part by the passage of the urethra.

When its fascial sheath is stripped off, the prostate has a more rounded outline, and the surfaces just described are not so clearly defined. The anterior border may now appear to be a surface rather than a border, and the antero-posterior diameter is considerably reduced.

The urethra enters the prostate at a point near the middle of its base, and leaves it at a point on its anterior border immediately above and in front of the apex.

The ejaculatory ducts enter a slit immediately in front of the posterior border of the base and run downwards and forwards to open into the prostatic portion of the urethra at the margins of the mouth of the prostatic utricle.

The wedge-shaped portion of the prostate which separates these ducts from the urethra is called the *median lobe* (Fig. 651). It projects upwards against the bladder, and is continuous with the bladder-wall immediately behind the urethral orifice. When hypertrophied, as it often is in old men, the median lobe of the prostate may cause a considerable elevation in the cavity of the bladder, which is of surgical interest, and to which the term **uvula of the bladder** is applied. The remaining part of the prostate is described as a pair of large *lateral lobes*, which are, however, not marked off from one another superficially.

In front of the prostate, between it and the pubis, there is a close venous network called the *prostatic plexus*, with which the deep dorsal vein of the penis communicates. That plexus is continued backwards, round the sides of the

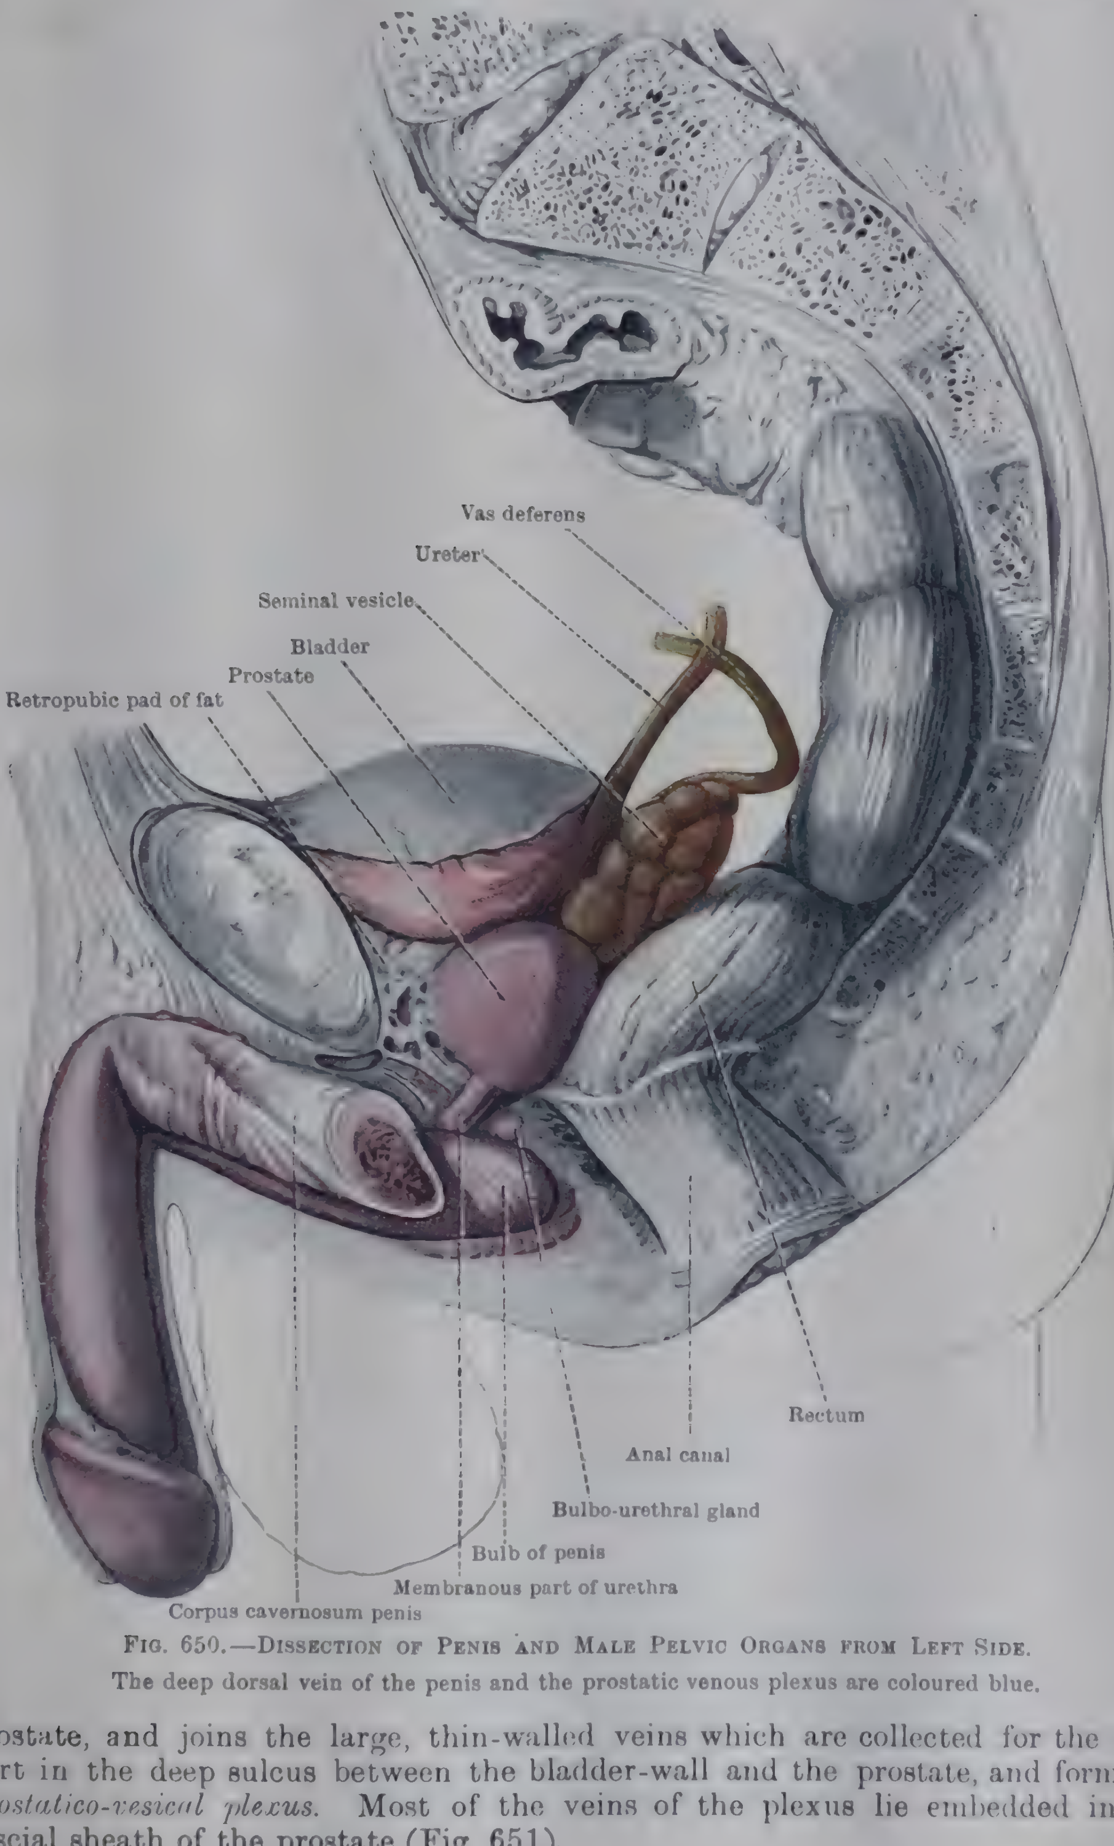

FIG. 650.—DISSECTION OF PENIS AND MALE PELVIC ORGANS FROM LEFT SIDE.
The deep dorsal vein of the penis and the prostatic venous plexus are coloured blue.

prostate, and joins the large, thin-walled veins which are collected for the most part in the deep sulcus between the bladder-wall and the prostate, and form the *prostatico-vesical plexus*. Most of the veins of the plexus lie embedded in the fascial sheath of the prostate (Fig. 651).

Fascial Sheath of Prostate.—This sheath is a dense fibrous portion of the pelvic fascia, and closely invests the prostate. Inferiorly the sheath becomes continuous with the fascia on the sphincter urethræ muscle and, through it, gains attachment to the sides of the pubic arch. In

front and at the sides, it is fused with the pubo-prostatic ligaments, by which it is connected with the pubic bones and the fascia on the levatores ani. Between the two medial pubo-prostatic ligaments there is a shallow depression, the floor of which is formed by a thin layer of fascia which connects the anterior part of the sheath of the prostate with the back of the pubic symphysis. The medial (or anterior) edges of the levatores ani muscles are immediately below the pubo-prostatic ligaments, and, when followed backwards, they are seen to embrace the lower part of the prostate.

Posteriorly the upward prolongation of the sheath is continuous with the fascial layers which enclose the ampullæ of the vasa deferentia and the seminal vesicles, and it is adherent to the peritoneum of the recto-vesical pouch. In this position it is spoken of as the *recto-vesical septum*.

Structure of Prostate.—Inside the fascial sheath the superficial part of the prostate is largely composed of matted interlacing bundles of plain muscle-fibres and fibrous tissue which form the capsule of the organ. The **capsule** is not sharply defined, for from its deep surface fibrous and muscular strands pass inwards, converging towards the posterior wall of the urethra, to become continuous with the mass of plain muscular tissue which surrounds this canal. These radially arranged strands divide the prostate into a number of incompletely defined

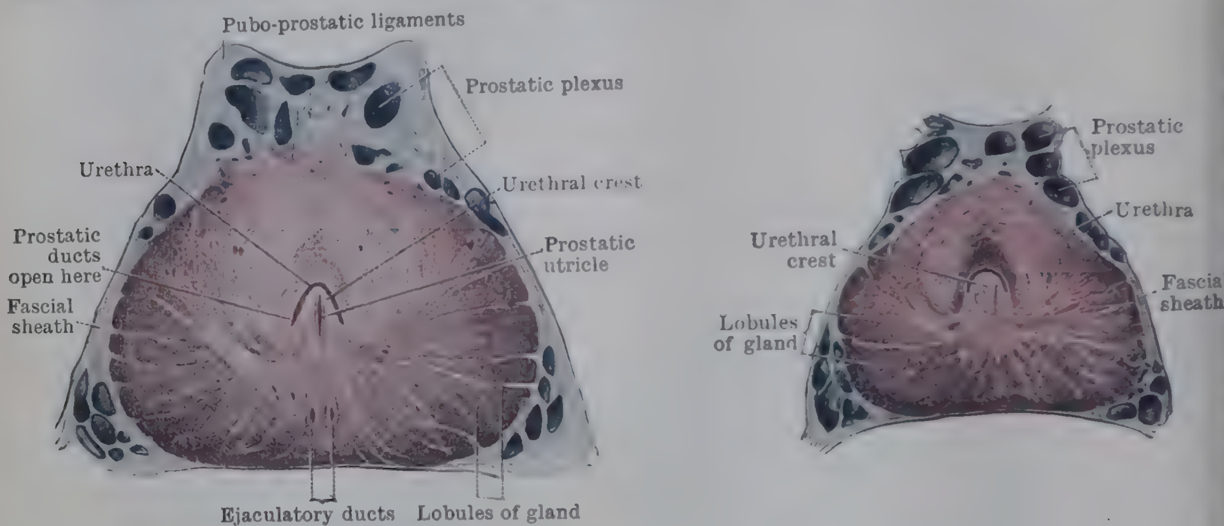

FIG. 651, A and B.—HORIZONTAL SECTIONS THROUGH PROSTATE.
Section A is at a higher level than B.

lobules, of which there are about fifty. The yellowish-coloured glandular tissue of the lobules is composed of minute, slightly branched tubules, the walls of which in certain places show numerous saccular dilatations. In the upper portion of the prostate the tubules are more convoluted, slightly dilated and shorter than in the lower part. The glandular tubules lead into the minute **prostatic ducts**—in number twenty or thirty—which open for the most part into a pair of grooves called the **prostatic sinuses**, which run along the sides of a median elevation —the **urethral crest**—in the posterior wall of the urethra.

The bulk of the glandular tissue is situated at the sides of the urethra and behind it. In front of its upper part there is a mass of plain muscular fibres which is continued upwards and backwards on its sides to form a part of the sphincter vesicæ. At a lower level striated muscular tissue, which is continuous with the deep part of the sphincter urethræ, occupies a position in front of the urethra.

The muscular tissue of the prostate is to be regarded as the thickened muscular layer of the wall of the urethra broken up and invaded by the prostatic glands, which arise and are developed from the lining layer of the canal during fœtal life.

Small at birth, the prostate enlarges rapidly at puberty. After the fourth decade the glandular tissue may atrophy, and the organ becomes more fibrous and diminishes in size. In many individuals, however, the glandular tissue persists and the prostate progressively enlarges (Swyer, 1944). Not infrequently calcareous concretions are found in it.

Vessels and Nerves of Prostate.—The **arteries** are branches of the middle rectal and inferior vesical arteries. The **veins** are wide and thin-walled; they form the prostatic plexus, which communicates with the vesical plexus and is drained into the internal iliac veins. In old men the veins of the prostate usually become much enlarged. The **lymph-vessels** (p. 1412) are associated with those of the seminal vesicle and the neck of the bladder. The **nerves** of the prostate are derived from the pelvic sympathetic plexuses.

BULBO-URETHRAL GLANDS

The **bulbo-urethral glands** are a pair of small bodies placed behind the membranous part of the urethra among the fibres of the sphincter urethræ. In old age they are often difficult to find without microscopical examination; in

young adults they are each about the size of a pea and are of a yellowish-brown colour. Placed deep to the perineal membrane, the glands lie below the level of the apex of the prostate and above that of the bulb of the penis (Figs. 632 and 650). Each gland is made up of a number of closely applied lobules, and is of the compound racemose type. The ductules of the gland unite to form a single **duct** which enters the bulb of the penis, and, after a relatively long course (about an inch), ends by opening into the spongy portion of the urethra by a minute aperture. The secreting acini are lined with columnar epithelium.

The glands receive their arterial supply from the arteries to the bulb.

Methods of Clinical Anatomical Examination.—The testis, epididymis, and lower end of the spermatic cord can be easily palpated in the living subject; and the back of the prostate and lower ends of the seminal vesicles and vasa deferentia can be palpated by a rectal examination.

FEMALE GENITAL ORGANS

The female genital organs are: (1) the ovaries, (2) the uterine tubes, (3) the uterus, (4) the vagina, (5) the external genital organs, (6) the greater vestibular glands, and (7) the mammary glands.

The reproductive glands in the female (Fig. 652) are a pair of **ovaries** placed one on each side in the cavity of the pelvis. In connexion with each ovary there is an elongated tube—the **uterine tube** or **oviduct**—which leads to the uterus and opens into its cavity. There is no direct continuity between the ovary and the uterine tube, such as exists between the other glands of the body and their ducts, but the ova, when shed from the ovary, pass into the pelvic opening of the tube and are conducted by it to the uterine cavity. The **uterus** is a hollow muscular organ which occupies a nearly median position in the true pelvis. It is joined by the uterine tubes above, and it communicates with the vagina below. The ovum, having passed through the tube, reaches the cavity of the uterus, and in it, if fertilization has taken place, the ovum undergoes its development into the embryo and fœtus. The **vagina** is the passage which leads from the uterus to the exterior, and has its external opening behind that of the urethra, within the **pudendal cleft**. In relation to the cleft there are a number of structures, included under the term *external genital organs,* which represent in the female the various parts of the penis and scrotum in the male. They are the **labia majora** and the **mons pubis**, the **labia minora**, the **clitoris**, and the **bulbs of the vestibule**. The **greater vestibular glands**, placed one on each side of the lower part of the vagina, are accessory organs of the female reproductive system.

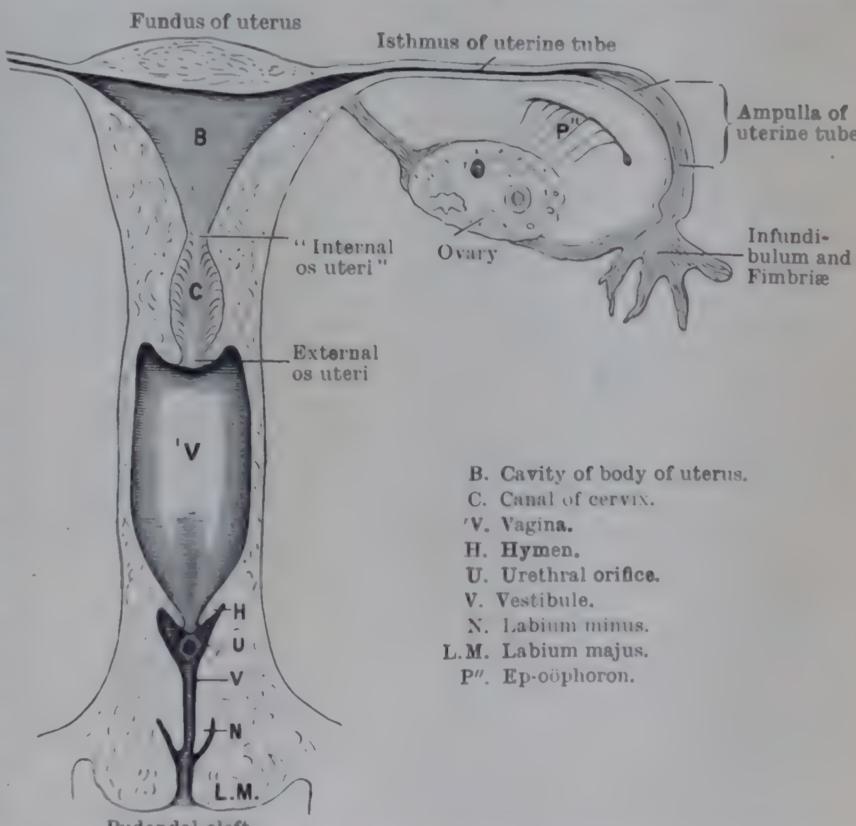

FIG. 652.—DIAGRAM OF FEMALE GENITAL ORGANS. (Symington.)

OVARIES

The **ovaries** are a pair of solid bodies, flattened from side to side, each about the size and shape of a large almond. Their length is usually between 1 inch and $1\frac{1}{2}$ inches, and the thickness from side to side about $\frac{1}{3}$ of an inch. In the adult the ovary is placed against the side-wall of the pelvic cavity, and is connected by a peritoneal fold with the broad ligament of the uterus. The position occupied by the ovary within the pelvic cavity is fairly constant, although the broad ligaments do not hold the organ firmly fixed in any definite place.

The ovary has two *ends*—upper and lower. The upper end is the larger and more rounded; it is termed the **tubal end**, as it is most intimately connected

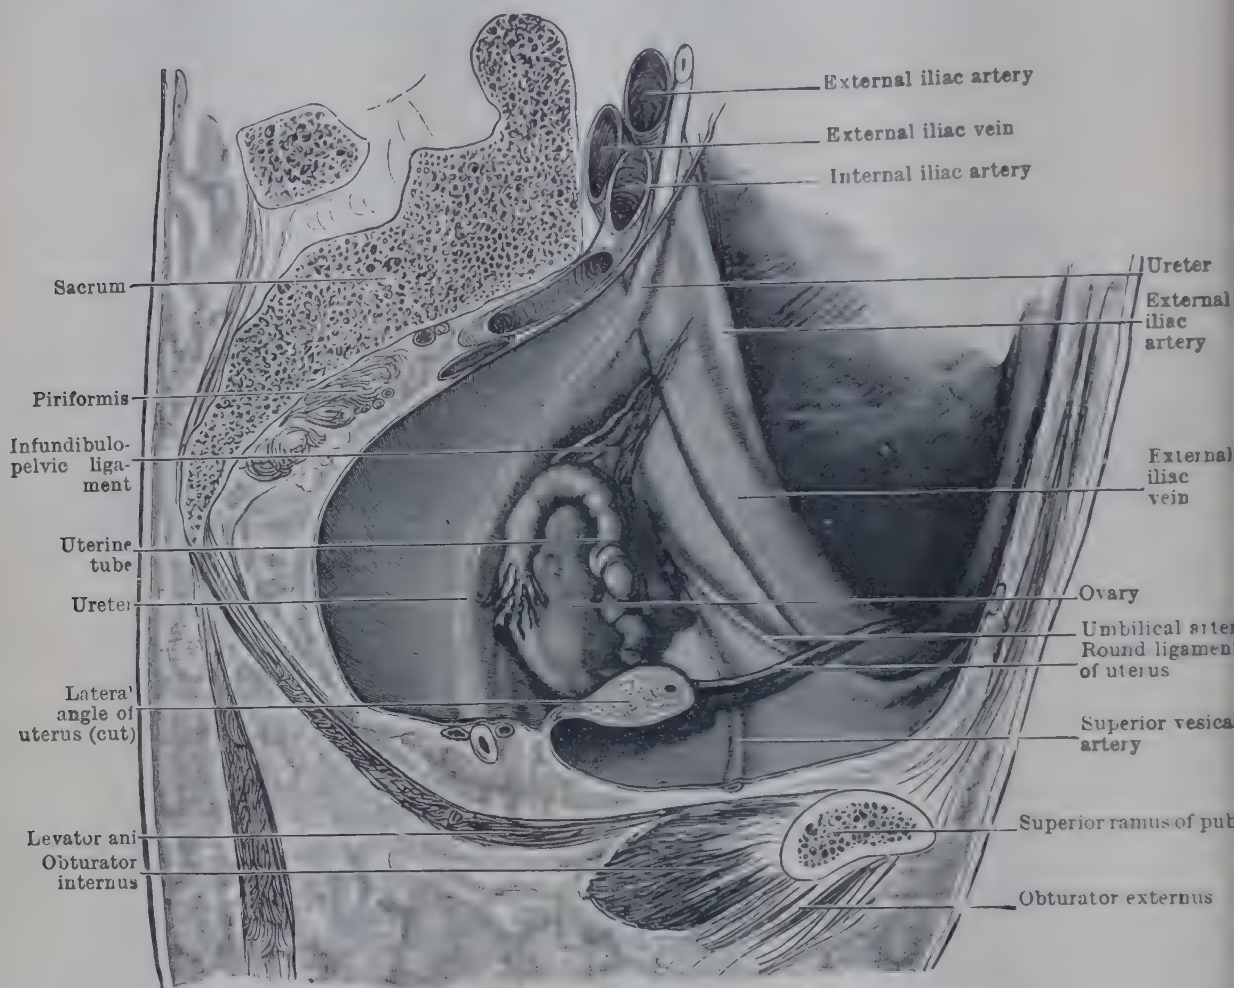

FIG. 653.—SIDE-WALL OF FEMALE PELVIS, SHOWING POSITION OF THE OVARY AND ITS RELATION TO THE UTERINE TUBE.

The pelvis was cut parallel to the median plane, but at some distance from it.

with the uterine tube. The lower end is more pointed; it is called the **uterine end**, since it is connected with the uterus by a fibrous cord termed the **ligament of the ovary**. The *surfaces* of the ovary are called **medial** and **lateral**, and the *borders* separating them are the anterior or **mesovarian border** and the posterior or **free border**. The free border is convex; the mesovarian border is straighter and narrower, and it is connected by two very short peritoneal layers, called the **mesovarium**, with the upper or posterior layer of the broad ligament of the uterus. The vessels and nerves enter the ovary at the mesovarian border, which is therefore termed its **hilum**.

Position and Relations of Ovary (Figs. 653, 656-658).—When the ovary is in its typical position its long axis is vertical. Its lateral surface lies against the wall of the true pelvis, and its medial surface looks into the pelvic cavity. The peritoneum of the pelvic wall, where the ovary lies against it, is depressed to form a shallow fossa between the ureter and the umbilical artery. Outside the peritoneum forming the floor of this fossa are the obturator nerve and vessels. The tubal end of

the ovary lies a little below the level of the external iliac vessels, and its uterine end is immediately above the peritoneum of the pelvic floor. The mesovarian border is immediately behind the line of the umbilical artery, and the free border is immediately in front of the ureter (Fig. 653). The medial surface of the ovary is largely covered by the uterine tube, which, passing upwards on it near its mesovarian border, arches over the tubal end and then turns downwards in relation to the free border and posterior part of the medial surface.

The description given corresponds to the typical position of the organ in women who have not borne children. When the uterus is much inclined towards the right side of the body the left ovary has its long axis directed obliquely downwards and medially, the right gland remaining vertical.

Connexions of Ovary.—When the ovary is in position a small peritoneal fold passes upwards from its tubal end and becomes lost in the peritoneum over the external iliac vessels and the psoas major muscle (Fig. 653). It is called the **infundibulo-pelvic ligament** and is continuous below with the mesovarium and, in front of it, with the broad ligament of the uterus. It contains between

The broad ligament has been spread out.
B. Diagrammatic Representation of Uterine Cavity.
The dense mass at the side of the cervix uteri represents the lateral cervical ligament.

its two layers the ovarian vessels and nerves as they pass down into the pelvis to enter the mesovarium and thus reach the hilum of the ovary. Anteriorly the ovary is connected with the broad ligament by a very short mesentery, or **mesovarium**, along the whole length of its mesovarian border. The uterine end of the ovary is connected with the lateral angle of the uterus by a round cord called the **ligament of the ovary**; this band lies in the free border of the medial part of the mesovarium, and is attached to the lateral angle of the uterus behind the point of entrance of the uterine tube. It is composed chiefly of plain muscle-fibres continuous with those of the uterus. The tubal end of the ovary is directly connected with the **ovarian fimbria**—one of the largest of the fimbriæ of the uterine tube (Fig. 654).

Descent of Ovary.—Like the testes, the ovaries at first lie in the abdominal cavity and only later attain a position in the pelvis. At birth the ovary lies partly in the abdomen and partly in the pelvis; soon, however, it takes up a position entirely within the true pelvis. As in the male, a **gubernaculum** is present in the early stages of development and is connected inferiorly with the tissues that become the labium majus; but in the female the gubernacula become attached to the para-mesonephric ducts, from which the uterus is developed. Consequently, the gubernaculum becomes the round ligament of the uterus in front and the ligament of the ovary behind; and it pulls the ovary down only as far as the pelvis: it is a rare abnormality for the ovary, instead of entering the pelvis, to take a course similar to that of the testis, and pass through the inguinal canal into the labium majus.

Structure of Ovary.—The ovary is, for the most part, composed of a fibro-areolar tissue, called the **stroma of the ovary**, richly supplied by blood-vessels and nerves. The stroma contains

very numerous spindle-shaped cells, white fibres, and some elastic tissue. The surface of the ovary is covered with an epithelium composed of columnar or cubical cells, and continuous with the flat-celled epithelium of the peritoneum which forms the mesovarium. The ovarian epithelium is a persistent portion of the "germinal" epithelium which covers the genital ridges of the embryo and from which the cells of the ovarian follicles are derived. The position in which it becomes continuous with the peritoneum can usually be distinguished as a fine white line near the hilum of the ovary. Shining through the epithelium of the fresh ovary (except in old age) a variable number of small vesicles can usually be seen—the **vesicular ovarian follicles**—in which the egg-cells or oöcytes are contained. The number of follicles visible, and also the size which each follicle reaches before it ruptures and sheds its contents, are by no means constant. When a follicle ruptures and discharges the oocyte, its walls at first collapse, but later the cavity becomes filled with extravasated blood and cellular tissue of a yellowish colour. The resulting structure, called a **corpus luteum**, slowly degenerates unless impregnation has taken place, and then it develops and becomes larger during pregnancy. As it atrophies, the cells of the corpus luteum disappear, and the structure, losing its yellow colour, receives the name of **corpus albicans**. After a time the corpus albicans completely disappears. Owing to the periodic rupture of the ovarian follicles, the surface of the ovary, which is at first smooth and even, becomes in old age dimpled and puckered. For details of these changes and an account of the hormones produced by the ovary, see Selye (1947).

A section through the ovary, especially in the young child, presents in its superficial

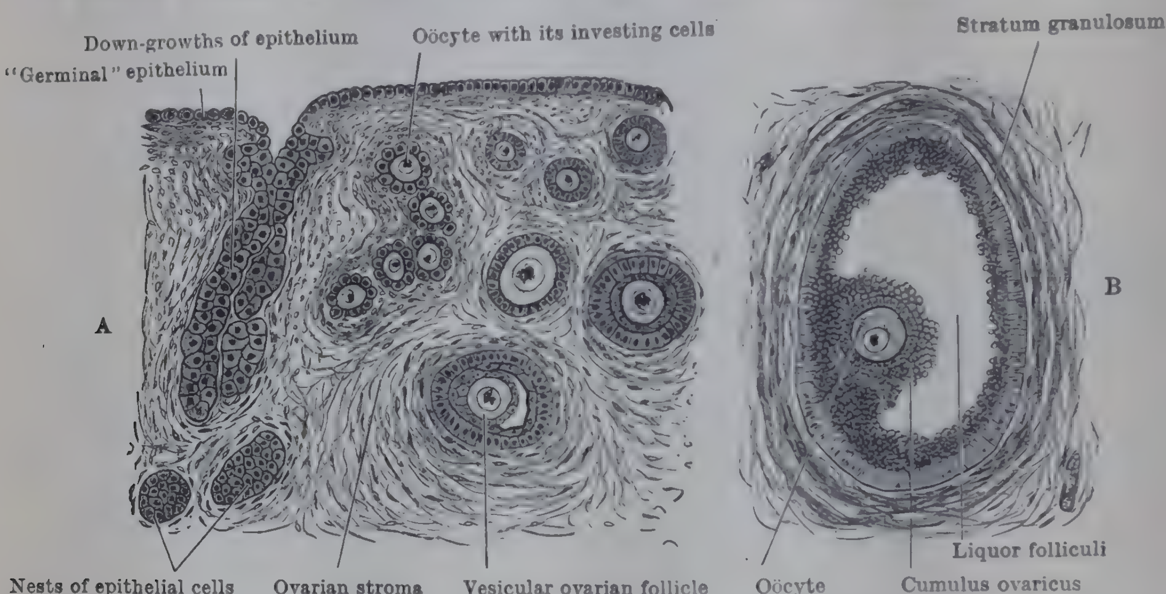

Fig. 655.—A. Diagrammatic Representation of the Manner in which Vesicular Follicles arise during Development of Ovary.

B. Diagram illustrating Structure of a Ripe or Vesicular Ovarian Follicle.

part a granular appearance which is due to the presence of large numbers of small follicles, or collections of epithelial cells, embedded in the fibro-areolar tissue near the surface of the ovary. The larger follicles lie deeper in the stroma, but when they become fully developed they pass towards the surface, where the ripe follicles may be seen bulging slightly and ready to burst. In the deepest part of the ovary the blood-vessels are most numerous, and there also some plain muscle-fibres are found.

The cells that compose the ovarian follicles are derived in part from the "germinal" epithelium which covers the developing ovary in the embryo. The epithelium, at first simple, grows down into the underlying tissue in the form of branching tube-like processes, or "egg-tubes". This takes place during fœtal development, and the branching, cellular processes, so formed, become broken up within the stroma into little nests or clumps of cells, each of which becomes a follicle. But in the human embryo the earliest formed nests of epithelial cells arise *in situ* and only at a later stage become connected with the "egg-tubes", derived from the ovarian epithelium. From the beginning, some cells of the "egg-tubes" are larger than the others; these are the oöcytes, while the cells round them become the investing cells of the follicle. The investing cells, at first flattened, form a single layer around each oocyte. Later, becoming columnar, as the follicle increases in size and sinks more deeply into the stroma, these cells divide in such a manner that the oöcyte becomes surrounded by a double layer of cells. Fluid—**liquor folliculi**—accumulates between the two cellular layers, except at one place, where the inner cells surrounding the ovum remain attached to the outer layer or **stratum granulosum**. To the inner cellular mass which encloses the oocyte the term **cumulus ovaricus** is applied (Fig. 655). The ripe follicle contains a relatively large amount of fluid, and the surrounding stroma becomes differentiated to form a capsule or **theca folliculi**. The capsule is composed of an *inner coat*, which is vascular in character, and an *outer coat*, which is more fibrous in structure. In the young child there are numerous small follicles in the superficial parts of the ovary, and the question whether any new ova are produced in the human ovary after birth has been much debated (p. 24).

Vessels and Nerves of Ovary.—The **ovarian arteries**, which correspond to the testicular arteries of the male, are a pair of long, slender vessels which spring from the front of the aorta below the level of origin of the renal vessels. Each gains the true pelvis in the infundibulo-pelvic ligament, and it enters the ovary at its mesovarian border. Close to the ovary the ovarian artery anastomoses with branches of the **uterine artery**. The blood is returned by a series of communicating **veins**, similar to the *pampiniform plexus* in the male.

The **lymph-vessels** of the ovary run with those from the upper part of the uterus to end in the lymph-glands beside the aorta and inferior vena cava (p. 1416).

The **nerves** of the ovary are derived chiefly from a plexus which accompanies the ovarian artery and is continuous above with the renal plexus. Other fibres are derived from the lower part of the aortic plexus and join the plexus on the ovarian artery. The afferent impulses from the ovary reach the central nervous system through the fibres of the posterior root of the tenth thoracic nerve.

UTERINE TUBES

The **uterine tubes** are a pair of ducts which convey the oöcytes, discharged from the follicles of the ovaries, to the cavity of the uterus (Fig. 654 and Pl. LXXII, p. 745). Each tube is about four inches in length, and opens at one end into the peritoneal cavity near the ovary, and at the other end by a smaller opening into the lateral part of the uterine cavity. The tube is enclosed in a fold of peritoneum called the **mesosalpinx**, which is a portion of the broad ligament of the uterus.

The **pelvic opening** of the tube is only about 2 mm. in diameter when its walls are relaxed, and much narrower when the muscular coat of the tube is contracted. It is placed at the bottom of a funnel-like expansion of the tube called the **infundibulum**, the margins of which are produced into a number of irregular processes, called **fimbriæ**, many of which are branched or fringed. The surface of the fimbriæ which looks into the cavity of the infundibulum is covered with a mucous membrane continuous with that of the tube, while the outer surface is clothed with peritoneum. The mucous surfaces of the larger fimbriæ present ridges and grooves which are continued into the folds and furrows of the mucous coat of the tube. One of the fimbriæ, usually much larger than the rest, is connected either directly or indirectly with the tubal end of the ovary, and to it the name **ovarian fimbria** is applied. The part of the tube continuous with the infundibulum is called the **ampulla**. It is the widest and longest portion of the tube, and is usually slightly tortuous and of varying diameter, being slightly constricted in some places and dilated in others. The ampulla ends in the narrower, thicker-walled, and much shorter **isthmus** of the tube, which joins the lateral angle of the uterus. The **uterine part** of the tube is embedded in the uterine wall, which it traverses to reach the cavity of the uterus (Fig. 654). The **uterine opening** is smaller than the pelvic opening, being about 1 mm. in diameter. The lumen of the canal gradually increases in width as it is traced from the uterus towards the ovary.

Course of Uterine Tube.—From the uterus, the uterine tube is directed at first horizontally towards the uterine end of the ovary, and then upwards in relation to the medial side of the mesovarian border, until it reaches the tubal end. It next arches backwards and then descends along the free border of the ovary, resting against its medial surface (Figs. 653, 656). The looped portion of the tube often covers almost the entire medial surface of the ovary. The fimbriated end is applied against the free border and lower part of the medial surface of the ovary, and from it the ovarian fimbria passes upwards to gain attachment to the tubal end. The fimbriated end of the uterine tube lies in the abdominal cavity until the ovary in its descent has entered the true pelvis.

Structure of Uterine Tubes.—The wall of each tube is composed of a number of concentric layers. First a **serous coat** of peritoneum, under which there is a thin **subserous coat** of loose areolar tissue containing many vessels and nerves. Internal to the subserous coat there is the **muscular coat** composed of two strata of plain muscle-fibres—a more superficial, thin stratum of longitudinally arranged fibres, and a deeper, thicker layer, the fibres of which are circularly disposed. Inside the circular muscular coat is a **submucous layer**, and then the lining membrane or **mucous coat**. In the part of the tube near the uterus the muscular layer is thicker than towards the other end, and in the isthmus it forms the chief part of the wall. The mucous membrane, on the contrary, is thickest towards the fimbriated end, and there it forms the chief part of the wall. The stratum of circular muscle-fibres is especially well developed near

the uterus. The mucous membrane is thrown into numerous longitudinal folds, which in the ampulla are exceedingly complex, the larger folds bearing on their surface numerous smaller ones. In transverse sections of that part of the tube, examined under the microscope, the folds of the mucous membrane look like large branching processes which project into the lumen of the tube and almost completely fill it. The mucous membrane is covered with a ciliated epithelium, the cilia of which tend to drive the fluid contents of the tube towards the uterus.

Vessels and Nerves of Uterine Tube.—The chief **artery** of the uterine tube is a tubal branch of the *uterine artery*, but it receives small branches of the *ovarian artery* also. The **veins** of the tube pour their blood partly into the *uterine* and partly into the *ovarian* veins. The **lymph-vessels** run with those of the ovary and the upper part of the uterus to the lymph-glands beside the aorta. The **nerves** are derived from the plexus that supplies the ovary, and also from the plexus in connexion with the uterus. The afferent fibres are believed to belong to the eleventh and twelfth thoracic and the first lumbar nerves.

EP-OÖPHORON AND PAR-OÖPHORON

The ep-oöphoron and the par-oöphoron are two vestigial structures found between the layers of the broad ligament.

The **ep-oöphoron** (Fig. 652) lies in the mesosalpinx between the uterine tube and the ovary. In the adult it consists of a number of small rudimentary blind tubules lined with epithelium. One of the tubules—the **duct of the ep-oöphoron**—lies close to the uterine tube and runs nearly parallel with it. It is joined by a number of **tubules** which enter it at right angles from the neighbourhood of the ovary. The duct is a persistent portion of the mesonephric duct, and represents the canal of the epididymis; the tubules are derived from the mesonephros and represent the efferent ducts of the testis (and probably also the ductuli aberrantes of the canal of the epididymis).

One or more small pedunculated cystic structures, called **vesicular appendices**, are often seen near the infundibulum of the uterine tube. They are supposed to represent portions of the cephalic end of the mesonephric duct.

The **par-oöphoron** is a collection of very minute tubules that lie in the mesosalpinx nearer the uterus than the ep-oöphoron. They represent the paradidymis in the male, and are derived from the part of the mesonephros which lies nearer the caudal end of the embryo. Though sometimes visible in the child at birth, the par-oöphoron in the adult can be recognized only by microscopic examination.

UTERUS

The **uterus** or womb (Figs. 656 and 658) is a hollow, thick-walled muscular organ that projects upwards and forwards above the bladder from the upper part of the vagina (Figs. 659 and 661).

Shape and Parts.—The upper two-thirds of the uterus, known as the **body**, is pear-shaped with the blunt end upwards, and the whole is slightly flattened from before backwards; the lower third, called the **cervix**, is cylindrical and tapers slightly at its extreme lower end, which projects through the anterior vaginal wall into the upper part of the cavity of the vagina, and thereby the cervix is divided into a *vaginal* and a *supravaginal part*. A slight constriction marks the junction of the body with the cervix.

In the centre of the extremity of the vaginal part of the cervix is a small opening—the **external os**—by which the cavity of the uterus communicates with that of the vagina. This part of the cervix is slightly flattened from before backwards, and the external os of a uterus which has not been pregnant has therefore the appearance of a short transverse slit bounded above and below by thick lips; in women who have borne children the slit is larger and has an irregular outline. The lower lip is thicker and more rounded than the upper, and both lips are usually in contact with the posterior wall of the vagina.

The uterine tubes enter the organ at its upper and lateral angles, where it attains its maximum breadth; and the rounded part above a line joining the points of entrance of the two tubes is known as the **fundus**. The uterus, therefore, is described as possessing an anterior or *vesical surface* and a posterior or *intestinal surface*, and these two surfaces are separated by right and left *lateral borders*. Both surfaces are convex, but the intestinal is much the more rounded. The length of the body is about two inches; its maximum breadth also is two inches;

and its thickness or depth is an inch. The cervix is an inch long and about an inch in diameter. During pregnancy the whole organ is greatly enlarged.

Position and Attachments.—The non-pregnant uterus lies completely within the cavity of the pelvis. It rarely lies exactly in the median plane, but is usually inclined slightly to one or other side, more frequently to the right. The lower end of the cervix is very firmly fixed to the wall of the vagina where it pierces that organ, being in fact structurally continuous with it. From this point the cervix projects upwards and forwards. From the upper end of the cervix, the body also projects upwards and forwards, but its direction is slightly more forwards than that of the cervix so that the cervix and body form a wide angle open downwards and forwards. In its usual position, therefore, the uterus is said

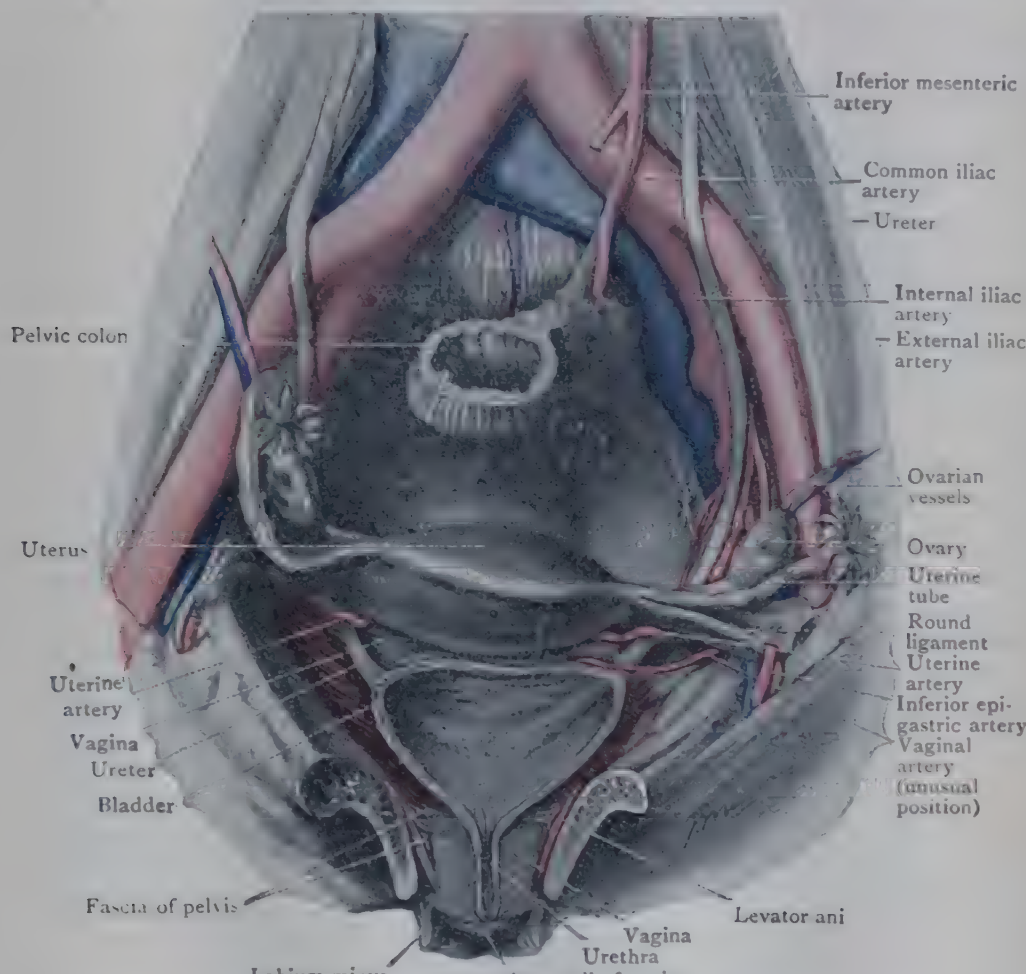

FIG. 656.—DISSECTION OF PELVIS OF MULTIPAROUS FEMALE, SHOWING SOME OF THE RELATIONS OF THE INTERNAL GENITAL ORGANS.

to be **anteverted** and **anteflexed**, for the whole organ projects forwards and upwards from the upper end of the vagina, and it is bent forwards at the junction of the cervix with the body. Although anteversion and anteflexion of the uterus are regarded as the normal condition, it should be realized that in many women the uterus is retroflexed or retroverted without producing any symptoms.

The peritoneum which covers the upper surface of the urinary bladder is reflected from the posterior edge of that organ upwards on to the uterus at the junction of the cervix with the body and then passes upwards and forwards, covering the anterior or vesical surface of the body. Thus, a rather deep **utero-vesical pouch** is formed (Fig. 659). From the vesical surface of the uterus the peritoneum passes over the fundus and then downwards and backwards, covering the intestinal surface of the body and supravaginal part of the cervix; it then passes on to the upper part of the back of the vagina and is reflected from it upwards and backwards on the anterior wall of the rectum (Figs. 657, 662). The peritoneal pouch between the back of the uterus and the front of the rectum is known as the **recto-uterine** or **recto-vaginal pouch**, the bottom of which is about three inches or rather less above the level of the anus. The two layers of peritoneum which

cover the vesical and intestinal surfaces of the uterus come together at its lateral margins and are then carried laterally as extensive peritoneal folds to the side-walls of the pelvis. These folds are known as the **broad ligaments of the uterus** (Figs. 654, 656), and they enclose between their two layers various important structures associated with the uterus.

The two layers of each broad ligament are continuous with each other at a free edge which is directed forwards and upwards; and they enclose some loose areolar tissue and a little plain muscle. To the contained tissue the name *parametrium* is given. In the upper part of the broad ligament the parametrium is small in quantity and the two layers of the ligament are close together, but

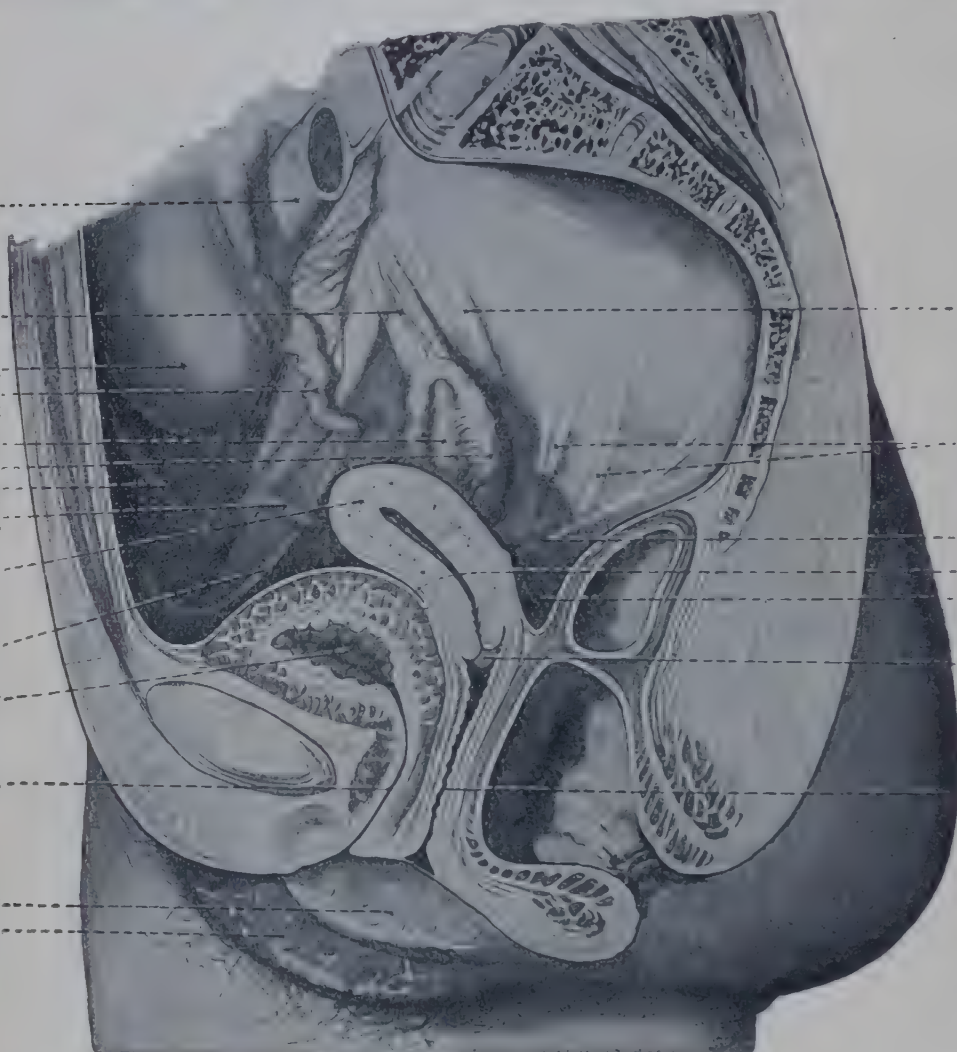

FIG. 657.—MEDIAN SECTION OF FEMALE PELVIS.

towards its root the parametrium increases considerably in amount and the two peritoneal layers diverge from each other. The anterior layer passes forwards into the floor of the paravesical fossa; the posterior layer forms a prominent, shelf-like **recto-uterine fold**, corresponding to the *sacro-genital fold* in the male, which curves backwards from the cervix uteri to the posterior wall of the pelvis a little lateral to the rectum. The two recto-uterine folds sometimes meet across the back of the cervix, forming a ridge known as the *torus uterinus.*

Enclosed in the broad ligament along its free edge is the *uterine tube*; and just below the entrance of the tube into the uterine wall two other structures also are attached to the uterus, namely, the *round ligament of the uterus* in front and the *ligament of the ovary* behind (Fig. 658). These three structures are all enclosed in the broad ligament, and while they are very close together at their attachments to the uterus, they diverge widely as they approach the pelvic wall. It thus happens that the attachment of the broad ligament to the uterus is almost a straight line but its attachment to the pelvic wall is drawn out into a sort of tripod (Figs. 658 and 659). The inferior part of the ligament passes laterally

from the side of the cervix to the side of the pelvis, and as the whole uterus slopes from above downwards and backwards the lower part of the broad ligament slopes in the same general direction. The anterior part of the ligament is drawn out by the round ligament of the uterus, which is a narrow flat band of fibrous tissue containing some plain muscle at its uterine end. It passes from the lateral angle of the uterus laterally, forwards, and very slightly upwards to the deep inguinal ring, crossing the umbilical artery and external iliac vessels, and, after hooking round the lateral side of the inferior epigastric artery and traversing the inguinal canal, it ends in the skin and subcutaneous tissue of the labium majus. In some cases a minute diverticulum of the peritoneal cavity accompanies the round ligament through the inguinal canal; it is the **vestige of the processus vaginalis**, which is formed in the fœtus in both sexes. The round ligament draws the anterior part of the broad ligament forwards and very slightly upwards.

The part of the broad ligament that is drawn out to enclose the uterine tube is known as the **mesosalpinx**. Laterally the mesosalpinx is continuous with the *infundibulo-pelvic ligament*, which crosses the external iliac vessels about an inch below their upper end, and this part of the broad ligament is therefore drawn upwards and slightly backwards (Fig. 658). The lateral part of the mesosalpinx is more free than the medial part, and this permits the lateral part of the uterine tube to curve down along the posterior border of the ovary and almost enclose that organ in a fold of the mesosalpinx itself, thus forming a peritoneal compartment known as the *bursa ovarica*. The mesosalpinx contains the ep-oöphoron and paroöphoron and terminal branches of the uterine artery.

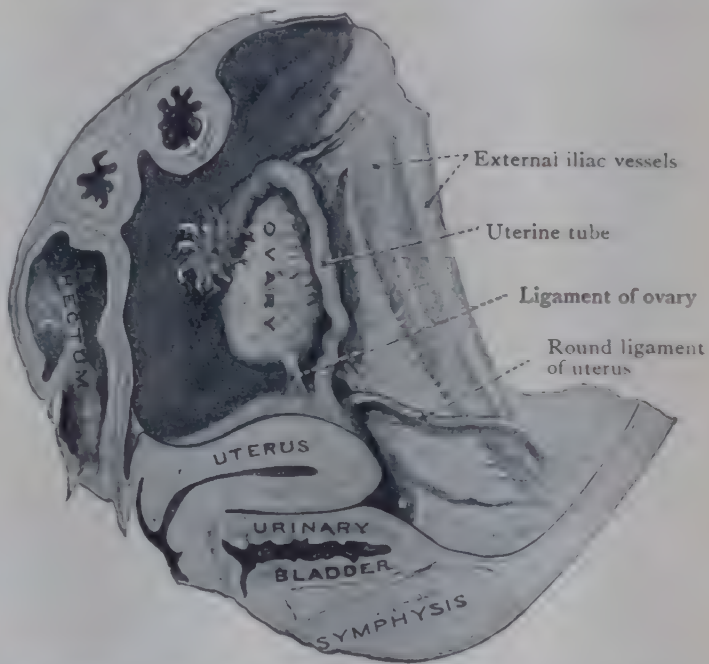

FIG. 658.—LEFT WALL OF FEMALE PELVIS TO SHOW TRIPOD ATTACHMENT OF LATERAL END OF BROAD LIGAMENT.
The ovary is much scarred owing to the shedding of ova.

The part of the broad ligament that is drawn out to enclose the ligament of the ovary is really the medial continuation of the mesovarium (Fig. 654 A), and, as the mesovarium is continuous laterally with the infundibulo-pelvic ligament also, the complete fold follows the same general direction as the mesosalpinx. It at first passes laterally as a narrow horizontal shelf which projects backwards and contains the ligament of the ovary in its free edge, but when it nears the ovary it becomes deeper and turns vertically upwards. In this part of its course it is called the **mesovarium** and becomes continuous above with the infundibulo-pelvic ligament. The *ligament of the ovary* is a round fibrous band, about an inch long, containing a considerable amount of plain muscle, and it is attached laterally to the lower pole of the ovary.

At the root of the broad ligament, where the two layers of peritoneum diverge to pass into the pelvic floor, a considerable amount of fibrous tissue and plain muscle occurs. This mass is the upper end of the fascial condensation which passes from the side of the vagina and the base of the urinary bladder to the fascia on the levator ani muscles. Its upper and more bulky part is attached medially to the side of the supravaginal part of the cervix and to the side of the upper third of the vagina, while laterally it fans out. Its posterior part passes backwards in the recto-uterine fold of peritoneum and gains an attachment to the front of the sacrum; this part is known as the *utero-sacral ligament*. The anterior part, passing directly sidewards to blend with the fascia on the levator ani muscle, is called the *lateral cervical ligament* (Mackenrodt, 1895). It has a

shallow anterior and a deep posterior surface, and in sagittal section it is shaped like an inverted letter U or J. On its upper rounded surface lie the ureter and uterine artery (Power, 1944). As already mentioned, it is really a condensation of fascia around the internal iliac artery and its branches.

The *ureter* passes from behind forwards and medially below the root of the broad ligament about three-quarters of an inch from the side of the cervix uteri; in this position it is crossed from lateral to medial side by the *uterine artery*, which first lies lateral to the ureter on the pelvic wall and then runs down in front of it to enter the root of the broad ligament and cross over it just at the level of the upper end of the cervix (Fig. 659). The uterine artery then turns upwards in the broad ligament and ascends beside the uterus. Near the upper

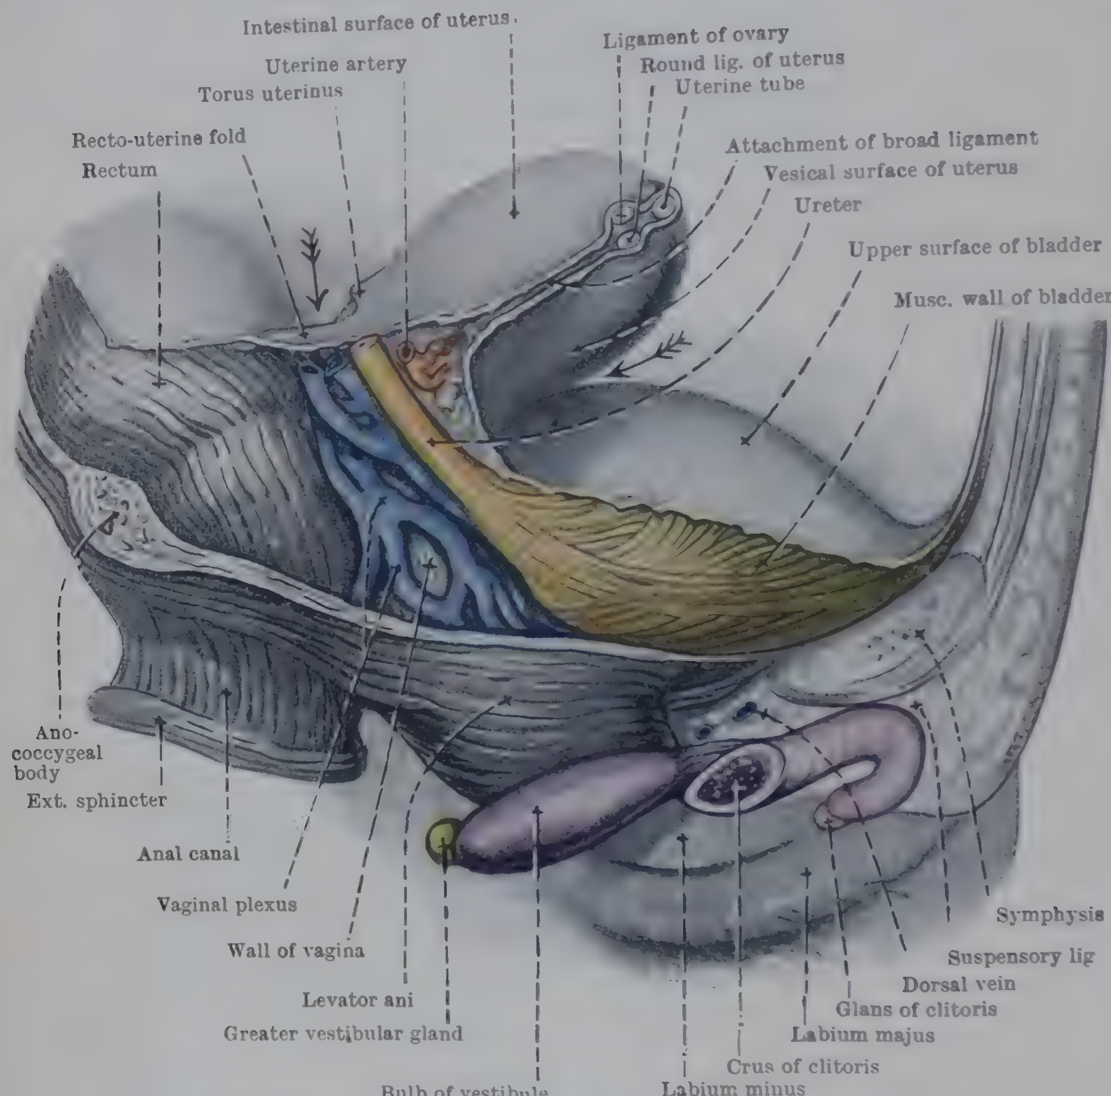

FIG. 659.—MODEL OF DISSECTION OF FEMALE PELVIC ORGANS.
The arrows point to the utero-vesical and recto-vaginal pouches.

end of the uterus the artery turns laterally into the mesosalpinx, where it lies about half an inch below the uterine tube. It ends by anastomosing with branches of the ovarian artery in the infundibulo-pelvic ligament. In addition to the structures described above, the broad ligaments contain some lymph-vessels and branches of the pelvic autonomic plexus.

Relations of Uterus.—*Anteriorly* the body of the uterus is separated from the bladder by the utero-vesical pouch of peritoneum; the front of the supravaginal part of the cervix is separated from the bladder by loose areolar tissue. *Posteriorly* the body and supravaginal part of the cervix are separated by a layer of peritoneum from the pelvic colon or coils of small intestine. *Laterally*, on each side, there is the broad ligament of the uterus with its contained structures. Of particular importance is the close relationship of the ureter and uterine artery to each other and to the side of the cervix. The uterus rises and falls as the urinary

bladder fills and empties. The vaginal part of the cervix pierces the anterior wall of the vagina and projects into its cavity, where it is clothed with mucous membrane. It tapers towards its lower end and is then abruptly truncated so that its lower extremity is blunt.

Cavity of Uterus.—In comparison with the size of the organ, the cavity of the uterus is small, owing to the great thickness of the uterine wall. The **cavity of the body** of the uterus, when viewed from the side, is a mere chink (Fig. 657); but when viewed from the front it is triangular with the base upwards (Fig. 654 B), and the sides of the triangle are convex inwards. The two lateral angles of the triangle mark the entrance of the two uterine tubes; at the median angle the cavity of the body becomes continuous with that of the cervix. The cavity of the cervix is called the **canal of the cervix**, and it extends from the internal os to the external os, where it opens into the vagina. It is a spindle-shaped passage, being narrower at its ends than in its middle part; and sections show also that its antero-posterior diameter is shorter than its transverse. In the body of the uterus the walls of the cavity are smooth and even, but in the cervix the mucous membrane forms a remarkable series of folds called the **arbor vitæ**. They consist of an anterior and a posterior longitudinal fold or ridge from which a large number of secondary folds or rugæ branch off obliquely upwards and laterally (Figs. 652 and 654).

Fig. 660.—Section of Uterus immediately before Onset of Menstruation.
The isthmus is distinguished from the body by relative lack of pre-menstrual vascular congestion.

Isthmus of Uterus.—In order to define an upper limit of the cervix it has been customary to describe an "internal os uteri" at its junction with the body (Fig. 652); but such a constricted opening between them does not in fact appear to exist in the non-pregnant uterus. The constriction in reality involves the lowest part of the cavity of the body, about 1 cm. in length, and this tubular portion is commonly known to obstetricians as the "isthmus" of the uterus (Fig. 654 B). Moreover, the separate identity of this part of the uterus has a functional basis, and the structure of its mucous coat is less complex than in the main part of the body (Frankl, 1933). Not only is it much less affected by the periodic changes of the menstrual cycle (Fig. 660), but in the last months of pregnancy it becomes more distinct and during labour is transformed into the "lower uterine segment" of the obstetricians. There is some evidence that the upper part of the cervix is incorporated into the lower uterine segment during labour; and, on the whole, it seems well to abandon the term "internal os" as redundant and to employ in its place the recognized expression **isthmus of the uterus**.

Supports of Uterus.—The uterine supports are mainly the bony pelvis and the pelvic floor, for although the uterus itself does not rest directly on these structures, yet it is supported by such organs as the rectum and urinary bladder, which do rest directly on them. The strength of the pelvic floor is therefore essential to the support of the uterus, and the strength of the floor is dependent on an intact *perineal body* (p. 466). This fibro-muscular mass is liable to injury and laceration during parturition; and it is of such importance in obstetrical practice that some obstetricians refer to it simply as "the perineum". The ligaments of the uterus function mainly by maintaining the uterus in a correct position of anteflexion and anteversion. The round ligaments keep the fundus forwards, while the utero-sacral keep the cervix back. The ligaments support the uterus against a sudden and temporary stress, but they are unable to resist sustained stress if the pelvic floor has given way. (See Smout and Jacoby, 1948.)

Structure of Uterus.—The uterine wall is composed of three chief layers—the serous, the muscular, and the mucous coats.

The **serous coat**, or *perimetrium*, is the peritoneal covering. Over the fundus and body it is very firmly adherent to the deeper layers, and cannot be easily peeled off without tearing either it or the underlying muscular tissue. Near the lateral borders of the uterus the peritoneum is less firmly attached, and over the back of the cervix it may readily be stripped off without injury to the underlying structures.

The **muscular coat** is composed of plain fibres, and forms the chief part of the uterine wall. Inferiorly the muscular coat of the uterus becomes continuous with that of the vagina. The more superficial layer of the muscular coat sends prolongations into the recto-uterine folds, into the round and broad ligaments of the uterus, and into the ovarian ligaments. Other fibres join the walls of the uterine tubes. The main branches of the blood-vessels and nerves of the uterus lie among the muscle-fibres. In the deeper layers of the muscular coat a considerable amount of fibrous tissue and some elastic fibres are to be found. At the isthmus the muscular fibres decrease and the fibrous tissue increases, and the muscular coat of the cervix contains more fibrous and elastic tissue than that of the body; hence its greater firmness and rigidity.

The deeper and thicker part of the muscular tissue of the uterus is considered by some anatomists to represent a lamina muscularis mucosæ, and is therefore described as part of the mucous coat. The deep and superficial portions of the muscular coat are, however, quite continuous, and there is no representative of a submucous vascular layer of tissue such as separates the muscular coat from the lamina muscularis mucosæ in the alimentary canal.

The **mucous coat** in the body of the uterus is smooth and soft and covered with columnar ciliated epithelium. Simple tubular glands, also lined with a ciliated epithelium, are present in the mucous membrane, and their deeper parts penetrate into the muscular coat. In the isthmus the glands are fewer, less deep, stain less intensely and are less affected by the menstrual cycle (Fig. 660). In the cervix the mucous coat is firmer and more fibrous than in the body, and its surface is not smooth but presents a number of peculiarly disposed ridges which have been mentioned already. Like the mucous membrane of the body of the uterus, that of the cervix is covered with a ciliated epithelium which passes into squamous epithelium just inside the external os of the uterus. In addition to unbranched tubular glands, numerous slightly branched glands are found in the cervix uteri. Both kinds of glands are lined with ciliated epithelium. In many cases little clear retention cysts are to be seen in the cervical mucous membrane. They arise as a result of obstruction at the mouths of the glands.

Differences in Uterus at Different Ages.—At birth the cervix uteri is relatively large, and its cavity is not distinctly marked off from that of the body by an internal os. At that time also the arbor vitæ extends throughout the whole length of the uterus. The organ grows slowly until just before puberty, when its growth is rapid for a time. As the body increases in size the mucous membrane becomes smooth and the arbor vitæ becomes restricted to the cervix. In women who have borne children the cavity remains permanently a little wider and larger than in those who have never been pregnant. In old age the uterine wall becomes harder and has a paler colour than in the young subject.

Variations.—In rare cases the uterus may be divided by a septum into two distinct cavities, or its lateral angles may be produced into straight or curved processes, called "horns". The latter abnormality recalls the appearance of the bicornuate uterus of some animals. Both the above conditions arise from an arrest in the fusion of the two separate tubes—the para-mesonephric ducts—which normally unite in the embryo to form the uterus.

Periodic Changes in Uterine Wall.—At each menstrual period a remarkable series of changes occurs which results in a periodic shedding of the superficial parts of the uterine mucous membrane. For a few days before menstruation begins, the mucous membrane gradually thickens and becomes more vascular, while at the same time its surface becomes uneven. Soon the superficial parts of the mucous membrane disintegrate and hæmorrhage takes place from the small superficial blood-vessels. In that way a hæmorrhagic discharge is caused, and the superficial parts of the uterine mucous membrane are shed at each period. When menstruation is over the mucous membrane is rapidly regenerated (see also p. 80, and consult Marshall, 1950; Selye, 1947).

Pregnant Uterus.—The pregnant uterus increases rapidly in size and weight, so that from being a pelvic organ 3 inches in length and about 1½ ounces in weight, it rises into the abdomen and becomes by the eighth month of pregnancy about 7 or 8 inches in length and sometimes as much as 2 lb. in weight. In shape the uterus is then oval or rounded, with a thick wall composed chiefly of muscle-fibres arranged in distinct layers. The fundus is very round and prominent. During labour the lower uterine segment (p. 779) is formed mainly by the isthmus, but the upper part of the cervix also is incorporated into it. The round ligaments are longer, and the layers of the medial part of the broad ligaments become separated by the growth of the uterus between them. The blood-vessels, especially the arteries, are very large and tortuous. The changes which occur in the mucous membrane of the pregnant uterus are described on p. 80 *et seq.* For changes in the pelvic floor during parturition, see Power (1946).

Involution of Uterus.—Immediately after delivery the uterus contracts, but it is still many times the size of the normal resting organ. It weighs about 2¼ lb. or 1000 gms. and lies against the anterior abdominal wall almost as high as the umbilicus. The peritoneum on its surface is thrown into wrinkles, and owing to the slackness of the ligaments the whole organ is extremely mobile. The cervix is lengthened and is flaccid, with thin walls and a widely open os. Sometimes on the second day after delivery the uterus rises above the umbilicus, apparently owing to the organ regaining elasticity, but from then onwards it rapidly shrinks. By the end of the first week it has diminished in weight to about 1 lb. or 500 gms., the wrinkles in its

peritoneal covering have disappeared and the cervix has shortened and become firmer. The ligaments of the uterus shorten as the uterus shrinks, and the pelvic floor also regains tone, so that the organ is less mobile. By the end of the second week it weighs 11 ozs. or 350 gms. and by the end of the eighth week it should be reduced to its resting size and should weigh 2 ozs. (60 gms.) or less. This process of gradual reduction of the uterus to its normal size is known as *involution*.

Vessels and Nerves of Uterus.—The uterus receives its **arterial supply** mainly from the *uterine arteries*, which are branches of the internal iliac arteries, and also from the *ovarian* branches of the aorta. The vessels derived from these two sources communicate freely with one another. Each uterine artery, reaching the side of the uterus, divides into a large branch which passes forwards to supply the body and fundus, and a much smaller branch which passes downwards to supply the cervix. The vessels distributed to the body and fundus have an exceedingly tortuous course. The branches of the uterine artery, having entered the muscular coat, break up within its deeper layers into smaller twigs which supply the muscular tissue and the mucous coat. The small uterine branch from the ovarian artery reaches the uterus in the region of the lateral angle. During pregnancy the arteries become enormously enlarged.

Numerous thin-walled **veins** form a plexus at the side of the cervix and pour their blood into the tributaries of the internal iliac vein.

The **lymph-vessels** from the fundus of the uterus join those from the ovary and end in *aortic lymph-glands*. One or two run along the round ligament to the *superficial inguinal lymph-glands*. The lymph-vessels from the cervix run to the sacral glands and all the iliac groups; those from the body end chiefly in the external iliac glands (p. 1412).

The **nerves** of the uterus are derived chiefly from a plexus—*utero-vaginal*—placed in the neighbourhood of the cervix uteri. Superiorly this plexus is continuous with the pelvic sympathetic plexuses, but it receives parasympathetic fibres also from the second and third or the third and fourth sacral nerves through the pelvic splanchnics.

Clinical observations indicate that afferent impulses reach the central nervous system from the uterus through the posterior roots of the tenth, eleventh, and twelfth thoracic nerves and the first lumbar nerves (Whitehouse and Featherstone, 1923).

VAGINA

The **vagina** (Figs. 657 and 661) is a passage about 3 inches in length, open at its lower end, and communicating above with the cavity of the uterus. The passage is directed downwards and forwards, describing a slight curve which is convex backwards. When the urinary bladder is empty, the axis of the vagina makes with the axis of the uterus an angle of slightly more than 90 degrees, but this angle increases as the bladder fills and raises the fundus of the uterus. Its anterior and posterior walls are in contact except at its upper end, where the cervix is inserted; and that is its widest part also. In transverse section the lower part is usually an H-shaped cleft, the middle part a simple transverse slit, while the lumen of the upper portion is more open. The cervix uteri enters the vagina through the upper portion of its anterior wall (Fig. 657). As more of the posterior part of the cervix than of the anterior part projects into the vagina, the recess between the vaginal wall and the cervix is deeper behind than in front or laterally. The term **anterior fornix** is applied to the recess in front, **posterior fornix** to the recess behind, and **lateral fornix** to the recess on each side. The *anterior wall* of the vagina is about 3 inches in length; the *posterior wall* is a little longer—about 3½ inches. At its lower end the vagina opens into the pudendal cleft between the labia minora. The opening is partly closed in the virgin by a thin, crescentic or annular fold, called the **hymen**, torn fragments of which persist around the opening, as the **carunculæ hymenales**, after the fold itself has been ruptured.

Relations of Vagina.—The vagina is related *anteriorly* from above downwards to the cervix uteri, the base of the bladder and ends of the ureters, from which it is separated by areolar tissue, and the urethra, to which it is intimately connected. Its upper end usually deviates a little to one side, with consequent asymmetrical relation to the ureters (p. 738). *Posteriorly* it is related from above downwards to the recto-vaginal peritoneal pouch for half an inch or more, then to the ampulla of the rectum, from which it is separated by a thin layer of very loose areolar tissue, and then to the perineal body. *Laterally* it is related on each side to the root of the broad ligament and the ureter crossed by the uterine vessels; lower down it is related to the levator ani muscle, a plexus of

veins intervening; and lower still it is related to the greater vestibular gland and to the bulb of the vestibule covered by the bulbo-spongiosus muscle. As the perineal membrane approaches the median plane, it turns downwards on each side of the vagina deep to the bulb of the vestibule and fuses below with the root of the labium minus.

Structure of Vagina.—The vaginal wall has a **muscular coat** composed of plain muscle-fibres, most of which are longitudinally disposed. Towards the lower end there are circular bundles of striated muscle-fibres, some of which are continuous with those which form a part of the

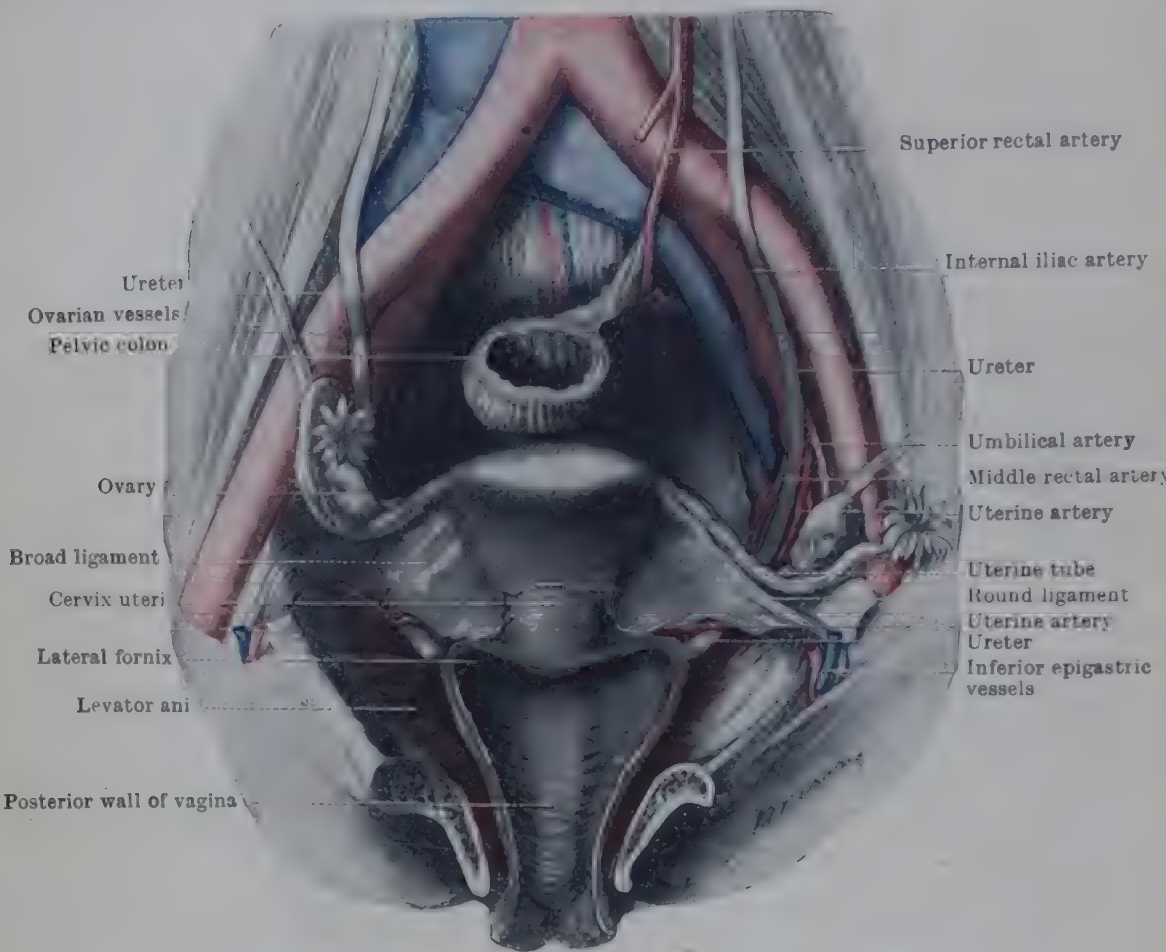

FIG. 661.—UTERUS AND VAGINA DISPLAYED BY FURTHER DISSECTION OF PELVIS OF MULTIPAROUS FEMALE SHOWN IN FIG. 656.

urethral wall. The **mucous coat** is thick and is corrugated by a number of transverse ridges or elevations known as **vaginal rugæ**; and it is covered with stratified squamous epithelium. In addition to the transverse rugæ, a slightly marked longitudinal ridge is to be seen on the anterior wall and another on the posterior wall. These receive the name **columns of rugæ**, and, like the transverse rugæ, they are seen best in young subjects and in the lower part of the vagina. The urethra lies in close relationship to the anterior column in its lower part, and hence that portion of the column is called the **urethral ridge**. Between the muscular and mucous coats there is a thin layer of vascular tissue which resembles erectile tissue; and in the mucous coat there are small nodules of lymphoid tissue.

The vaginal wall is surrounded by a layer of loose, vascular areolar tissue which contains numerous large communicating veins.

Vessels and Nerves of Vagina.—The **arteries** on each side are the *vaginal artery*, the vaginal branch of the *uterine artery*, the vaginal branches of the *middle rectal artery*, and branches of the *internal pudendal artery*. The **veins** form a plexus around the vaginal wall, and drain their blood into the tributaries of the *internal iliac veins*.

The **lymph-vessels** from the upper part of the vagina join the *external* and *internal iliac glands*, and those from the lower part end in the *superficial inguinal glands* (p. 1412).

The **nerves** of the vagina are derived from the *utero-vaginal plexus* and from the *vesical plexus*. Parasympathetic fibres are derived from the *third* and *fourth sacral nerves*.

Methods of Clinical Anatomical Examination.—The interior of the vagina and the vaginal part of the cervix can be inspected through a vaginal speculum. By a bimanual examination—two fingers of one hand in the vagina and the other hand on the anterior abdominal wall above the pubic crests—the fundus of the uterus can be felt when the fingers in the vagina press the cervix forwards and upwards. Normal uterine tubes

nnot be felt, but if thickened or inflamed they can often be palpated in a bimanual .amination.

The external os of the uterus is usually at the level of the spines of the ischium, which can be felt from the vagina; if the os is below this level, the uterus is prolapsed. The vaginal part of the cervix and the external os can be felt by a finger in the rectum. The

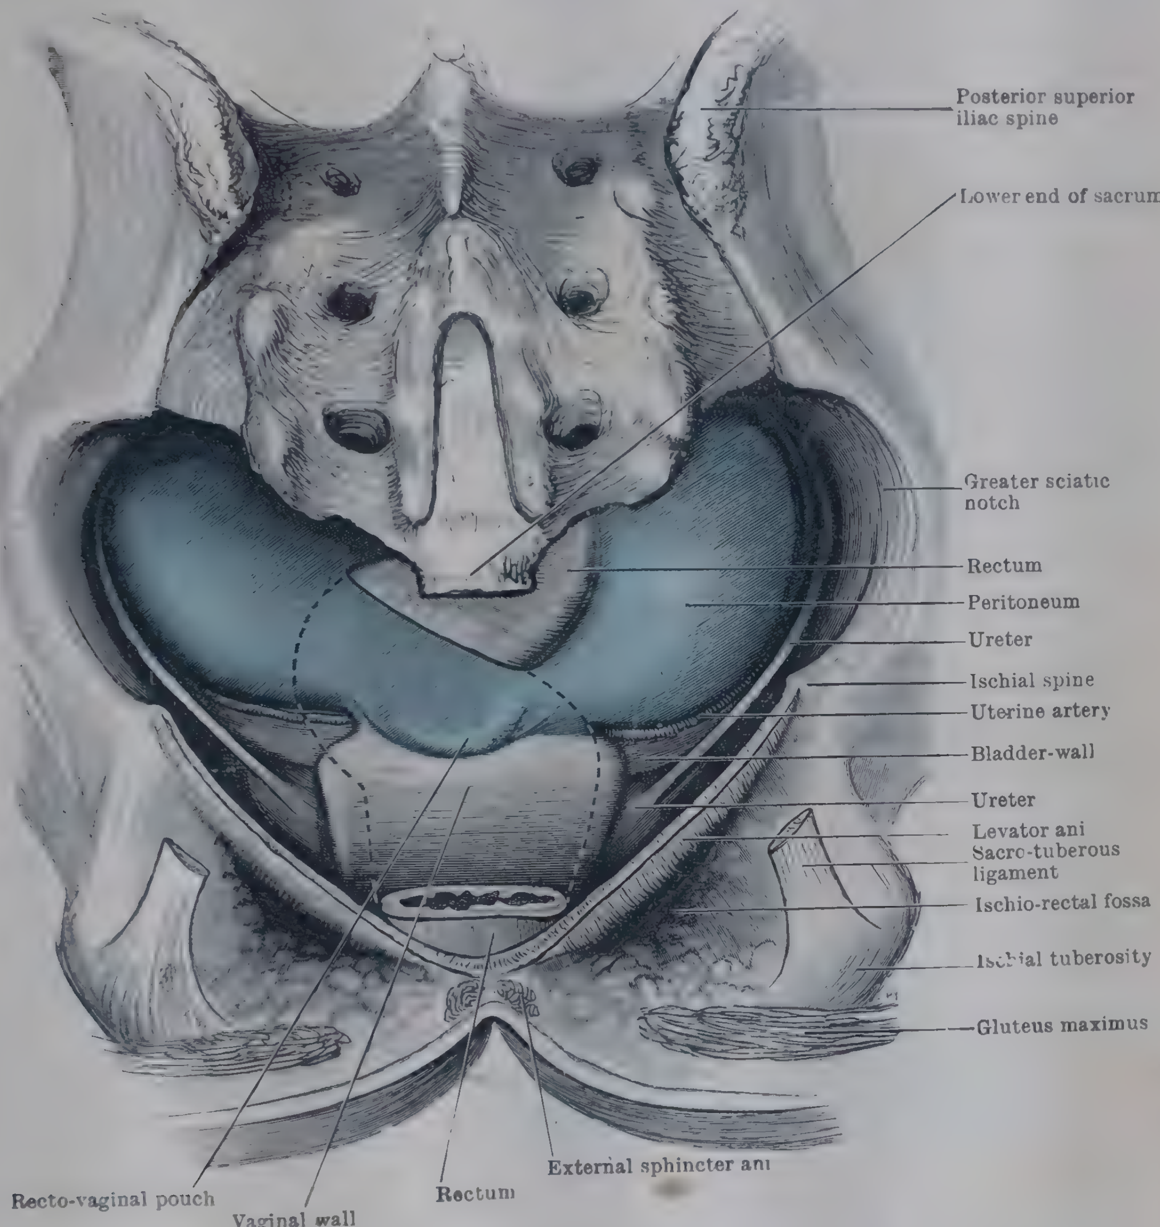

Fig. 662.—Vagina, Base of Bladder, and Recto-Vaginal Pouch from Behind.

The coccyx and the sacro-tuberous and sacro-spinous ligaments have been removed. The levatores ani h: been separated and drawn laterally. A considerable portion of the rectum has been removed, but position is indicated by the dotted lines. The recto-vaginal pouch is probably not quite so deep usual. The triangular interval between the ureter and uterine artery was filled by a mass of fibr muscular tissue.

pregnant uterus can be palpated as soon as it has risen above the pelvic cavity and lies against the anterior abdominal wall.

Radiographic Examination.—Materials opaque to X-rays can be injected into the uterus and thence into the uterine tubes, so that the shape of the uterine and tubal cavities and the position of the organs may be shown (Pl. LXXII, p. 745).

A fœtus in a pregnant uterus can be demonstrated by X-rays after the fourth month of pregnancy.

FEMALE EXTERNAL GENITAL ORGANS

The collective term **pudendum muliebre** or **vulva** is applied to the female external genital organs, *i.e.*, to the mons pubis and the labia majora and the structures which lie between the labia (Fig. 663).

Labia Majora.—The labia majora represent the scrotum in the male, and they form the largest part of the female external genital organs. They are the boundaries of the **pudendal cleft**, into which the urethra and vagina open. Each labium is a prominent, rounded fold of skin, narrow behind where it approaches the anus, but increasing in size as it passes forwards and upwards to end in a median elevation—the **mons pubis**. The mons pubis lies over the pubic symphysis, and, like the labia majora, it is composed chiefly of fatty and areolar tissue, and is covered with hair. The skin of the lateral, convex surface of each labium majus contains numerous sebaceous glands and resembles that of the scrotum in the male, but the medial surface is flatter and smooth and has a more delicate cutaneous covering. In some cases the posterior ends of the labia majora are connected across the middle line, in front of the anus, by a slight transverse fold — the **posterior commissure.**

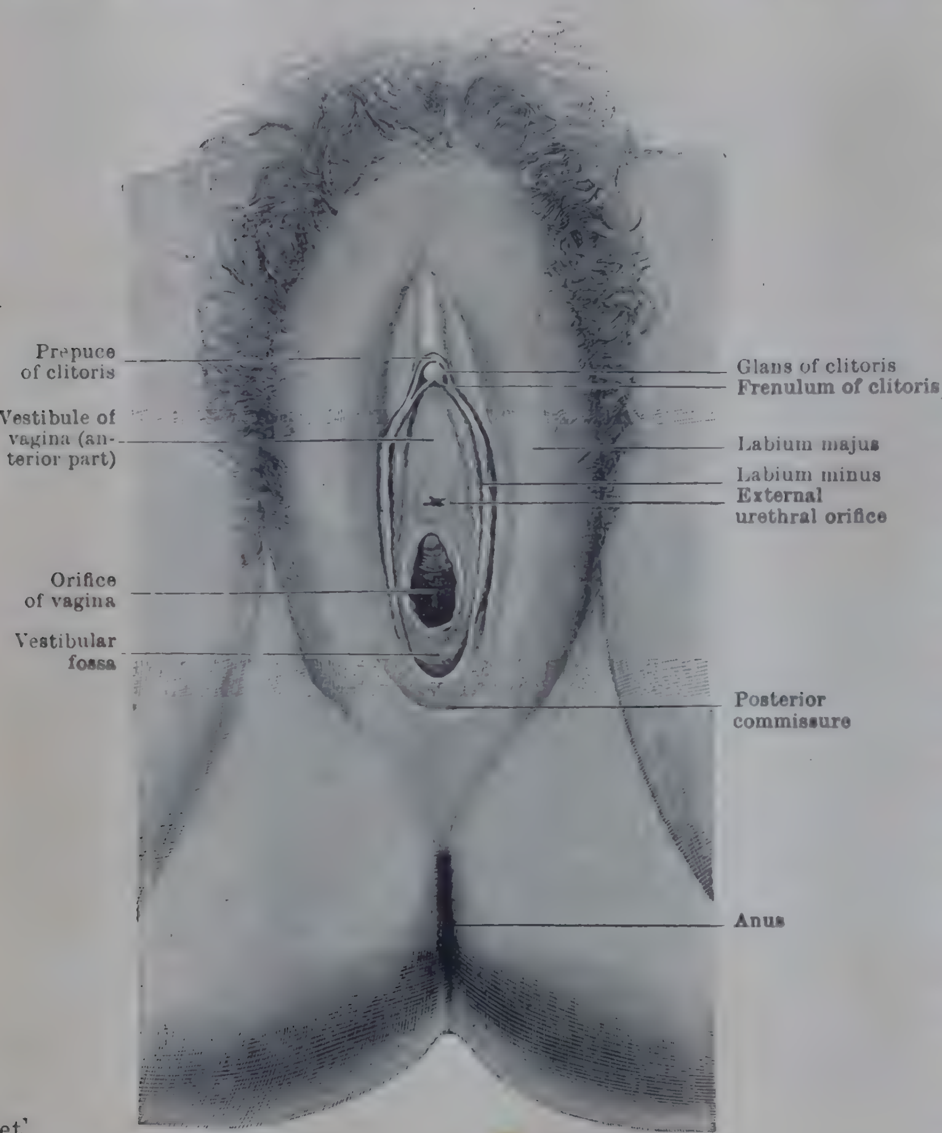

FIG. 663.—FEMALE EXTERNAL GENITAL ORGANS.
The frenulum labiorum is seen stretching across behind the vestibular fossa.

Usually the mons and the labia majora are the only visible parts of the external genital organs, since the labia are in contact with each other and completely conceal the structures within the pudendal cleft.

The round ligament of the uterus ends in the skin and fibro-fatty tissue of the labium majus. The superficial layer of the subcutaneous tissue resembles that of the scrotum, but contains no muscular fibres.

The **nerve-supply** corresponds with that of the scrotum—the anterior part of each labium being supplied by branches of the ilio-inguinal nerve, and the posterior part by branches from the pudendal nerve and by the perineal branch of the posterior cutaneous nerve of the thigh. The **blood-vessels** are derived from the external pudendal branches of the femoral and from the labial branches of the internal pudendal vessels.

Labia Minora.—The labia minora are a pair of much smaller and narrower longitudinal folds of skin usually completely hidden in the cleft between the labia majora. Their posterior parts diminish in size and end by gradually joining the medial surfaces of the labia majora. In the young subject a slightly raised transverse fold is usually seen connecting the posterior ends of the labia minora; to this fold the term **frenulum labiorum** is applied. Traced forwards, each labium minus divides into two portions—a lateral and a medial. The lateral portions of

the two labia unite over the glans clitoridis and form for it a fold or covering called the **prepuce of the clitoris**. The medial portions, uniting at an acute angle, join the glans and form the **frenulum of the clitoris**. The skin of the labia minora resembles that on the medial surface of the labia majora, being smooth, moist, and pink in colour. The medial surfaces of the labia minora are in contact with each other, and their lateral surfaces with the labia majora. The labia minora and the frenulum are devoid of fat.

The openings of the urethra and vagina are in the median plane, between the labia minora, which must be separated to bring them into view.

Vestibule of Vagina.—The vestibule is the name applied to the space between the labia minora. In its floor are the openings of the urethra, the vagina, and the ducts of the greater vestibular glands.

The **vestibular fossa** is the part of the vestibule behind the vaginal opening and in front of the frenulum labiorum.

The **external urethral orifice** is immediately in front of that of the vagina, and is about one inch behind the glans clitoridis. The opening has the appearance of a vertical slit or of an inverted V-shaped cleft whose margins are prominent and in contact with each other. Sometimes on each side of the urethral orifice there may be seen the minute opening of the para-urethral duct (see p. 753).

The **orifice of the vagina** varies in appearance with the condition of the **hymen**. When the hymen is intact the opening is small, and is seen only when that membrane is put on the stretch. When the hymen has been ruptured the opening is much larger, and round its margins are often seen small projections—**carunculæ hymenales**—which are fragments of the hymen.

The **hymen** is a thin membranous fold which partially closes the lower end of the vagina, and is perforated usually in front of its middle point. The position of the opening gives the fold, when stretched, a crescentic appearance. The opening in the hymen is sometimes cleanly cut, sometimes fringed. The membrane is not stretched tightly across the lower end of the vagina, but is so ample that it projects downwards into the pudendal cleft. The opening is thus a median slit whose margins are normally in contact.

On each side of the vaginal opening, in the angle between the labium minus and the under surface of the carunculæ hymenales, is the opening of the duct of the **greater vestibular gland**. It is usually just large enough to be visible to the unaided eye.

Numerous minute mucous glands — the **lesser vestibular glands**—open into the vestibule between the urethral and vaginal orifices.

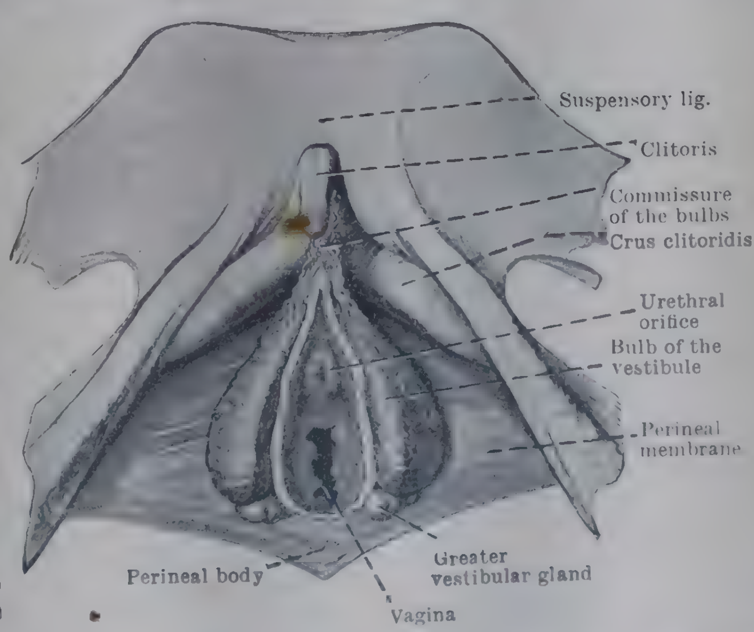

Fig. 664.—Dissection of Female Perineum to show Clitoris, Bulb of the Vestibule, and the Greater Vestibular Glands.

Clitoris.—The clitoris is the morphological equivalent of the penis, and it has a body, a pair of crura, and a minute glans on the summit of the body. Unlike the penis, the clitoris is not traversed by the urethra.

The **body** is composed for the most part of erectile tissue resembling that of the penis. It is about an inch in length, and is bent upon itself, forming an angle open downwards. It tapers towards its distal end, which is covered by the glans. It is enclosed in a dense fibrous coat and is divided by an incomplete **septum** into a pair of cylindrical **corpora cavernosa clitoridis**, which diverge from

each other at the root of the clitoris to form the **crura clitoridis**. A fibrous *suspensory ligament* passes from the body of the clitoris to the pubic symphysis (Fig. 664).

The **glans clitoridis** is a small mass of erectile tissue fitted over the pointed end of the body, and, like the glans penis, it is covered with a very sensitive epithelium. The **prepuce**, which hoods over the glans, and the **frenulum clitoridis**, which is attached to it inferiorly, are continuous with the labia minora (Fig. 663).

The **crura clitoridis** diverge from the body posteriorly, and are attached to the sides of the pubic arch. Each is continuous with one of the corpora cavernosa, and has a firm fibrous sheath, which is covered by the corresponding ischio-cavernosus. In structure the crura and body of the clitoris resemble the corpora cavernosa penis, while the glans more closely resembles the bulbs of the vestibule, with which it is connected by a slender band of erectile tissue (Fig. 664).

In the seal and some other animals a bone—the *os clitoridis*, which represents the os penis of the male—is developed in the septum of the clitoris.

The **arterial supply** of each crus is the deep branch from the internal pudendal. The glans is supplied by the dorsal arteries of the clitoris.

The **nerve-supply** of the clitoris is derived partly from the pelvic sympathetic plexuses and partly from the dorsal nerves of the clitoris, which are branches of the pudendal nerves.

FIG. 665.—DIAGRAMS TO ILLUSTRATE MANNER IN WHICH URETER, VAS DEFERENS, AND URINARY BLADDER ARISE IN THE EMBRYO.

The structures developed from the cloaca are indicated in blue, those from the mesonephric duct in red, and the ectoderm in black.

The manner in which the rectum and bladder become separated and acquire openings into the ectodermal cloacal fossa is shown in II and III.

R. Rectum.
Ur. Urogenital canal.
U. Ureter.
VD. Vas deferens.
VS. Seminal vesicle.
WD. Mesonephric duct.

Bulbs of Vestibule.—These are a pair of masses of erectile tissue which correspond developmentally to the two halves of the bulb of the penis, but are almost completely separated from each other by the vagina and the urethra—being only slightly connected in front by a narrow median part called the **commissure**. Each bulb is thick posteriorly, and more pointed in front, where it joins the commissure. It rests against the lateral wall of the vagina and the lower surface of the perineal membrane. Superficially it is covered by the bulbo-spongiosus muscle. The commissure lies in front of the opening of the urethra, and is connected by a slender band of erectile tissue with the glans clitoridis. The bulb is for the most part composed of minute convoluted blood-vessels held together by a very small amount of areolar tissue; they frequently anastomose with one another, and with the vessels of the commissure and the glans clitoridis.

The **blood-supply** of the bulb is derived from a special branch of the internal pudendal.

GREATER VESTIBULAR GLANDS

The **greater vestibular glands** are placed one on each side of the lower part of the vagina, below the perineal membrane and concealed by the posterior parts of the bulbs of the vestibule. Each is about the size and shape of a small bean; and it has a long slender duct which pierces the perineal membrane and opens into the vestibule in the angle between the labium minus and the hymen (Figs. 659, 664).

DEVELOPMENT OF UROGENITAL ORGANS

General Account.—In tracing the developmental history of the urogenital passages it is convenient to begin with an embryo about 2·5 mm. in length. At that time a longitudinal duct on the lateral side of the mesodermal somites begins to develop on each side of the body. With the exception of the pronephros, the anterior portion of the cloaca and the proximal part of the allantois, that duct, which has received the name of *mesonephric duct* (Wolffian duct), is the earliest formed structure from which, or in connexion with which, the parts of the adult urogenital system arise.

The mesonephric duct serves as the canal for the primitive excretory organs—the pronephros and the mesonephros of the embryo. With the atrophy of these organs the duct suffers modification; yet adults of each sex possess structures which have their embryonic origin from it. In the male the **canal of the epididymis**, the **vas deferens**, and the **ejaculatory duct** are directly developed from the mesonephric duct; in the female the **duct of the ep-oöphoron** and the **vesicular appendices** are vestigial structures having a like origin. The **ureter** and its **pelvis** and the collecting tubules of the kidney arise in both sexes as an outgrowth from the mesonephric duct. In the male the **seminal vesicle** is developed as a diverticulum from it.

The primitive excretory organs—the **pronephros** and the **mesonephros**—develop in connexion with the anterior part of the mesonephric duct, and they correspond respectively to the functional kidneys of some primitive vertebrates (pronephros) and of the fishes and amphibia (mesonephros). In the human embryo the pronephros is functionless and soon becomes vestigial, and it is replaced by the far more important mesonephros. With the development of the permanent kidney or **metanephros** the mesonephros atrophies; yet some of its tubules persist in the adult. The **efferent ductules** of the testis, the **ductuli aberrantes** and the **paradidymis** in the male, and the tubules of the **ep-oöphoron** and of the **par-oöphoron** in the female, are structures which owe their origin to the tubules of the mesonephros.

After the formation of the mesonephric ducts another pair of longitudinally disposed canals are developed, called the **para-mesonephric ducts** (Müllerian ducts). Each duct begins as a solid outgrowth of cells from the wall of the body-cavity in the region of the mesonephros, but it soon acquires a lumen which opens at its cephalic end into the body-cavity. The ducts then grow slowly in a caudal direction and at their caudal ends they unite with each other in the median plane. From them are formed in the female the **uterine tubes**, the **uterus**, and the **vagina**; and in the male the **appendices of the testis** and the **prostatic utricle**.

The mesonephric and the united para-mesonephric ducts open at their caudal ends into the ventral or urogenital part of the **cloaca**, which in the course of development becomes transformed into the **urinary bladder** and the **urogenital canal** of the embryo (Fig. 665). The developing ureter at first arises as a diverticulum from the mesonephric duct at a short distance from the point where that duct joins the cloaca. Soon, however, the ureters acquire independent openings into the cloaca, and these openings become gradually shifted farther from each other and from those of the mesonephric ducts. The ureters come to open into the anterior portion of the cloaca, which lies nearer to the head of the embryo than the part with which the mesonephric ducts are connected. The cephalic portion of the anterior subdivision of the cloaca which receives the ureters becomes the urinary bladder and the upper part of the urethra. The caudal part, lying below the level of the entrance of the mesonephric ducts, is called the *urogenital canal* and is represented in the adult male by the lower part of the prostatic urethra and the whole of the membranous portion; in the female by the lower part of the urethra and the part of the pudendal cleft which immediately surrounds the openings of the urethra and vagina (Figs. 674, 675). The united para-mesonephric ducts open into the caudal part of the cloaca or urogenital canal between the mesonephric ducts. In the male the position of the opening, which is represented in the adult by the orifice of the prostatic utricle, remains almost unchanged. In the female, on the other hand, a shortening of the urogenital canal causes the opening, which in that sex is represented by the vaginal orifice, to appear on the surface of the body in the pudendal cleft.

After the complete separation of the cloaca into anterior or urogenital and posterior or rectal divisions, the rectum establishes a communication with the exterior in the floor of the shallow depression known as the ectodermal **cloacal fossa**. At a little later time the urogenital canal also joins the cloacal fossa at a point in front of the opening of the rectum. The ectodermal cloacal fossa lies in front of the vestigial tail, and extends forwards as far as a tubercle known as the **cloacal tubercle**, which later gives rise to the **genital eminence** and a pair of elevations called the **labio-scrotal folds**. The genital eminence becomes converted into the **clitoris** or **penis** according to the sex. The labio-scrotal folds, extending backwards on each side, form the **labia majora** of the female, and, fusing posteriorly, give rise to the **scrotum** in the male. In the female the lower part of the urogenital canal opens out to form a part of the floor of the pudendal cleft of the adult, and the shortening of the canal leads to the urethra and the vagina having independent openings into the cleft the margins of the cleft becoming elongated to form the **labia minora**. In the male the slit-like opening of the urogenital canal is prolonged forwards by an active growth at the base of the genital eminence, and, its margins uniting, it gives rise to the penile portion of the **urethra**.

Mesonephric Duct and Embryonic Excretory Organ

The **mesonephric duct** arises in the mesoderm of the intermediate cell-mass (p. 51), about the fifteenth day, as a solid cord of cells, and occupies a position immediately lateral to the mesodermal somites and medial to the body-cavity. During the fourth week this cellular cord acquires a lumen (Fig. 666), and about the end of the same week the duct in its growth reaches the cloaca. As soon as the cloaca has become divided into dorsal and ventral parts, the mesonephric duct ends in the cephalic part of the ventral division, which becomes the bladder and urogenital canal (Figs. 667, 668).

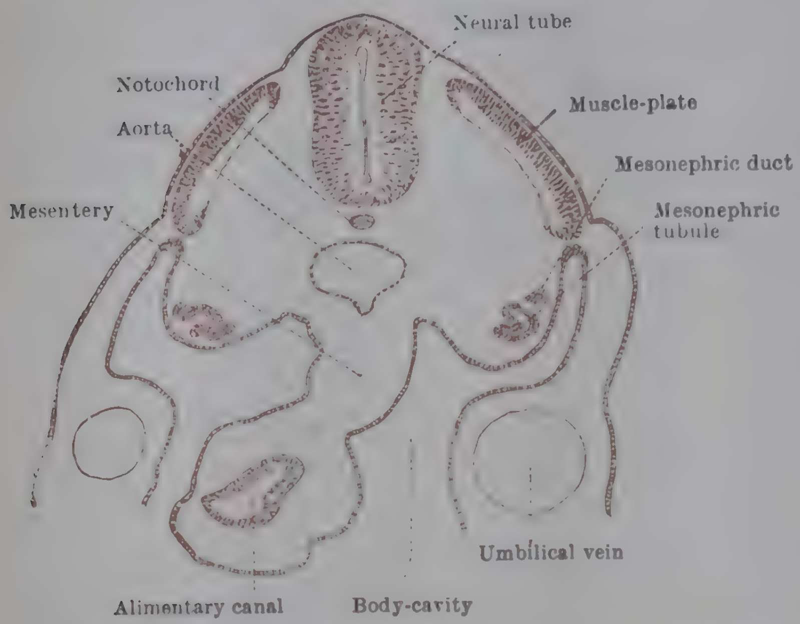

Fig. 666.—Transverse Section of 5 mm. Human Embryo.

The **mesonephros** is developed in the mesoderm of the intermediate cell-mass immediately adjoining the mesonephric duct, and it consists of a number of minute transversely arranged tubules, each of which opens by one end into the mesonephric duct, while its other end is blind. The transverse tubules, like the canal into which they open, are at first solid cellular structures, and only later acquire a lumen. Increasing rapidly in length and number, the tubules become twisted and tortuous, and the blind end of each dilates to form a capsule invaginated upon itself and containing a bunch of capillary blood-vessels similar to the *glomeruli* of the adult kidney. It would appear that primitively one tubule is developed in the portion of the intermediate cell-mass (nephrotome) which corresponds to each mesodermal somite, but, in higher vertebrates at all events, such a correspondence between the number of somites and the number of tubules cannot be demonstrated. In the tailward part of the mesonephros the tubules are very numerous—more numerous than the segments in that region. The tubules

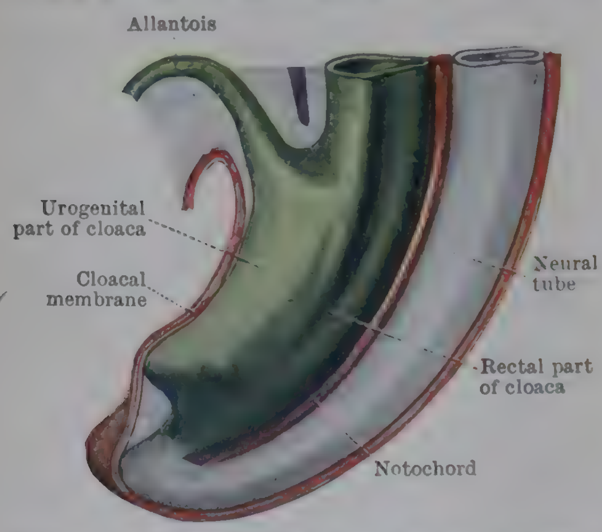

Fig. 667.—Tail-End of 3 mm. Human Embryo, before the time at which the Mesonephric Ducts reach the Cloaca. (Keibel, 1896.)

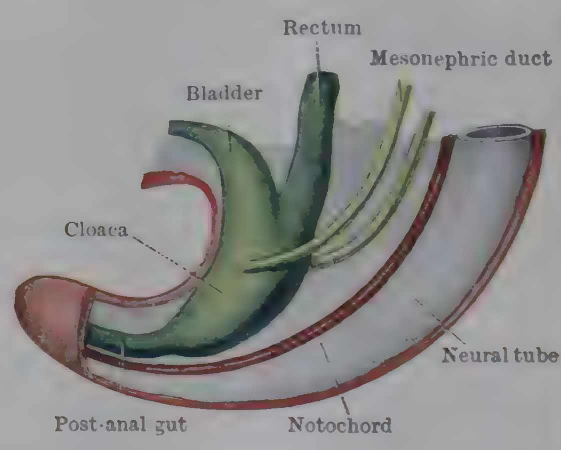

Fig. 668.—Tail-End of 4·2 mm. Human Embryo. The mesonephric ducts open into the anterior part of the cloaca. (Keibel, 1896.)

of the mesonephros arise in all segments from the sixth cervical to the third lumbar. The tubules in the headward part atrophy and disappear at a very early time, even while others are being formed towards the caudal end of the embryo. When at its greatest development (fifth to eighth week) the mesonephros is a relatively large glandular mass composed of tubules which resemble in a general way those of the adult kidney. At that time it bulges into the dorsal part of the body-cavity, and extends from the region of the liver to the caudal end of the cavity. Along its lateral surface lies the mesonephric duct (Fig. 669).

As the permanent kidney or metanephros is developed, the mesonephros atrophies; a portion of it, however, is retained *in the male*, and forms the excretory apparatus of the testis. The mesonephric duct becomes the canal of the epididymis and the vas deferens of the adult (see p. 793). *In the female*, when the permanent kidney is formed, the mesonephros and its

duct undergo atrophy to a greater extent than in the male, and they are represented only by the vestigial structures in the broad ligament of the uterus (see pp. 774 and 793).

In anamniate vertebrates—fishes and amphibia—the mesonephros persists as the excretory organ of the adult.

Pronephros.—The mesonephric duct originally served as the duct of the still earlier excretory organ—the **pronephros**. In the human embryo the pronephros arises earlier than the mesonephros, when the embryo possesses only ten segments, and its tubules are represented by coiled, solid cords of cells. The pronephros is found in the headward segments of the embryo only, and it atrophies at a very early time in development.

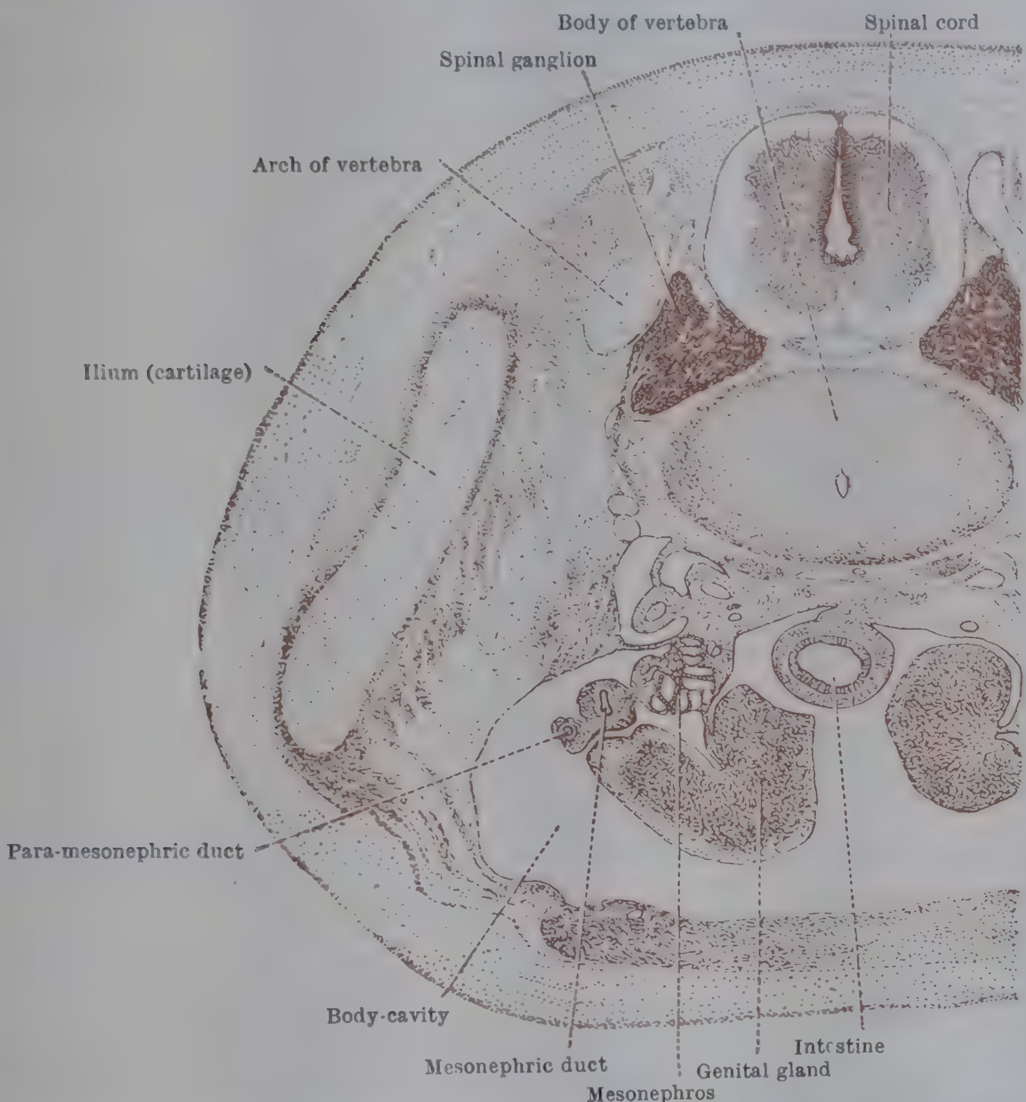

Fig. 669.—Transverse Section through Lower Part of Trunk of Human Embryo of about 7 Weeks. (Symington.)

Ureter and Permanent Kidney

The permanent kidney or **metanephros** has a double origin. The *secretory tubules* are developed from an extension of the tissue from which the mesonephros is derived—the metanephros proper; but the *collecting tubules* grew out from the ureteric bud of the mesonephric duct.

The ureter arises as a tubular diverticulum from the mesonephric duct close to the point where the duct joins the cloaca (Figs. 670 and 671). The diverticulum appears during the fifth week, and grows headwards, dorsal to the body-cavity. Even in its very early condition the portion of the outgrowth which lies nearest its origin from the mesonephric duct, and from which the adult ureter is developed, is more slender than the distal part, which becomes branched and grows out to form the pelvis and calyces of the ureter. From the calyces numerous collecting tubules grow out and acquire connexions with the glandular or uriniferous tubules of the kidney. The uriniferous tubules of the kidney arise independently of the ureter in the *metanephric cap*—a tailward prolongation of the tissue which, nearer the head, gives origin to the tubules of the mesonephros. The tissue in which the permanent kidney-tubules arise is caudal to the third lumbar segment. The blind, distal end of each tubule soon dilates to form a capsule which, becoming invaginated on itself, encloses a tuft of capillary blood-vessels. The renal corpuscles arising in this manner are found in the human kidney as early as the eighth week. It must be specially noted that the origin of the collecting tubules and their branches is different from the origin of the secreting tubules. The short junctional tubules of the adult lie in the

region where these developmentally distinct portions of the kidney unite. If the junctional tubules fail to develop, the secreting tubules have no outlet and a *congenital cystic kidney* is the result.

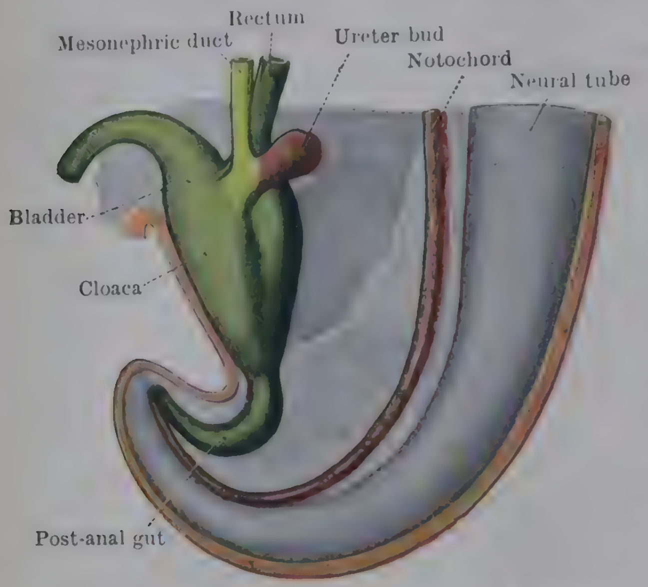

FIG. 670.—TAIL-END OF 6·5 MM. HUMAN EMBRYO.
The cloaca is dividing into rectal and urogenital parts. The ureter is arising as a bud from the mesonephric duct. (Keibel, 1896.)

As the ureter increases in length, it separates from the mesonephric duct, and acquires an independent opening into the ventral part of the cloaca nearer the head of the embryo than that of the mesonephric duct. The part of the cloaca which receives the ureters becomes the urinary bladder.

The metanephric cap, in which the uriniferous tubules arise, lies at first on the medial side of the bud-like outgrowth which represents the ureter; at a later time it comes to lie dorsally. As the ureter grows towards the head-end of the embryo the cell-mass which gives rise to the uriniferous tubules follows it; hence, the metanephric tissue ceases to lie at the caudal end of the mesonephros. Variations in the origin of the renal arteries are due to the change in position of the kidney during development; the blood-supply is at first from the internal iliac artery, but as the kidney moves head-wards it is supplied by branches from the common iliac and finally from the aorta.

As the ureter divides to form the calyces, the metanephric cap becomes broken up into numerous cell-masses—one for each branch of the ureter, and later one for each of the collecting tubes which grow out from the calyces. The formation of uriniferous tubules within the cell-masses is continued until a few days after birth. The kidney is at first a distinctly lobulated body, and shows at birth, and sometimes even in the adult, distinct traces of its original division into lobules (Fig. 679, p. 802).

URINARY BLADDER

The main portion of the urinary bladder is formed from the cephalic part of the ventral division of the cloaca. This, at an early time, becomes flattened dorso-ventrally and produced laterally into two horn-like projections in the region where the mesonephric ducts open (Fig. 671). Its tailward part becomes constricted to form the urogenital canal. Little by little the caudal ends of the mesonephric ducts open out and take part in the formation of the wall of the bladder and the upper portion of the prostatic part of the urethra. The openings of the ureters become shifted laterally, but the final position of the openings of the mesonephric ducts is close to the median plane in the prostatic part of the urethra. The urinary bladder has therefore a double origin: its main portion is derived from the cloaca and is therefore entodermal; the rest of it corresponds approximately to the trigone and is mesodermal in origin, for it arises from the opened-out caudal ends of the mesonephric ducts. The extreme cephalic end of the ventral part of the cloaca tapers gradually, and beyond the umbilicus is continuous with the allantois. This part of the cloaca is the *urachus*; it loses its lumen about the fifth week, and in the adult is represented by a fibrous cord—the median umbilical ligament (Begg, 1930).

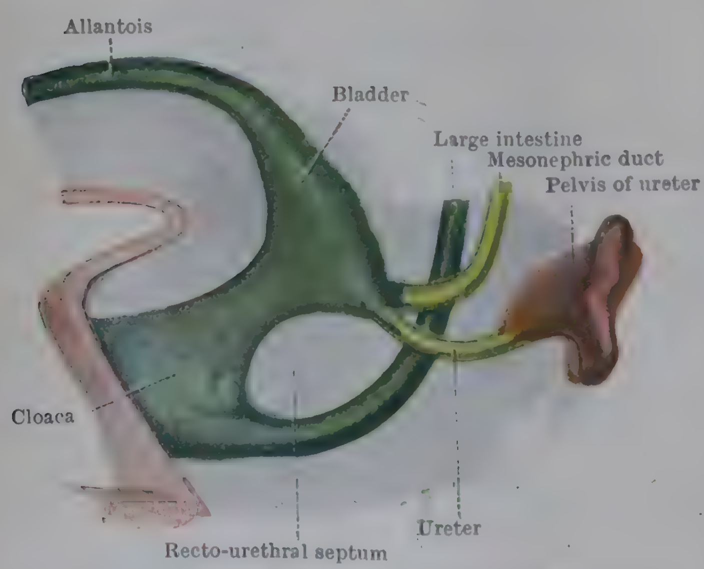

FIG. 671.—TAIL-END OF 11·5 MM. HUMAN EMBRYO.
The cloaca is becoming separated into rectal and urogenital portions by the formation of the recto-urethral septum. The ureter has acquired a separate opening into the ventral division of the cloaca. (Keibel, 1896.)

The cavity of the urachus is sometimes not lost so early, and in rare cases it persists in the child or adult as a pervious channel that extends from the apex of the bladder to the umbilicus. Here it may open on the surface of the body.

Malformations.—Simple malformations of the bladder are uncommon. The gross malfor-

mation called *ectopia vesicæ* or *extroversion of the bladder* is probably due to rupture of the cloacal membrane (p. 57) at a very early stage of development. The lower part of the anterior abdominal wall is deficient (in complete extroversion the pubic symphysis is absent) and the bladder is represented by an exposed, irregular area of mucous membrane—which corresponds roughly to the trigone—continuous with the surrounding skin. The ureters open on the exposed surface, and, in the male, the malformation is commonly associated with epispadias (see below).

Male Urethra

The first part of the male urethra has an origin similar to that of the basal part of the bladder, and is derived from the ends of the mesonephric ducts. The remaining portion—beyond the openings of the ejaculatory ducts of the adult—is derived from the urogenital canal or caudal division of the ventral part of the cloaca. The urogenital canal is early divided into a

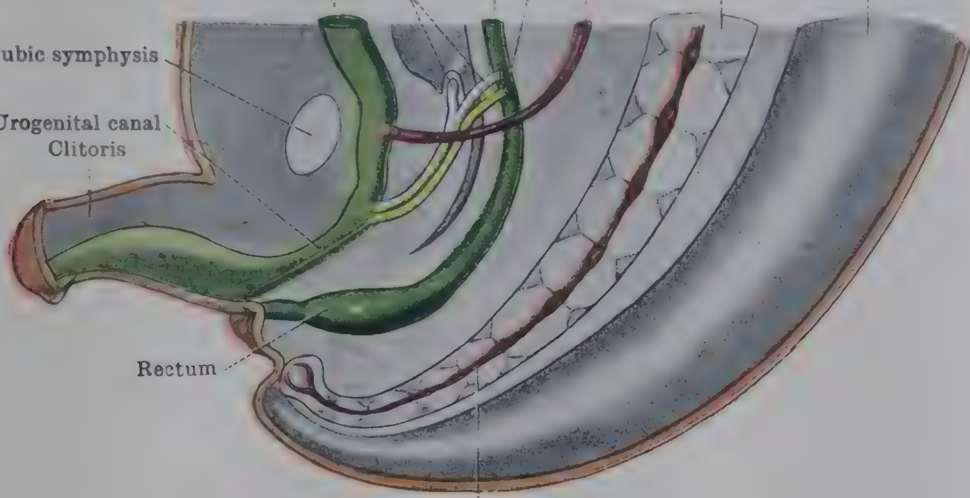

Fig. 672.—Tail-End of 25 mm. Female Human Embryo.

The rectum has acquired an external opening and the entoderm of the urogenital canal is continued into the genital eminence (clitoris). (Keibel, 1896.)

pelvic part which lies in the future true pelvis and a penile part which occupies the region where the corpus spongiosum is developed. The latter part of the urogenital canal becomes filled with closely and irregularly packed cells which later, breaking down, re-establish the canal and give origin to a slit-like opening in the region in front of the anus. The canal for some time opens at a rhomboidal fossa situated in the groove at the base of the glans penis. In the glans a septum composed of densely packed cells is formed, and these cells, at a later stage, break down and form a groove the lips of which unite and enclose the terminal portion of the urethra. It is doubtful if any portion of the male urethra owes its origin to the ectoderm, but there is some evidence that the septum of the glans is ectodermal, in which case the part of the canal which traverses the glans must have a like origin (Fig. 676 C).

Malformations.—Malformations of the male urethra are not uncommon. They are due mainly to failure of closure of the urethra at the two critical points—the junction of the membranous and spongy parts, and at the base of the glans penis. Such abnormal openings of the urethra on the under surface of the penis constitute the malformation known as *hypospadias*, which varies in degree; abnormal formation of the terminal part of the urethra in the glans with persisting opening at the base is the simplest and commonest variety. Complete hypospadias, associated with cryptorchism and failure of formation of the scrotum, gives rise to pseudo-hermaphroditism in the male. (See also the Development of the External Genital Organs, p. 794 and Fig. 676.)

The cause of simple *epispadias*, in which the urethra opens on the dorsal surface of the penis in front of the symphysis, is obscure; but it is often associated with extroversion of the bladder.

Female Urethra

In the female the part of the urethra near the internal urethral orifice is developed from the caudal ends of the mesonephric ducts and has an origin similar to that of the basal portion of the bladder. The lower part of the passage is derived from the urogenital canal. When the urogenital canal opens on the surface it is continued forwards as a sulcus on the genital eminence, as in the male sex. The margins of the slit-like opening do not unite, but form the labia minora of the adult, and the sulcus which appears on the glans clitoridis is closed without forming a canal. At first the fused caudal ends of the para-mesonephric ducts open into

the urogenital canal, but, later, a shortening and spreading out of the lower portion of the urogenital canal, to form a part of the pudendal cleft of the adult, is responsible for bringing the opening of the fused para-mesonephric ducts (the vaginal orifice) to the surface. The female urethra corresponds to the part of the male passage which lies above the opening of the prostatic utricle.

Genital Glands

In the development of the genital glands, male and female, a differentiated thickened portion of the peritoneal epithelium is first recognized. This specialized epithelium, known as the **germinal epithelium**, is situated to the medial side of the mesonephros and of the mesonephric and para-mesonephric ducts. It covers a longitudinally disposed elevation called the **genital ridge**. The germinal epithelium is not strictly limited to the ridge, but extends a little beyond its limits. The genital ridge is soon found to have numerous epithelial cells embedded in its stroma of fibrous tissue, and some of them appear to originate, in both sexes, by a proliferation from the deep surface of the germinal epithelium that covers the ridge. In both sexes, however, the earliest-formed epithelial cells appear to arise in the genital ridge independently and at first are not connected with the cells that cover the genital gland. From these epithelial cells the male seminiferous tubules and female vesicular follicles with their contained ova are developed. The tissue which gives rise to the genital ridge occurs in all the body-segments from the sixth thoracic to the second sacral, but the cephalic end of the ridge atrophies before the germinal epithelium can be recognized in the more caudal segments, and only about one-fourth of the ridge gives origin to the permanent genital gland.

Fig. 673.—Urogenital Passages at the Indifferent Stage of Development.

Ureter : solid green. Mesonephric duct : dotted green ; the origin of the seminal vesicle is indicated. Para-mesonephric ducts : orange. Rectum, bladder, and urogenital canal : red.

In the male, as early as the thirty-third day, the epithelial cells embedded in the stroma of the developing testis have become arranged into a network of cords within which certain larger cells are irregularly scattered. The larger cells are relatively few in number and are known as **primordial sperm-cells**. They undergo frequent division, and in the later stages they are not to be distinguished from the other cells of the cords. The cellular cords undergo direct transformation into the **convoluted tubules**, the **straight tubules**, and the **rete testis**. At a very early stage the superficial part of the stroma of the developing testis becomes denser, and gives origin to the **tunica albuginea**. The tissue surrounding the cellular cords becomes converted into the septa of the testis and the mediastinum. A lumen can first be recognized in the seminiferous tubules in the seventh month. The rete testis becomes connected secondarily with the efferent ductules of the testis, which are derived from tubules of the mesonephros, and thus the mesonephric duct becomes the passage for the secretion of the testis.

Fig. 674.—Male Urogenital Passages.

Ureter and vas deferens : solid green. Prostatic utricle : orange. Bladder, pelvic part of urethra and rectum : red. Penile part of urethra : black.

In the female, large epithelial cells are found in the stroma of the developing ovary beneath the germinal epithelium as early as the thirty-third day. These **primordial ova** are much more numerous than the primordial sperm-cells of the male, and they form a very characteristic feature of the developing ovary. At first they are isolated, but later—about the fifth week—they become surrounded by smaller cells which arise from the germinal epithelium. Each primordial ovum, surrounded by its cells, becomes a **primordial follicle**, the further development of which has already been described (pp. 21 and 772). During the later stages the epithelium has the appearance of growing down into the stroma in the form of long, branching, cellular processes which break up into little nests of cells to form the future follicles. The proliferation of cells from the surface epithelium goes on until birth, but the source of the ova themselves and whether any new ova are produced after birth are still unsettled questions (p. 24).

Descent of Testis and Ovary.—The descent of the testis into the scrotum and of the ovary into the pelvis have been considered in the main text (pp. 761 and 771).

Genital Ducts

As has been stated already, the male ducts arise from the mesonephric ducts and the female from the para-mesonephric ducts. The embryos of both sexes at first have well-developed mesonephric and para-mesonephric ducts, which are arranged in a very definite manner. The mesonephric ducts, communicating directly with the tubules of the mesonephros, lie at first parallel to each other, and at a considerable distance apart. As they pass towards the caudal end of the embryo they approach each other, and each becomes enclosed in a fold of peritoneum called the **plica urogenitalis.** More caudally the ducts become closely approximated to each other, and are embedded in a cord-like mass of fibro-areolar tissue to which the term **genital cord** is applied. They finally open into the ventral division of the cloaca.

The para-mesonephric ducts open freely into the body-cavity at their cephalic ends, and lie to the lateral side of the mesonephric ducts. As they are traced tailwards they cross ventral to the mesonephric ducts and enter the genital cord; in this cord they unite and form a median canal which opens into the ventral division of the cloaca between the mesonephric ducts (Fig. 673). The manner in which the ureters become separated from the mesonephric ducts has been described already.

Ducts in the Male.—The seminiferous tubules of the testis become connected with the mesonephric duct through a fusion of certain tubules of the mesonephros with the **rete testis.** The connexion is definitely established in the third month. The number of tubules that take part varies considerably, but corresponds to the number of **efferent ductules** found in the adult. The connecting tubules, becoming more convoluted where they join the mesonephric duct, form the **lobules of the epididymis.** The **canal of the epididymis** is directly formed from the cephalic part of the mesonephric duct, and the **vas deferens** from the more caudal portion. The **ducturi aberrantes** and the **paradidymis** are to be looked upon as persistent tubules of a more caudal portion of the mesonephros which have failed to become connected with the tubules of the testis.

The **seminal vesicles** are developed in the third month as evaginations from the mesonephric ducts near their caudal ends. Each at first is a longitudinal groove in the wall of the vas deferens, and then closes over and becomes cut off from the main tube except at the point where, later, the duct of the seminal vesicle joins the vas to form the **ejaculatory duct.**

The para-mesonephric ducts atrophy in the male embryo, but the appendices of the testis are vestigial remains of their cephalic portions, and the **prostatic utricle** represents the caudal fused portions which, in the embryo, occupy the genital cord (Fig. 674).

Ducts in the Female.—The para-mesonephric ducts in the female retain their openings into the body-cavity, and their cephalic portions become the uterine tubes. Their fused caudal parts, which at first join the urogenital canal, give rise to the **uterus** and **vagina.** The persisting portion of the septum which separates the extreme caudal ends of the ducts forms a plug that develops into the **hymen of the vagina.** The manner in which the original position of the opening of the para-mesonephric ducts becomes shifted, by the formation of a new passage or by the shortening of the urogenital canal, has been mentioned already (p. 792). The final position of the opening is in the pudendal cleft (Koff, 1933).

The mesonephric ducts and the mesonephros atrophy in the female, but traces of them are found in the ep-oöphoron and par-oöphoron (Fig. 675). In the fœtus the mesonephric duct can be traced along the side of the uterus as far as the upper end of the vagina.

Fig. 675.—Female Urogenital Passages.

Derivatives of para-mesonephric duct: orange. Ureter: solid and dotted green. The ep-oophoron is indicated in green between the uterine tube and the ovary. Bladder, urethra, and rectum: red.

Malformations.—Variations of the uterus have been mentioned on p. 780 as due to the arrest of the fusion of the para-mesonephric ducts. Such failure of union may be so complete that the uterus and vagina appear to be double, or a dividing septum may persist in one or other of these organs or in both. The vagina may fail to reach the surface, or the simple malformation of "imperforate hymen" may result from failure of the terminal plug to break down.

Accessory Glands

The glandular portion of the **prostate** arises as a series of solid outgrowths from the epithelium of the urogenital canal during the third month. The outgrowths are simple at first, but become branched and finally acquire a lumen. They are arranged in three groups—an upper and a lower dorsal, and a ventral group. The glands of the ventral group soon become reduced in number and often completely disappear; those of the upper dorsal group form the chief part of the prostate. The prostatic glands arise in both sexes; but in the female, where they are known as *para-urethral glands*, they are few in number and not densely packed as in the male. The muscular tissue of the prostate is derived from the muscular wall of the urethra.

The **bulbo-urethral glands** arise in the third month as outgrowths from the epithelium of the urogenital canal. The **greater vestibular glands** arise in the same manner.

External Genital Organs

The external genital organs are developed in the region of the ectodermal cloacal fossa, and the male and female are alike in the earlier stages (Spaulding, 1921). The fossa at first extends

Fig. 676.—External Genital Organs of Human Embryos.

A. Embryo of 20 mm.
B. Slightly larger.

Indifferent stage: the genital eminence and the labio-scrotal folds are evident.

Formation of scrotum. The labio-scrotal folds, formerly best marked at the sides of the genital eminence, have grown backwards and united behind the primitive urogenital opening to form the scrotal raphe. The genital folds embrace the base of the genital eminence or penis. The glans is very prominent.

Behind the glans penis the urethra opens in a diamond-shaped fossa at the proximal end of which the median raphe ends. The prepuce is formed behind the constriction which marks off the glans, and grows forwards to cover it.

A little horn-like process of epithelium is present on the summit of the genital eminence.

on the ventral aspect of the body almost from the tail to the umbilical cord. At its cephalic end there is a tubercle known as the **cloacal tubercle**, and at its caudal end there is a **coccygeal tubercle.** Immediately in front of the coccygeal tubercle the anus is formed, and between the anus and the cloacal tubercle the urogenital canal opens on the surface by a median slit-like aperture—the **primitive urogenital opening**—the margins of which are raised up to form the **genital folds.**

The cloacal tubercle early becomes divided into: (1) an apical **genital eminence**, which occupies the median line and lies at the cephalic end of the primitive urogenital opening; and (2) a **basal portion**, which lies nearer the umbilicus and also curves round the sides of the genital eminence. At a later time the basal part is continued to form a pair of prominent folds at the sides of the cloacal fossa. These folds are called the **labio-scrotal folds** and, *in the female*, give rise to the labia majora. The genital folds give origin to the labia minora, and the genital eminence becomes the clitoris. On the clitoris at a very early date a relatively large glans is marked off by a surrounding sulcus. *In the male* the labio-scrotal folds grow backwards, and, meeting behind the primitive urogenital opening, fuse together. In that way the opening is pushed forwards. The genital eminence elongates rapidly owing to a growth at its basal part, and a sulcus which is formed on its cloacal aspect gradually becomes converted into a canal by the progressive union of the genital folds. Soon the urogenital opening is found to lie nearer the apex than the base of the eminence, which has now given rise to the penis. For some time the opening in the male lies at the base of the glans penis and is rhomboidal in outline. At a later time, owing to the breaking down of a dense septum of epithelial cells which appears within the glans, a sulcus, and finally a canal, arises within that part of the penis; thus, the terminal part of the urethra is formed. When the opening at the base of the glans is closed the continuous urethral passage is established. The main portion of the urethra is entodermal

in origin, but there is some evidence that the part in the glans has its origin from the ectoderm (Fig. 676).

Hermaphroditism.—*True hermaphroditism*—the presence of both testis and ovary—is exceedingly rare in the human subject; in any case, the two glands, or the two constituents of a mixed ovo-testis, are never both functional.

Pseudo-hermaphroditism is defined as the association of the genital glands of one sex with external genital organs that resemble those of the other sex. Complete hypospadias in the male, as noted on p. 791, gives rise to the commonest variety; the external genital organs, through failure of the testes to descend and of the labio-scrotal folds to unite, may closely resemble those of the female. The opposite condition, with enlargement of the clitoris to simulate a penis and possible descent of the ovaries, is much less common. It is probable that these conditions, in which secondary sex-characters also are affected, are due to disturbance of the normal regulation of development by internal secretions.

MAMMARY GLANDS

The mammary glands are accessory organs connected with the female reproductive system. Each gland is situated on the front of the thorax in the superficial fascia of the hemispherical elevation known as the mamma or **breast**. It usually extends from the level of the second rib to that of the sixth rib, and it lies on the pectoralis major and, to a less extent, on the obliquus externus abdominis and the serratus anterior. The **nipple** is situated near the summit of the breast, usually at the level of the fourth intercostal space; the lactiferous ducts open on it by minute apertures, and it is surrounded by a coloured, circular area of skin called the **areola**. The skin of the nipple is thrown into numerous wrinkles, and on the areola it exhibits many minute, rounded projections due to the presence of underlying cutaneous glands. These **areolar glands** are considered to represent rudimentary portions of the mamma. The colour of the nipple and areola varies with the complexion, but in young subjects it is usually a rosy-pink, and it changes to a deep brown during the second and third months of the first pregnancy. Also, during pregnancy, the areola increases in size and its glands become more marked. The nipple contains a considerable number of plain muscle-fibres, and it becomes firmer and more prominent as a result of mechanical stimulation.

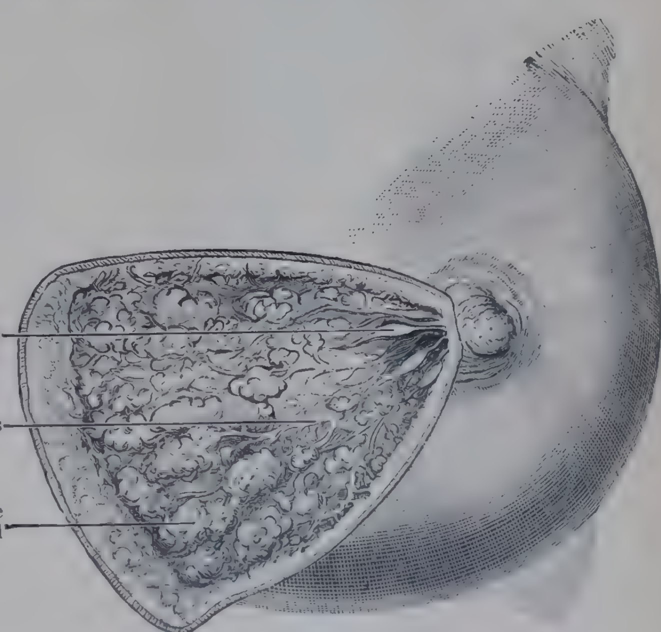

FIG. 677.—DISSECTION OF THE BREAST.

The size and appearance of the breasts vary much, not only in the different races of mankind but also in the same person under different conditions. In the young child they are small, and there is little difference between those of the male and female. Their growth is slow until the approach of puberty, and then the female mammary glands increase rapidly in size. At each pregnancy the breasts become large, and they attain their greatest development during lactation. The size of the breast depends partly on the amount of superficial fat and partly on the amount of glandular tissue present.

Structure of Breast.—The mamma is composed of a mass of glandular tissue traversed and supported by strands of fibrous tissue, and covered with skin and a thick layer of fat. The glandular tissue forms a flattened conical mass, the apex of which corresponds to the position of the nipple, while its base is loosely connected to the deep fascia of the muscles on which the gland lies. In section it is readily distinguished from the surrounding fat by its firmer consistence and by its pinkish-white colour. It is composed of fifteen to twenty lobes divided into

lobules, which make its superficial surface and edges very uneven—the inequalities of its surface being filled up by processes of the fatty tissue which covers the gland. The fatty covering is incomplete in the region of the areola, and here the lactiferous ducts pass into the nipple. The **lobes** radiate from the nipple, each lobe being quite distinct from the others and possessing its own duct; the **lobules** are bound together and supported by a considerable amount of fibro-areolar tissue, which forms the **stroma** of the gland (Figs. 677, 678).

The alveoli of the gland and the secretory epithelium which lines them vary much under different conditions. At puberty the mammary gland is composed chiefly of the ducts and the stroma of fibro-areolar tissue; at that time the alveoli are small and few in number. During lactation, when the gland is fully functional, the alveoli are enlarged, distended with fluid, and much more numerous. The epithelial cells are cubical and filled with fat-globules. When the gland is not secreting, the alveoli become small and reduced in number, and the cells of the lining epithelium, which are then small and glandular, do not contain fat-globules.

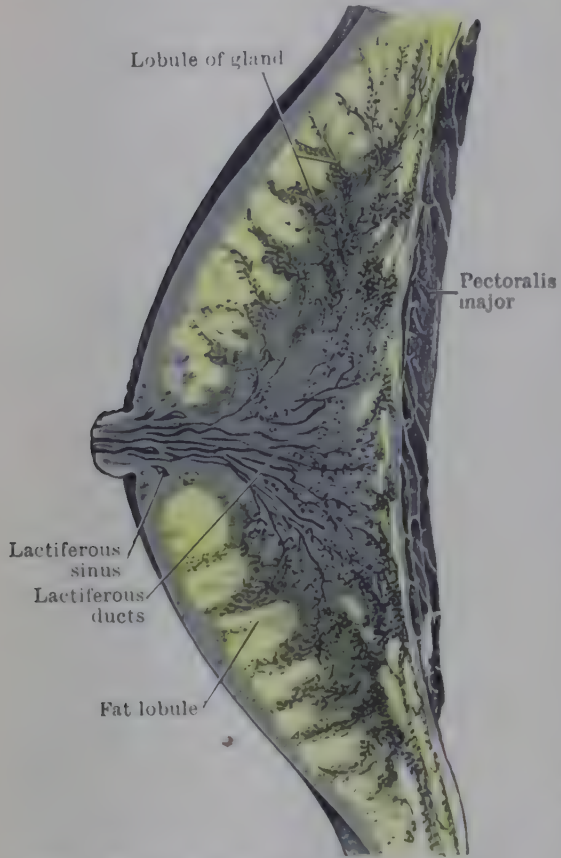

FIG. 678.—SECTION THROUGH A BREAST. Prepared after immersion in nitric acid as recommended by the late Sir Harold Stiles.

The **lactiferous ducts**, passing towards the nipple, become enlarged to form small, spindle-shaped dilatations called **lactiferous sinuses**; then, becoming once more constricted, each duct passes, without communicating with its neighbours, to the summit of the nipple, where it opens on the surface.

In the male the various parts of the breast are represented in a rudimentary condition.

The presence of milk-glands is characteristic of the class Mammalia; and the number of pairs of glands in each group of animals bears some relation to the number of young usually produced at each birth.

Variations.—Asymmetry in the development of the breasts is very common—the left mamma being very often larger than the right. Absence of one or both mammæ is a very rare abnormality which may or may not be associated with absence of the nipples. When one nipple only is present it is usually the left. The presence of supernumerary glands or nipples is not very uncommon. The term **polymasty** has been applied to cases in which more than the normal number of mammæ are present, and **polythely** to those in which additional glands, in a rudimentary condition, are represented by accessory nipples. Usually the accessory glands, or nipples, are present on the front of the thorax, and in most instances they occur below and a little to the medial side of the normal site. When the abnormal glands are found above the normal site they generally lie farther from the median plane. Much more rarely, accessory glands have been found on the abdomen, in the axilla, or in some other situation, including even the back of the trunk. As many as three extra pairs of mammæ have been found in the same person, and cases in which the probable representatives of mammary glands were even more numerous have been recorded. Asymmetry is very common in those abnormal structures. Examples of polymasty and polythely occur in the male as well as in the female. In some women the accessory breasts have yielded milk during lactation; in most cases the abnormal organs are very rudimentary—being represented only by a minute nipple or a pigmented areola. Polymasty and polythely are supposed to represent a reversion to an ancestral condition in which more than two mammary glands were normally present, and in which probably many young were produced at each birth. In this connection it is interesting to observe that usually the accessory glands occur in positions normally occupied by mammary glands in lower animals. In the course of the development of the breasts in man, specialized areas of the epidermis, similar to those which give origin to the mammæ, have been observed both above and below the region in which the adult mammæ are developed. These areas appear to be present normally, but usually they disappear at an early stage in the history of the embryo. In some other mammals rudimentary mammary glands may occur, as, for instance, in lemurs and in cows.

A slight functional activity of the mammary glands of the male about the time of puberty is stated to be a not very uncommon occurrence.

Vessels and Nerves of Breast.—The mamma receives its **arterial** supply from the perforating branches of the *internal mammary artery* and from the external mammary branches of the *lateral thoracic*. Additional supply is derived from some of the intercostal vessels. The **veins** from the gland pour their blood into the *axillary* and *internal mammary veins*. Some small superficial veins from the breast join tributaries of the external jugular.

The **lymph-vessels** of the breast are very numerous, and for the most part join the lymph-glands of the axilla. They take origin from an extensive *perilobular plexus*. The majority follow the lactiferous ducts and thus converge towards the nipple, and they join a plexus situated beneath the areola (*subareolar plexus*). From this plexus the main efferent vessels pass to the *anterior* (*pectoral*) *axillary glands*, but it is important to remember that free communication exists between all the subgroups of axillary glands. In addition, vessels pass from the deep surface of the lateral part of the breast directly to the lower axillary glands, and a few run either through or behind the pectoral muscles to the *apical axillary glands*. A few vessels from the medial part of the breast, following the course pursued by the perforating arteries, may join the lymph-glands situated along the course of the internal mammary artery. It is also to be remembered that a few, probably irregular, communications exist across the median plane with the lymph-vessels of the opposite breast; and, further, that under diseased conditions communications may exist with lymph-vessels in the upper part of the sheath of the rectus abdominis, and so with the *retrosternal* and *internal mammary* glands. The surgical importance of the facts regarding the lymphatic drainage of the breast cannot be exaggerated (see also p. 1430 and Fig. 1171).

The **nerve-supply** of the gland is derived from the **intercostal nerves** of the fourth, fifth, and sixth intercostal spaces. Along the course of these nerves sympathetic filaments reach the breast from the thoracic part of the sympathetic trunk. The nipple has a particularly rich nerve-supply (Cathcart *et al.*, 1948).

Development of Mammary Glands

The mammary glands are developed as ingrowths of the ectoderm into the underlying mesodermal tissue. In the human embryo a thickened raised area of the ectoderm can be recognized in the region of the future gland at the end of the fourth week. The thickened ectoderm becomes depressed in the underlying mesoderm, and thus the mammary area soon becomes flat, and finally sunk below the level of the surrounding epidermis. The mesoderm, where it is in contact with the ingrowth of the ectoderm, is compressed, and its elements become arranged in concentric layers which, at a later stage, give rise to the stroma of the gland. The ingrowing mass of ectoderm cells soon becomes flask-shaped and then grows out into the surrounding mesoderm as a number of solid processes which represent the future ducts of the gland. These processes, by dividing and branching, give rise to the future lobes and lobules, and, much later, to the alveoli. The mammary area becomes gradually raised again in its central part to form the nipple. A lumen is formed in each part of the branching system of cellular processes only at birth; and with its establishment is associated the secretion of a fluid resembling milk which often takes place at that time. The lactiferous sinuses appear as thickenings on the developing ducts before birth.

In those animals which possess a number of mammary glands—such as the cat and pig—the thickening of the ectoderm, which is the first indication of the development of those glands, takes the form of a pair of ridges that extend from the level of the forelimb towards the inguinal region. The ridges converge caudally, and at their terminations lie not far from the median line. By the absorption of the intervening portions the ridges become divided up into a number of isolated areas in connexion with which the future glands arise. Similar linear thickenings of the ectoderm have been recognized in the human embryo also, and the usual positions assumed by the accessory glands when present lead us to suspect that in all probability the ancestors of man possessed numerous mammary glands arranged, as in lower animals, in two lines that converge as they approach the inguinal region.

For a detailed study of the development of the mamary glands in the monkey, with full bibliography, see Speert (1948).

DUCTLESS GLANDS

by the late A. B. Appleton, M.A., M.D.
Emeritus Professor of Anatomy, University of London

The term "ductless" is applied to certain glands whose products reach the circulation without passing through any special channels or ducts. They differ widely in structure, function, and development, exhibiting a diversity similar to that of glands in general.

Glands.—From the functional point of view a gland may belong to one (or more than one) of the following categories:

(1) **excretory** (*e.g.*, kidney);
(2) **secretory**: A. *exocrine* (*e.g.*, salivary and intestinal glands);
B. *endocrine* (*e.g.*, thyroid, testis, hypophysis cerebri);
(3) **reproductive** (testis and ovary);
(4) **vascular** (*e.g.*, spleen, lymph-glands, thymus, tonsil).

Glands may be classified also with reference to their developmental history. Thus, they are referable to one or other of the primary germ-layers of the embryo—ectoderm, mesoderm, or entoderm. Later stages in development also provide a basis for classification. For instance, certain glands are described as "**pharyngeal derivatives**", with reference to their mode of development, namely, thyroid, parathyroids, thymus, and tonsils. In a similar manner the hypophysis cerebri and the pineal body have been associated in a "cerebro-glandular" group.

The reproductive and vascular glands are sometimes grouped together as "**cytogenic**", with reference to their cell-producing functions.

The same gland may belong to more than one category. The pancreas, for example, has both exocrine and endocrine functions; and the testis and ovary belong to both reproductive and endocrine categories. There is reason to believe that the thymus, which belongs to the vascular group, serves also as an endocrine organ.

Of the *ductless glands*, some have endocrine functions and others belong to the vascular group. But in different ways both of these varieties of ductless glands are intimately related to the vascular system.

Endocrine Glands.—These organs produce chemical substances, commonly known as hormones [ὁρμᾶν (horman) = to excite], which control and modify the functional activity of the cells of other tissues in specific ways. They are the basis of a great chemical system which co-ordinates the activities of the various tissues; and their physiological and clinical importance is such that special text-books are devoted to them (Sharpey-Schafer, 1924-1926; Goldzieher, 1939; Selye, 1947). The study of the various aspects of these organs is now generally known as *endocrinology*.

The effects produced by hormones may be either excitatory or inhibitory, and the general term "autacoid" [αὐτός (autos) = self; ἀκέομαι (akeomai) = repair or make good] is thus sometimes employed to describe the products of endocrine glands.

Histologically the endocrine glands exhibit various grades of specialization (Cowdry, 1932, 1944). These grades probably illustrate the steps by which the structural and functional differentiation of endocrine organs took place in the course of evolution. The production of a hormone has, indeed, fundamental resemblance

to an activity displayed by all living cells, for these all give off substances into the circulation which affect the activities of other cells. Hormones are distinguished by the specific nature of the effects they produce; in some instances they are recognized only by these effects.

The first stage in the differentiation of a tissue as an endocrine organ is illustrated by certain tissues (*e.g.*, gastric and duodenal mucosa) which, though primarily adapted by their structure to some other function, also produce a hormone as a secondary function without any evident cytological differentiation of the cells concerned. The placenta and plain muscle-tissue may be mentioned as other examples of this stage.

A second stage in differentiation is illustrated in organs such as the pancreas, in which there is a recognizable specialization of structure as well as of function. In this organ some of the cells remain epithelial in structure and act as an exocrine secretory organ, whilst other cells are budded off from the epithelium in the course of development to form the "islets of Langerhans", which act as a purely endocrine organ. The testis and the ovary (ovarian follicles and corpus luteum) also are examples.

It is not yet settled whether the specific hormone of the testis is produced by the interstitial cells or by the tubular genital epithelium. If the latter view proves to be correct, the testis as an endocrine gland would fall to be graded in the first stage.

A further stage of differentiation is seen in the thyroid and parathyroid glands; for in the development of these glands there comes about a complete separation from the pharyngeal epithelium of masses of cells destined for specialization with an endocrine function. Chromaffin tissue and the thymus may perhaps be included here.

Lastly, two masses of cells, each of specialized structure and function, may come into such intimate relation in the course of development as to constitute a single organ from the topographical point of view. Examples are furnished by the buccal and neural parts of the hypophysis cerebri, and by the cortex and medulla of the suprarenal gland. It has been suggested that such close approximation may perhaps allow important interactions which influence the respective functions.

In this chapter the more specialized endocrine glands alone are described, namely, those which belong to the third and fourth grades. Certain other organs of doubtful hormone-producing function are included, namely, the carotid body, the glomus coccygeum, the pineal body, and the thymus.

Vascular Glands.—These are organs which develop in intimate relation to the vascular and reticulo-endothelial systems (p. 831). They serve as reservoirs and germinating centres for the cellular constituents of these systems. Certain of these glands exhibit a special structure which fits them to act also as filtering organs—the lymph-glands for lymph, the hæmolymph-glands and spleen for blood; but in certain others, such as the lymphatic nodules in the walls of the alimentary canal, there is no such provision.

The tonsil, lymph-glands, and lymphatic nodules are dealt with elsewhere in this text-book: the thymus and spleen are included in this Section.

The organs described in this Section are taken in the following order:—

(1) The *Suprarenal Glands*, which are compound organs including chromaffin and cortical tissue.

(2) The *Chromaffin System*, of ectodermal origin, including the medulla of the suprarenal gland and various "paraganglionic" masses of chromaffin tissue.

(3) The *Cortical System*, of mesodermal origin, represented by the cortex of the suprarenal gland and by the occasional "accessory cortical bodies".

(4) The *Organs of the Pharyngeal Pouches*, of entodermal origin and developed from the walls of the pharynx, including the thyroid and parathyroid glands and the thymus.

(5) The *Cerebro-Glandular Organs*, of ectodermal origin, consisting of the hypophysis cerebri and the pineal body.

(6) The *Spleen*.

Form and Development of Glands.—In the living body, glands are soft, plastic structures, and the details of their form are continuously subject to modification by the pressure of adjacent structures. Many of them have a lobulated shape which arises from their mode of development, but in some instances this appearance is eventually obscured or disappears (cf. young and adult kidneys, Figs. 611 and 679).

The special secreting cells of an exocrine gland are developed from the walls of a tubular structure which may be of simple form (p. 579) or may exhibit an elaborate system of branches such as is seen in compound racemose glands. The tubular structure with its branches eventually forms the gland-duct and its tributaries. In some instances the tubular form is not seen while the secreting cells are developing, but instead elongated columns of cells are first formed which only later become canalized (*e.g.*, in the development of the liver, p. 681). The secreting cells of some of the endocrine and vascular glands likewise arise from the walls of tubular structures which later disappear—a mode of development that is the outcome of a progressive specialization of function (*e.g.*, the organs of the pharyngeal pouches).

As glands grow, the glandular tissue accommodates itself between adjacent structures, and, if deeply embedded in the body, the whole mass may become moulded to reflect their contours, *e.g.*, the thymus (Fig. 702). A gland thus frequently shows impressions made by adjacent blood-vessels or bones; or it may even surround structures, as in the case of the parotid salivary gland.

The majority of glands are extremely vascular, especially those of the endocrine and vascular categories. The glandular cells are thus brought into intimate physiological relationship with the whole of the blood of the body in a relatively short time.

The nerves which supply glands terminate in two ways. They may end in the walls of blood-vessels and influence the functions of the gland through their control over the blood-supply (*e.g.*, the thyroid and the suprarenal cortex); or they may end in direct relation with the actual secreting cells (*e.g.*, the suprarenal medulla).

SUPRARENAL GLANDS

The **suprarenal glands** (Figs. 679-686) are normally two in number, situated one on each side of the vertebral column in intimate relation with the supero-medial aspects of the kidneys.

Each gland consists of a relatively thick layer of cortex enclosing a medulla. It is extremely vascular: the amount of blood that passes through it, relative to its size, surpasses that in any other organ in the body, with the possible exception of the thyroid gland. Arterial blood enters the gland from a plexus on the surface of the cortex and passes through the cortical tissue to the medulla, whence it is drained by the venous system (Fig. 685).

The cortex and medulla are of different developmental origin; they are in effect two distinct endocrine organs—though it is possible that the function of the medulla is influenced by its intimate vascular relationship with the cortex. The *cortex* plays an indispensable rôle in the body. Interference with its function affects distribution of water in the body; the endothelium of capillaries becomes more permeable and tissue fluid increases. It secretes hormones (*cortins*) which are closely related to the sex-hormones and are included with them in the 'steroid' group. The cortex also stores vitamin C and lipoids. The *medulla* secretes a hormone (*adrenalin*) which reinforces the action of the sympathetic nervous system and facilitates carbohydrate metabolism. This is perhaps the only hormone which has so far been actually recognized in its cells of origin and whose discharge into the blood-stream can be followed microscopically (Fig. 684).

The cortex is essential to life; the medulla is not essential. Nor does the medulla display the functional changes of size which are seen in the cortex under various circumstances (*e.g.*, during menstruation, after extirpation of the contra-lateral gland, in certain disturbances of metabolism, and under the influence of one of the hormones of the hypophysis cerebri).

In colour the cortex is yellow, owing to the contained fatty substances. The medulla is seen in a section of the fresh healthy gland as a dark streak within the yellow cortex; it becomes brown on treatment with a dilute solution of chromic acid (chromaffin reaction).

The post-mortem size of the gland varies within wide limits, mainly on account of the great modifications produced by certain pathological conditions.

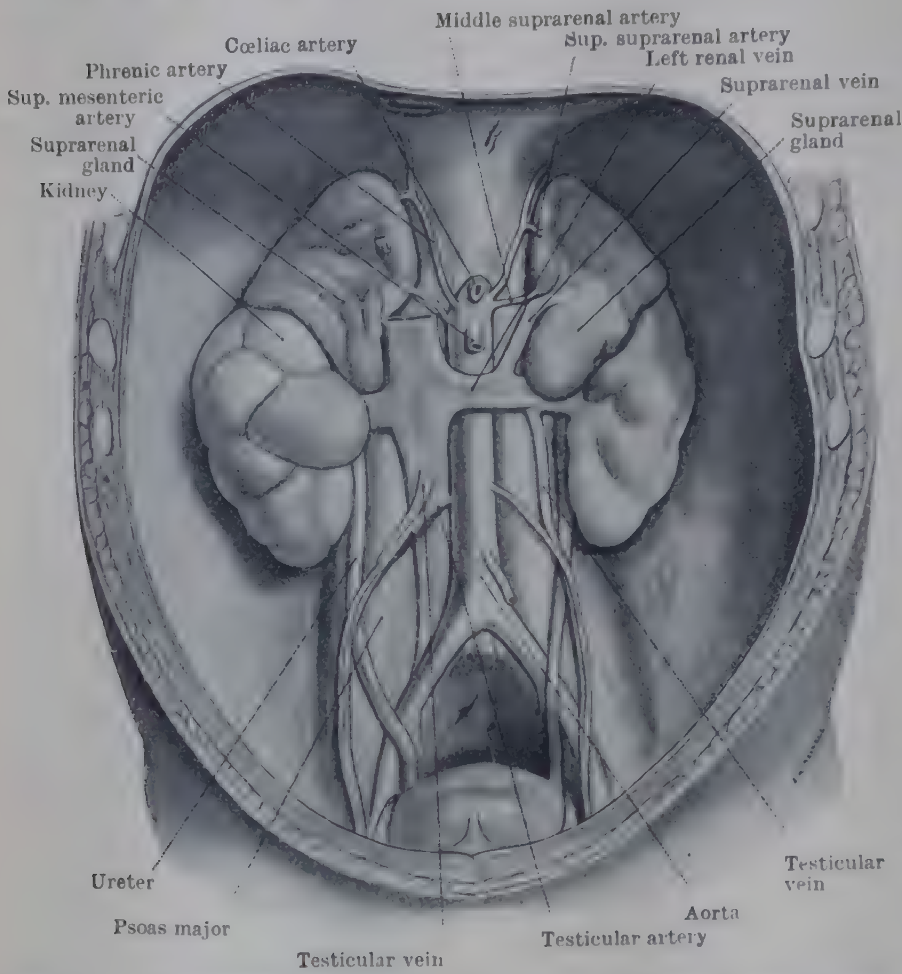

FIG. 679.—POSTERIOR ABDOMINAL WALL OF FULL-TERM FŒTUS, ILLUSTRATING THE RELATIVELY LARGE SIZE OF THE SUPRARENAL GLANDS AND THE LOBULATION OF THE KIDNEYS.

The average dimensions of the suprarenal glands are as follows: height, 3-5 cm.; breadth, 2·5-3 cm.; thickness, slightly under 1 cm.; and the weight is 7-12 gm. The medulla forms only about one-tenth part of the whole gland. The glands are relatively much larger in the fœtus than in the adult. Even at birth they are still relatively large (Fig. 679); they are indeed little smaller than in the adult.

Rarely only one gland is present; occasionally one is quite small, the other unusually large; as a rule they are unequal in size, the left being more frequently the larger. Sometimes the two glands are fused (cf. horseshoe-kidney).

Frequently there are accessory glands. These develop in the neighbourhood of the main gland and usually remain there, but may become attached early in embryonic life to originally adjacent organs which subsequently change their position. As a result, they may be found not only beside the main gland but also in the broad ligament of the uterus, on the spermatic cord, or even attached to the epididymis. Like the main glands, true accessory suprarenals are compounded of cortex and medulla, and require to be distinguished from the purely chromaffin bodies and accessory cortical bodies which may be found in any of the positions in which accessory suprarenal glands occur.

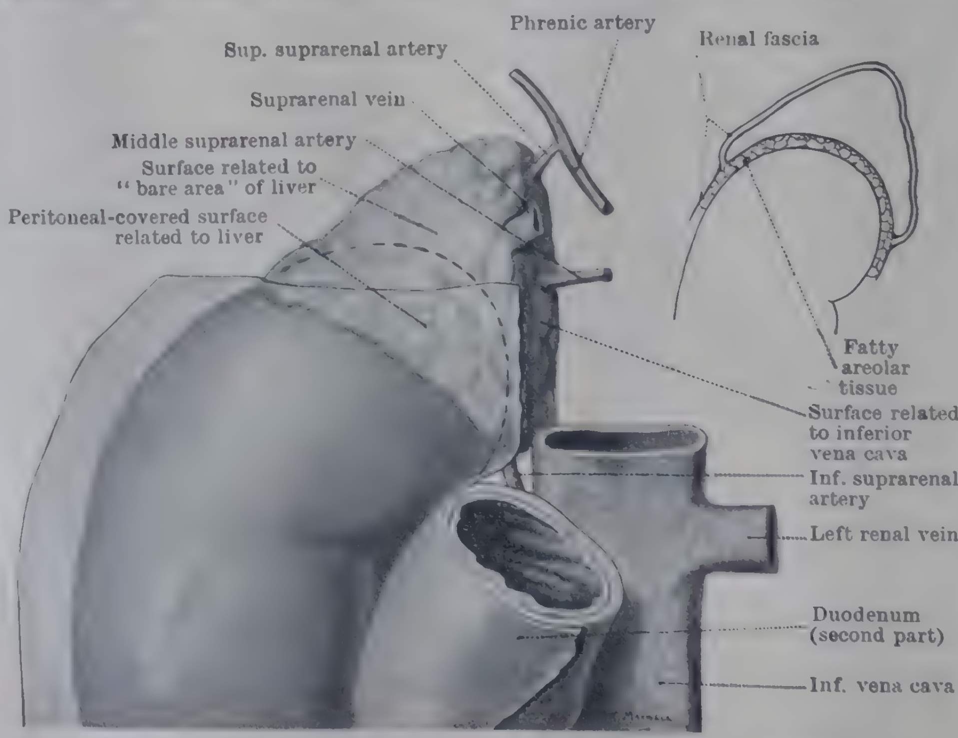

FIG. 680.—RIGHT SUPRARENAL GLAND WITH ITS RELATION TO PERITONEUM AND SOME ADJACENT STRUCTURES. The small diagram is a schematic vertical section illustrating the relation of the gland to the kidney and the renal fascia.

Form and Relations.—The suprarenal glands differ slightly in their form, which is moulded by adjacent structures. The right gland is more or less triangular, the left is semilunar and extends farther down the medial side of the kidney than the right one. Each presents a posterior and an anterior surface: the right one has also an antero-medial surface. The posterior surface comprises a lower portion, which is moulded on the medial part of the upper pole of the kidney, and an upper portion which lies against the diaphragm. The anterior relations differ on the two sides. The left gland (Fig. 681) is situated behind the lesser sac of peritoneum, which separates it from the stomach; the infero-medial extremity is, however, sometimes separated from the lesser sac by the splenic artery and the body of the pancreas. The right gland is related by its antero-medial surface to the inferior vena cava. Its anterior surface is related to the liver, being in immediate contact with it in its upper part but separated from it in its lower part by peritoneum. The cœliac plexus and ganglia are situated between the two glands.

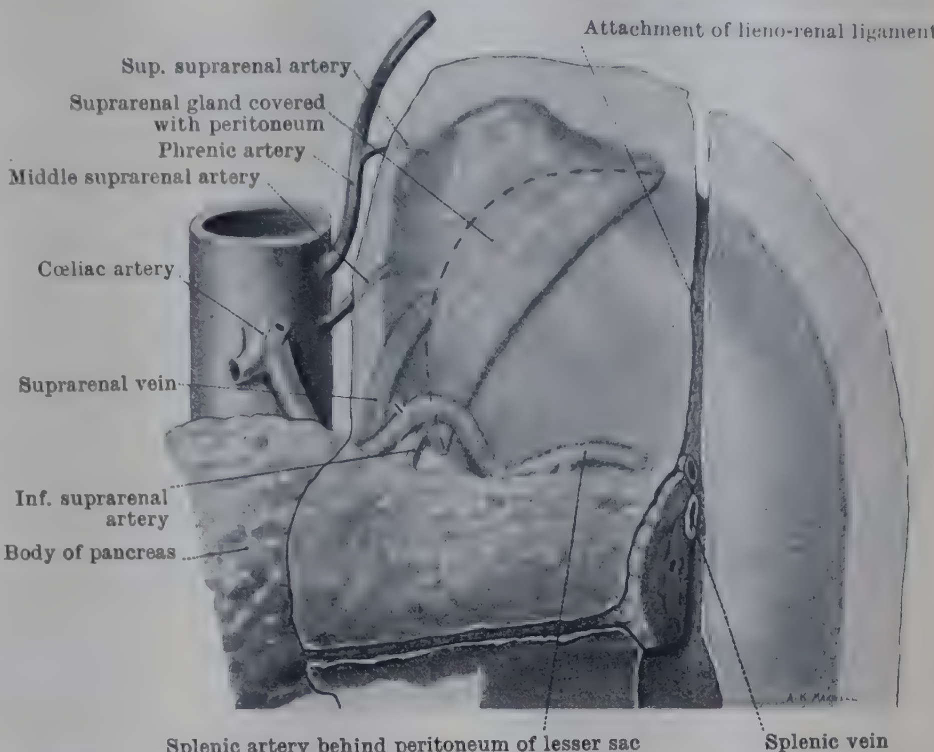

FIG. 681.—LEFT SUPRARENAL GLAND WITH ITS RELATION TO PERITONEUM AND SOME ADJACENT STRUCTURES. (See also Fig. 616, p. 732.)

The suprarenal gland is separated from the kidney by a small amount of fatty areolar tissue, and is enclosed along with the kidney by the renal fascia (Fig. 680).

A cleft is found in each gland where the suprarenal vein leaves it. The cleft or *hilum* is situated in the right gland on the antero-medial surface, in the left one near the lower end of the medial margin.

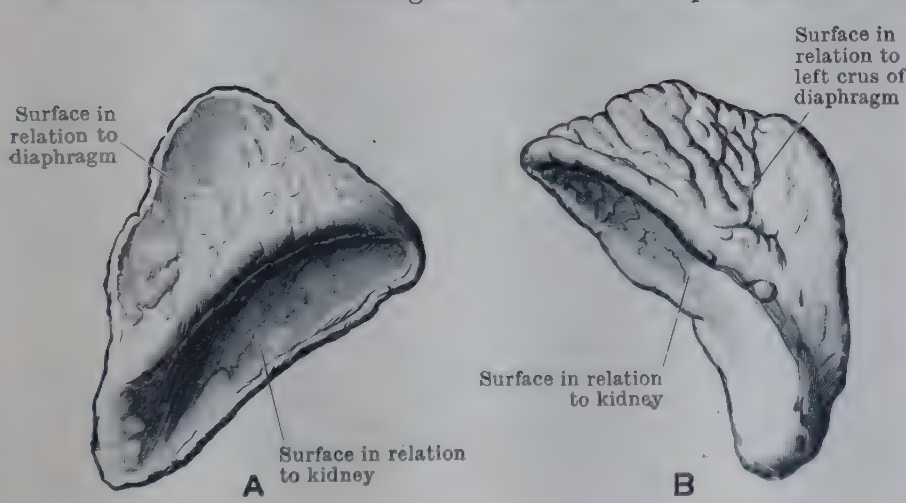

FIG. 682.—SUPRARENAL GLANDS ISOLATED AND VIEWED FROM BEHIND.
A. Right. B. Left.

The level of the gland varies in relation to the adjacent structures. Thus, the infero-medial part of the right gland is sometimes overlapped by the duodenum, and the area covered with peritoneum is correspondingly restricted. On the left side the pancreas and splenic artery sometimes lie at a lower level than the gland. In the infant the spleen makes contact with the upper part of the left suprarenal; sometimes it still does so in the adult. Respiratory movements bring about modifications in the relations, for the suprarenal is displaced along with the kidney by movements of the diaphragm.

Vessels and Nerves.—The abundance of the blood-supply of the suprarenal glands should be emphasized again. Each gland receives three **arteries**—one direct from the aorta, one above from the phrenic artery, and one below from the renal artery (Figs. 680, 681). Each gland is drained by a single large **vein** which emerges through the hilum, the right one to join the inferior

vena cava, the left to join the left renal vein behind the body of the pancreas. The arrangement of the blood-vessels within the gland is described with its structure. Numerous **lymph-vessels** pass from the suprarenal glands to the aortic lymph-glands.

The *medulla* of the gland is more richly supplied with nerves than any other organ; they come from the last few thoracic segments and reach the gland through the *splanchnic nerves* and the *cœliac plexus.* The nerve-filaments form a plexus of medullated and non-medullated nerve-fibres in the fibrous capsule before they pass into the gland. Some of the fibres are postganglionic fibres from nerve-cells scattered along the sympathetic nerves or in the gland itself (Swinyard, 1937); others are preganglionic fibres which end in synaptic relation with the secretory cells of the medulla (Hollinshead, 1936). It has been shown that stimulation of the nerve-filaments that enter the gland results in an increased outflow of adrenalin into the blood.

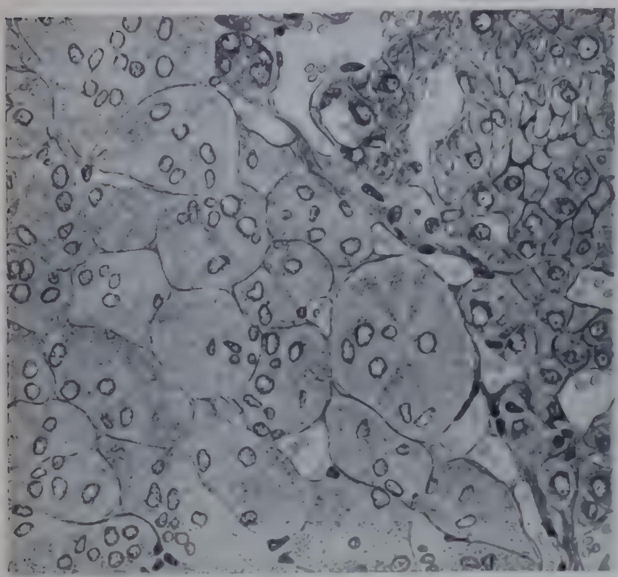

FIG. 683.—SECTION OF SUPRARENAL GLAND OF RABBIT, showing medulla and adjacent reticulate zone of cortex. (Cramer, 1919.)

There is no evidence that the *cortex* receives any nerve-supply. Fibres in the cortical zone in Bielschowsky preparations appear to be reticular and not nerve fibres (Swinyard, 1937).

Structure.—The suprarenal gland consists of a highly vascular central mass of chromaffin tissue—the *medulla*—enclosed within a thick parenchymatous layer of cortical substance—the *cortex*—which in turn is enveloped in a capsule of fibrous tissue.

The **cortex** of the human suprarenal is so folded or convoluted as to increase its surface of contact with the medulla. From the deep aspect of the capsule, trabeculæ of fibrous tissue pass inwards to support the glandular parenchyma. In the superficial part of the cortex the trabeculæ interlace freely so as to enclose a series of small rounded clusters of cortical cells, thus forming the *zona glomerulosa* (Fig. 685, 1); in the intermediate region of the cortex elongated cell-columns, usually formed of two or three rows of cortical cells, lie at right angles to the surface, forming a *zona fasciculata* (Fig. 685, 2); in the

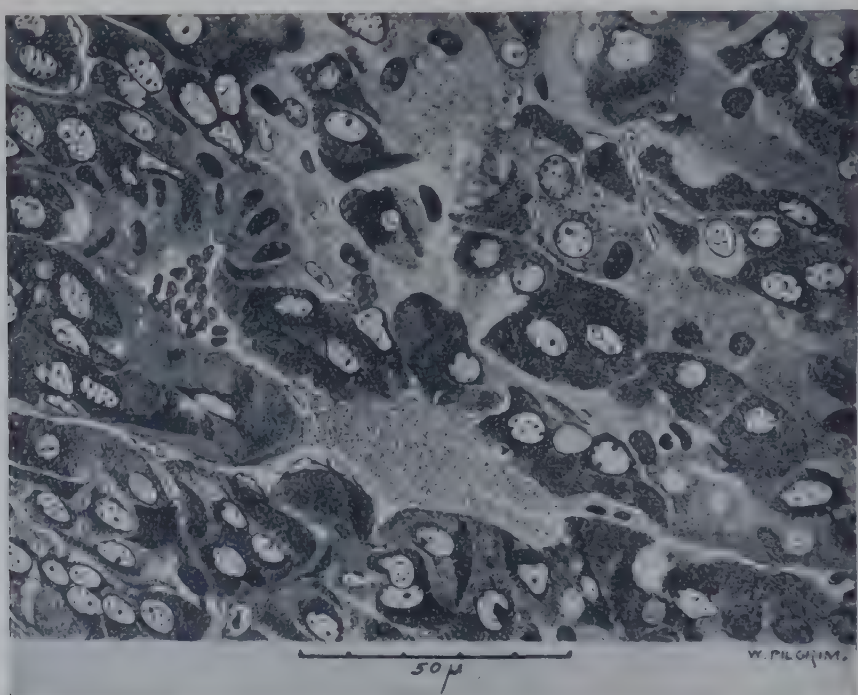

FIG. 684.—MEDULLA OF MOUSE'S SUPRARENAL GLAND, showing discharge of adrenalin in asphyxia. Granules of adrenalin blackened by osmic acid are seen in the medullary cells (in different phases of activity) and in the venous spaces. (Cramer, 1928.)

deepest part of the cortex the cell-columns are more irregularly arranged and form a reticulum—*zona reticulata* (Figs. 683, 685, 3). The zone of cortex adjacent to the medulla is intimately involved in the sex-hormone mechanisms in mice and has been termed the X zone or androgenic zone. Injection of certain gonadotropic hormones causes degeneration of this zone in young mice (McPhail & Read, 1942). Senile degeneration of cells occurs in the zona reticulata while new formation occurs at the junction of the glomerular and fasciculate zones (Hoerr, 1931).

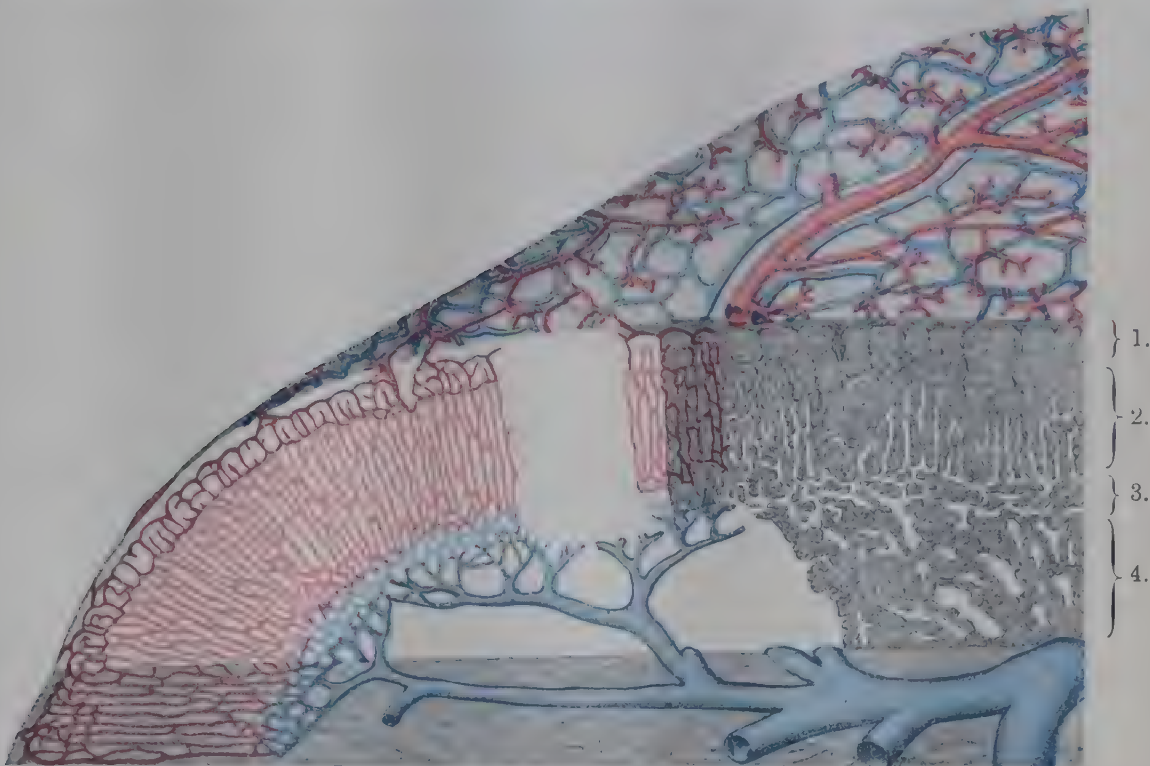

FIG. 685.—RECONSTRUCTION OF SUPRARENAL GLAND OF A DOG. (Flint, 1900.)
The upper part of the figure shows the arrangement of blood-vessels on the surface of the gland, the lower part their arrangement within its substance.
1. = Zona glomerulosa. 2. = Zona fasciculata. 3. = Zona reticulata. 4. = Medulla.

The cortical parenchyma consists of large polyhedral cells arranged in the interstices of the fibrous trabeculæ. The cells contain more or less granular lipoid material, fat, and pigment which gives a yellow colour to the cortex as a whole. The cortex is richer in cholesterol than any other tissue in the body. Ascorbic acid (vitamin C) is stored in the fasciculate and reticulate zones. The glomerular zone is larger and richer in fat in females than in males, and swells with each menstruation and pregnancy. As the blood passes between the columns of the fasciculate zone it gains cortical hormones and undergoes a form of filtration or detoxication; a reticulo-endothelial kind of function is thus attributable to the cortical cells (Hartman, 1942).

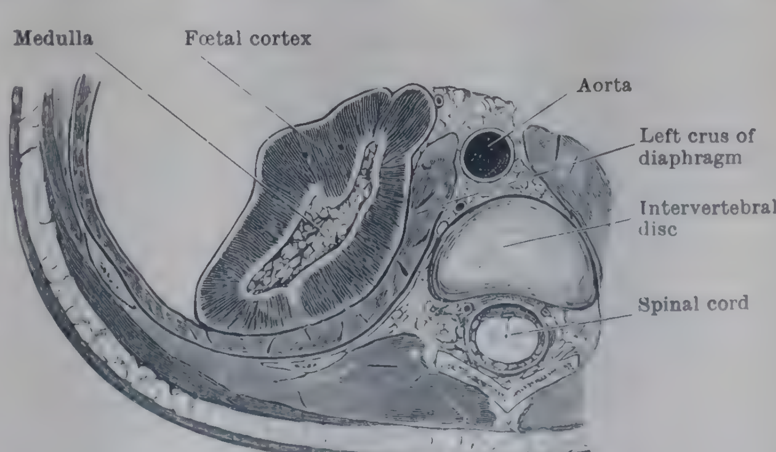

FIG. 686.—TRANSVERSE SECTION THROUGH SUPRARENAL GLAND OF A NEW-BORN CHILD *IN SITU*.

The **medulla** (Fig. 685, 4) is formed of a spongework of cell-columns separated by anastomosing venous sinusoids. The cells are large and granular and exhibit the characteristic chromaffin reaction. In a fresh gland the medulla is of a dark-red colour owing to the presence of blood in its sinusoidal spaces.

Adrenalin is produced by the cells of the medulla. Its precursor can be demonstrated as granules within the cells either by the chromaffin reaction or by blackening

with osmic acid. During actual secretion the granules blackened by osmic acid can be seen also in the venous spaces (Fig. 684—see also Bennett, 1941).

Vascular Pattern.—From the main blood-vessels, smaller vessels enter at numerous points in the fibrous capsule and run in the trabeculæ, forming a close network around and between the cell-masses and columns of the zona glomerulosa and zona fasciculata (Fig. 685). In the zona reticulata the blood-vessels open up to form a venous plexus which is continuous with the sinusoidal plexus in the medulla, and thus with the central efferent vein of the medulla which emerges at the hilum of the organ as the suprarenal vein. Few of the arterioles that enter the cortex pass directly through into the medulla. Most of the blood which reaches the medulla first passes through capillaries in the cortex. Endothelial cells which line these capillaries are of the "specific endothelial" type (see p. 832), showing pronounced phagocytic properties.

These vessels thus act as a filter or shield to the blood which reaches the medulla. The medulla is, moreover, the first tissue in the body to receive *cortin* or vitamin C from the cortical tissue.

Development of Suprarenal Glands.—The cortical system is a derivative of the cœlomic epithelium (mesoderm). Proliferative activity in this layer between the root of the mesentery and the mesonephros is evident at the 7 mm. stage, when numerous buds of cells develop from the deep surface of the mesothelium. These cells rapidly form a mass of cortical cells separate from the mesothelium. In Man the greater part of that tissue is ultimately included in the suprarenal cortex, but small masses may separate off, sooner or later, to form either independent cortical bodies or portions of accessory suprarenals (see p. 802). At the 12 mm. stage the main cortical mass is seen to lie in a tailward prolongation of the dorsal portion of the pleuro-peritoneal membrane called the suprarenal ridge (Zuckerkandl, 1912).

Meanwhile the sympatho-chromaffin primordium of the medulla has appeared, as early as the 5 mm. stage. The cells of that tissue early make contact with the cortex-primordium and commence to invade it at the 14 mm. stage. About this time adrenalin can be identified in the gland but the chromaffin reaction does not develop until considerably later, in the 22nd week (Lucas Keene & Hewer, 1927). Not until the 19 cm. stage does the immigrant chromaffin tissue reach the neighbourhood of the central vein and form a true medulla (Zuckerkandl, 1912). Envelopment of the medulla by the cortex is incomplete for a long time; this is probably due as much to progressive cortical overgrowth as to chromaffin invasion. Nerve-fibres and nerve-cells migrate into the gland at an early stage of development—fourteenth day of pregnancy in the mouse, one day after the primordium of the medulla first (McPhail & Read, 1942).

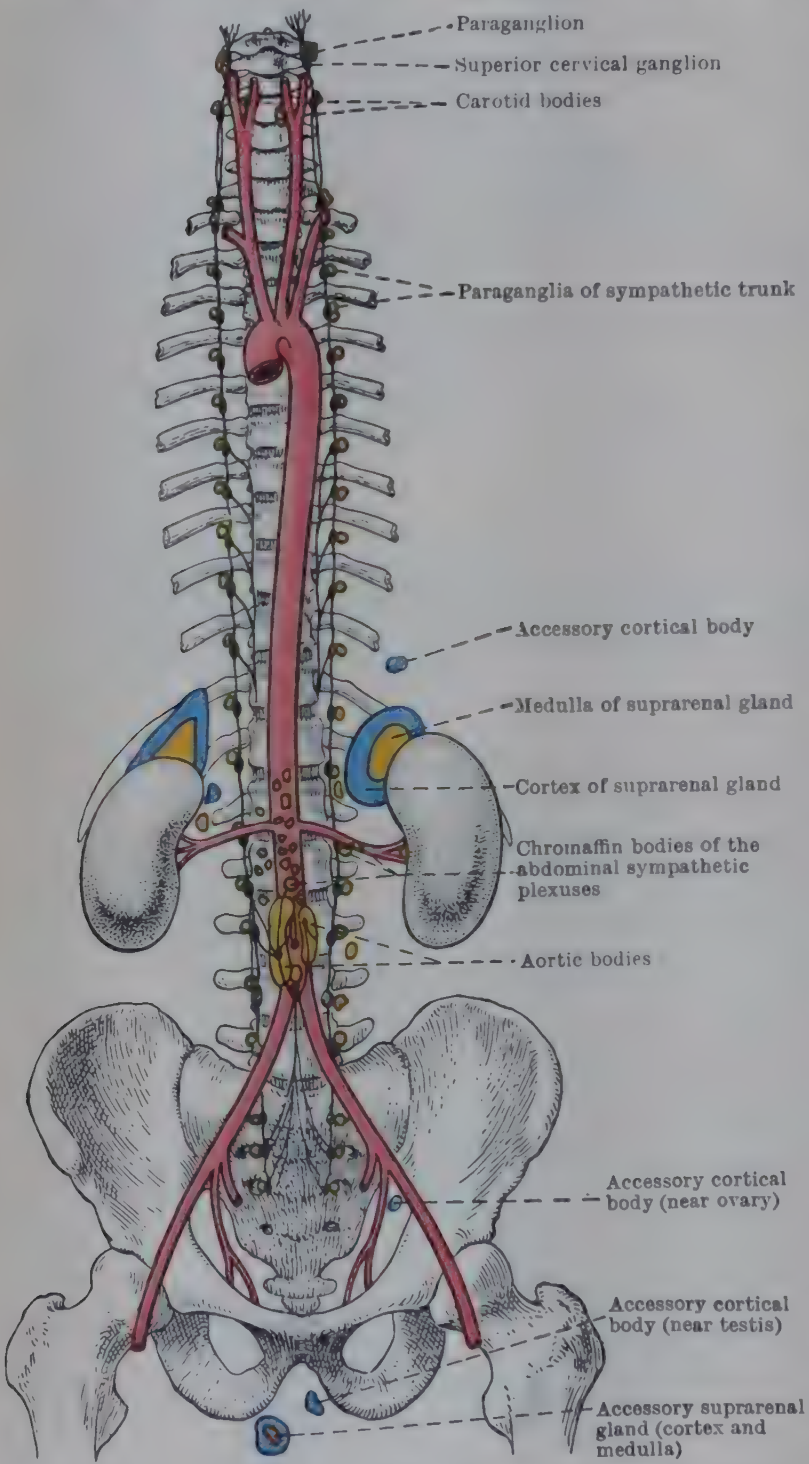

FIG. 687.—DIAGRAM OF THE CHROMAFFIN AND CORTICAL SYSTEMS. Modified from Swale Vincent (1922). Chromaffin tissue = yellow; cortical tissue = blue.

The relatively bulky *foetal cortex* degenerates progressively during the last ten weeks of intra-uterine life. At birth two parts of the cortex are distinguished, a still bulky fœtal cortex and a thin, overlying true cortex (Fig. 686). The characteristic cortical tissue of the fœtus disappears in the course of the first year and the volume of the entire cortex thus diminishes rapidly for a time. It is worthy of note that the small size of the suprarenal glands of anencephalic human fœtuses is due to the absence or the early atrophy of the fœtal cortex (Elliott & Armour, 1911); but the relation of this fact to the maldevelopment of the brain is obscure.

The final specialization of the cortex is not complete until much later. The definitive zona reticulata does not begin to appear until the fourth post-natal month, although the inner zone of the fœtal cortex is sometimes so named. The zona fasciculata is differentiated as such within three weeks after birth, but the zona glomerulosa not until the second or third years. Until then it appears to be represented by a layer of incompletely specialized cells immediately underneath the fibrous capsule. In the prepuberty period there is accelerated growth of the cortex; and in middle age its involution begins.

CHROMAFFIN SYSTEM

This system comprises a large number of masses of tissue similar in development, structure, and micro-chemical reactions to the medulla of the suprarenal gland.

The tissue is called chromaffin, or chromaphil, on account of its affinity for chromium salts, which give a brownish reaction with it. The general distribution of the masses of tissue which form the system is shown in Fig. 687. They all originate in intimate

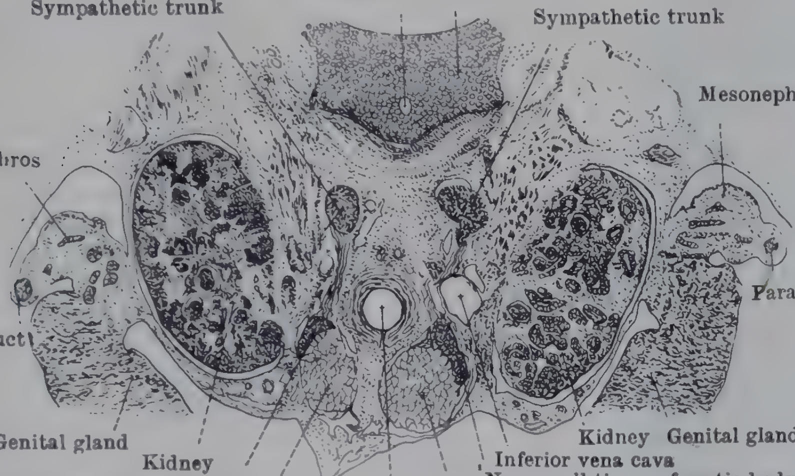

Fig. 688.—Transverse Section of Part of Abdominal Region of a 25 mm. Human Embryo. Seen from below, showing aortic bodies.

association with the rudiments of the sympathetic nervous system. Indeed, the characteristic chromaffin cells and the neurons of the sympathetic ganglia are derivatives from a common mother-cell. Chromaffin cells are innervated by preganglionic fibres and in this respect are comparable with postganglionic neurons.

The chromaffin system includes **paraganglia** associated with the ganglia of the sympathetic trunk and with the collateral ganglia of the abdominal region, but none, so far as is known, associated with the terminal sympathetic ganglia. It includes also the medullary portions of the suprarenal glands, and possibly the carotid bodies and the glomus coccygeum. While the similarity of all chromaffin tissue points to a common function, it is by no means certain that the paraganglia secrete a hormone like the adrenalin of the suprarenal medulla; but, like the secretory cells of the medulla, the paraganglia are innervated through preganglionic fibres (Hollinshead, 1937).

(i) The *paraganglia associated with the ganglia of the sympathetic trunk* are rounded masses of chromaffin tissue, 1-3 mm. in diameter, placed inside, half inside, or immediately outside the capsules of the ganglia. Typically one paraganglion, but occasionally more than one, is associated with each ganglion.

(ii) The *paraganglia of the sympathetic plexuses* occur both in association with the prevertebral ganglia and scattered throughout the plexuses. They may be very numerous—as many as seventy have been counted, though the number is usually much smaller. Increase in the number may be due to subdivision.

The most prominent paraganglia of the sympathetic plexuses are the two **aortic bodies** (aortic paraganglia) which lie anterior to the aorta in the region of the origin of the inferior mesenteric artery (Fig. 687). In the new-born child they are paired elongated structures, usually about a centimetre in length. Up to the age of 12-18 months they show increase in growth and in secretory activity. After the middle of the second year they—with many other paraganglia —undergo retrogressive changes. By the period of puberty they have practically ceased to be visible to the naked eye, though vestiges may be recognized, at least under the microscope, to a much later period of life. Even at the height of their development the aortic bodies are subject to considerable variation in size, form, and arrangement. They are commonly more or less asymmetrical and are often connected by a commissure. That appears to be a typical embryonic feature and is characteristic of the growth period, becoming progressively rarer during the period of decline. After the fourth year the commissure is no longer met with. In the vicinity of the aortic bodies there are numerous smaller masses of like character and of varying size and shape. Fig. 688 illustrates the relations of the aortic bodies to the structures in their vicinity. The darker stippled areas along the periphery of the bodies represent developing sympathetic ganglia of the abdominal plexus.

Paraganglia are found also in relation to viscera, where they may have originated in common with the 'peripheral' sympathetic ganglionic groups. The viscera to which they have been found related include the kidney and ureter, the suprarenal gland, the prostate, the paroöphoron and ovary, and the epididymis.

Carotid Body.—The carotid body is situated in close but slightly variable relation to the bifurcation of the common carotid artery (Fig. 689), adjacent to the carotid sinus (p. 1121). Frequently the gland lies deep to the bifurcation; sometimes it is wedged in between the roots of the internal and external carotids; sometimes it is placed between them at a slightly higher level.

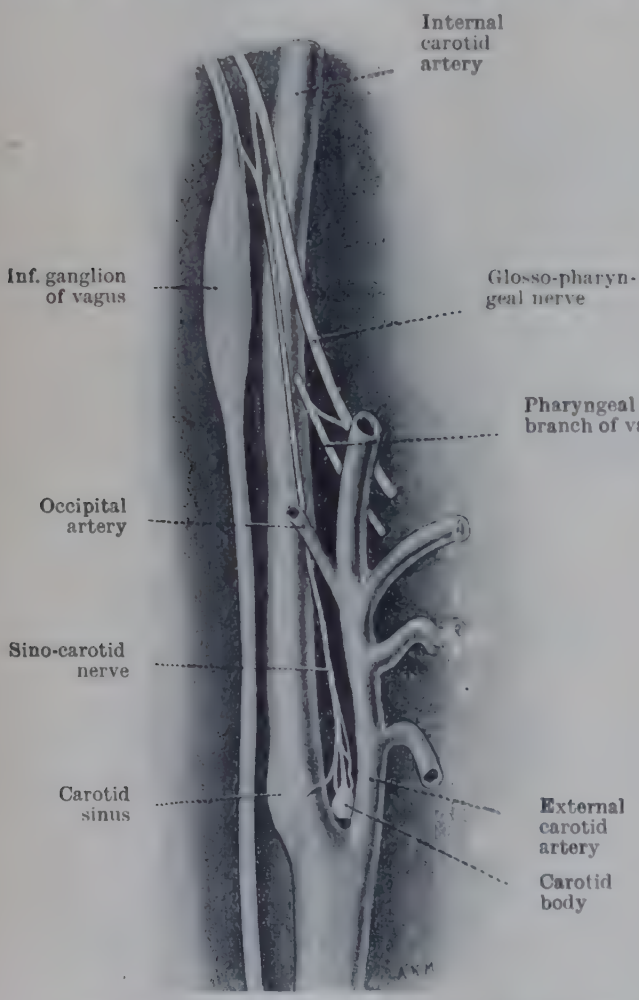

Fig. 689.—Carotid Body and the Sino-Carotid Nerve with its Principal Connexions.

It is a small neuro-vascular structure of a shape that varies with its position. When free from pressure from its surroundings it is oval; when situated between the internal and external carotids, it is wedge-shaped. On the average its height is about 7 mm., its breadth 1·5-5 mm. It sometimes comprises two or more separate nodules. Its colour is yellowish-grey to brownish-red.

Structure.—The carotid body consists of cellular groups or nodules surrounded by, and interspersed with, fibro-areolar tissue. The nodules are permeated by small arteries which are provided with abundant sensory nerve-endings. Some large chromaffin-like cells are present, and for this reason the carotid body has commonly been regarded as a part of the chromaffin system. Its structure and the abundant sensory nerves which pass into the sino-carotid nerve-plexus point, on the other hand, to a close relationship with the reflex depressor functions of the carotid sinus.

Nerve-Supply.—Numerous afferent nerves pass from the carotid sinus and carotid body to a *sino-carotid plexus*. From this plexus an *intercarotid* or *sino-carotid nerve* (Fig. 689) passes upwards with the pharyngeal branch of the glosso-pharyngeal nerve and divides into two branches, one of which joins the inferior ganglion of the vagus, the other the glosso-pharyngeal nerve. Other nerve-filaments from the plexus pursue an independent but similar course, and join the glosso-pharyngeal and vagus nerves and the cervical sympathetic trunk. The afferent fibres pass mainly to the glosso-pharyngeal nerve; but some of those from the *carotid sinus* join the vagus, and it is probable that some afferent fibres from the carotid body do so also.

Development.—The carotid body is developed as a condensation of mesenchyme around the third aortic arch (Boyd, 1937). Nerve-fibres of the glosso-pharyngeal nerve enter this condensation, and neuroblasts derived from the ganglion of the nerve subsequently migrate along the fibres into the developing organ.

Similar structures are developed in relation with the fourth and sixth aortic arches and form bodies which, on the left side, are adjacent to the aorta and the ductus arteriosus.

Glomus Coccygeum.—This is a small vascular body measuring 2-3 mm. in diameter. It lies immediately anterior to the tip of the coccyx in intimate relation with a branch of the median sacral artery and with the ganglion impar of the sympathetic trunks. Usually it is associated with a group of smaller bodies of similar structure.

Structure.—The glomus and its satellite bodies are enclosed in a fibrous capsule which ensheaths them individually. The characteristic feature of the glomus is the presence of masses of polyhedral cells, with large nuclei, surrounding the lumina of tortuous sinusoidal blood-spaces. From these spaces capillary channels extend among the investing masses of closely packed cells. Though they resemble the cells of the carotid body, none of the cells appear to give the characteristic chromaffin reaction ; hence, the paraganglionic nature of the glomus is extremely doubtful if not wholly excluded.

Development of Chromaffin System.—All chromaffin tissue develops in intimate relation with the sympathetic nervous system. The cells of both appear to be derivatives of a common mother-tissue whose elements in all probability originate from cells which migrate at an early period from the neural crest, or from the wall of the neural tube, or from both of those sources (see Development of Autonomic Nervous System, p. 1146).

In the 16 mm. embryo, sympatho-chromaffin tissue is met with in situations which more or less correspond to the distribution of the sympathetic nervous system. Differentiation of chromaffin cells from sympathetic neuroblasts begins about the 18 mm. stage (eighth week), but is not completed till late in the period of gestation, if then. The process is characterized by increase in the size of the chromaffin cells and a diminution of the intensity of their reaction to ordinary stains. Later, the specific chromic-staining reaction develops, but its period is uncertain and it may even fail to appear at all, as in the carotid body in some animals. It is stated that if any cells in a given area differentiate as chromaffin cells, all do ; so that, in spite of their intimate relationship and common origin, an intermixture of chromaffin and sympathetic cells is extremely rare.

The aortic bodies develop as the chief masses of a paired discontinuous series associated with the prevertebral plexuses. Cranially this series is originally continuous with the primordium of the medulla of the suprarenal gland on each side. The aortic bodies are prominent structures in the two-months embryo (see Fig. 688). The paraganglia associated with the ganglia of the sympathetic trunk appear a little later.

The earliest stages of development of the glomus coccygeum are still obscure. Its presence has not been recognized with certainty before the end of the fourth month of intra-uterine life. In support of the view of its sympathetic derivation is its indubitably intimate nervous connexion with the terminal ganglion impar of the sympathetic trunks.

CORTICAL SYSTEM

The single constant representative of this system in higher vertebrates is the mass of tissue that forms the **cortex of the suprarenal gland**. Masses of similar tissue, however, are not infrequently met with in various situations, forming **accessory cortical bodies**. The positions in the human body which may be occupied by accessory cortical masses are indicated in Fig. 687.

Accessory cortical bodies may be associated with chromaffin medullary tissue, as is the case in the suprarenal itself, but the majority, including the smaller bodies, are purely cortical. The justification for regarding the suprarenal cortex, with the occasional accessory cortical masses, as representing a distinct system, is based upon both phylogenetic and ontogenetic considerations. These warrant the conception of an originally more extensive distribution of cortical tissue, distinct from the chromaffin system. In the higher vertebrates the cortical system would appear to have undergone concentration, thus coming to be represented mainly by the cortex of the suprarenal gland.

COMPARATIVE ANATOMY OF CHROMAFFIN AND CORTICAL SYSTEMS

A knowledge of the main facts of the comparative anatomy of these systems throws light on their arrangement and function in man. Chromaffin tissue similar to that of mammals is found throughout the vertebrates, but its situation is different in various groups. In the Cyclostomata (*e.g.*, the lamprey) it is arranged in thin strips on the walls of the larger arteries. Cortical tissue, rich in lipoids, also is recognized ; it is arranged in small lobulated masses (the "inter-renal corpuscles") in the walls of the posterior cardinal veins and renal arteries. In the Elasmobranchii—the cartilaginous fishes of which the dog-fish is representative—chromaffin bodies are arranged segmentally (the so-called "suprarenals") in close relation to the ganglia of the sympathetic trunk. The cortical tissue in these fish is represented by a pair of yellow "inter-renals" in the region of the kidney.

It is only in the Tetrapoda (vertebrates possessing paired limbs) that cortical tissue and chromaffin tissue come into intimate topographical relation. Thus, in the Amphibia there is a composite organ—the "adrenal"—which is applied to each kidney. The greater part of each mass is made up, as in Man and other mammals, of columns of cortical cells, but at the borders of the gland collections of chromaffin cells occur. Among the higher Tetrapoda the detailed relation of the cortical and chromaffin tissues varies. In the Sauropsida (reptiles and birds) the chromaffin tissue almost completely surrounds the cortical or "inter-renal" tissue, whereas in Mammalia the cortical tissue encloses the chromaffin tissue.

The very long phylogenetic history of both chromaffin and inter-renal tissues points to the fundamental part played by endocrine systems similar to that of the human suprarenal gland in the co-ordinating hormone-apparatus of vertebrates generally. It seems possible that the paraganglia and the accessory cortical bodies of Man have endocrine functions similar to, if not identical with, the medulla and cortex respectively of the suprarenals, but definite confirmation of this is not yet available. Nor is it yet known what differences of function are brought about by the difference of topographical relationship between the "inter-renal" and chromaffin tissue in Amphibia, Sauropsida and Mammalia respectively. Differences of detail in the Mammalia include a tendency to folding or convolution of the suprarenal cortex in Man and various other primates, and variations in the number of accessory cortical bodies. In some mammals (*e.g.*, the rabbit) they are numerous; in others (*e.g.*, the dog) they are rare—facts which have a bearing on the interpretation of the results of extirpation experiments.

For further information, consult the monographs of Bourne (1949) and Hartman & Brownell (1949).

Organs of the Pharyngeal Pouches

This group of organs is developed from epithelium derived from the embryonic pharynx, and they illustrate an advanced stage in the histological differentiation of endocrine glands (see pp. 799, 800).

In an early phase of vertebrate evolution, entodermal epithelium lined the recesses of the pharyngeal cavity, and in one instance—the thyroid—it was sufficiently elaborated to justify the appellation of an exocrine gland (as still seen in the larval lamprey—see p. 815). Subsequently the epithelium of the recesses acquired specific endocrine functions and was isolated during embryonic development from the general pharyngeal epithelium to form separate extra-pharyngeal organs.

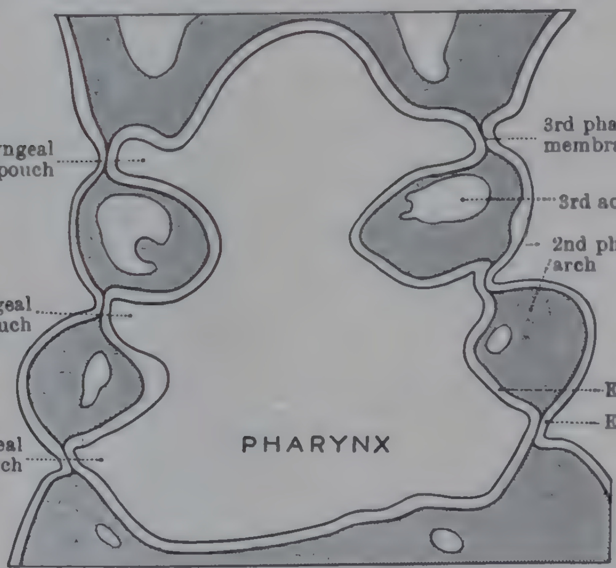

Fig. 690.—Section through Pharynx of 4 mm. Human Embryo, showing the Pharyngeal Pouches and Membranes. (After Norris, 1938.)

Early Development of Pharynx.—In the Section on Embryology, a description is given of the processes which lead to the formation of the embryonic mouth and pharynx (pp. 62-65). The primitive pharynx is formed from the cephalic part of the fore-gut and is brought into continuity with the oral pit by the breaking down of the *bucco-pharyngeal membrane* (Fig. 75). The position of that membrane is such that the greater part of the floor of the mouth is derived from the fore-gut and is therefore lined with entoderm.

The part of the fore-gut which forms the primitive pharynx is flattened dorso-ventrally and has narrow side-walls that consist of alternate thick and thin portions (Fig. 83, p. 68). The thickenings are termed **pharyngeal arches**, and they contain the *aortic arches* (p. 91 and Figs. 85, 690, 691).

The first pair of thickenings form the caudal boundary of the mouth, and each is called a **mandibular arch**; the second pair are the **hyoid arches**. Externally the arches are separated by depressions called *external pharyngeal grooves*; internally they are separated by pockets of the cavity called *pharyngeal pouches* (Fig. 690). Between successive pharyngeal arches the ectodermal lining of the grooves makes contact with the entodermal lining of the pouches, so that there is merely a thin "pharyngeal membrane" separating the cavity of the pharynx from the exterior (Figs. 690). In gill-breathing animals these

membranes disappear when the gill-slits are formed. At a later stage branchial branches of certain cranial nerves (5th, 7th, 9th, and 10th) grow ventrally through the pharyngeal arches (Fig. 912, p. 1048); and later still cartilaginous bars (pp. 204, 207) are formed within the arches.

Only the first four *separating membranes* become so thinned that entoderm and ectoderm make contact, and in the case of the fourth membrane this phase is of short duration. The fifth and other pharyngeal pouches are probably represented by a ventral diverticulum known as the *ultimo-branchial recess* or "caudal pharyngeal complex", which opens along with the fourth pouch and at no time comes close to the surface; there is, indeed, no external pharyngeal groove corresponding to it (Fig. 691).

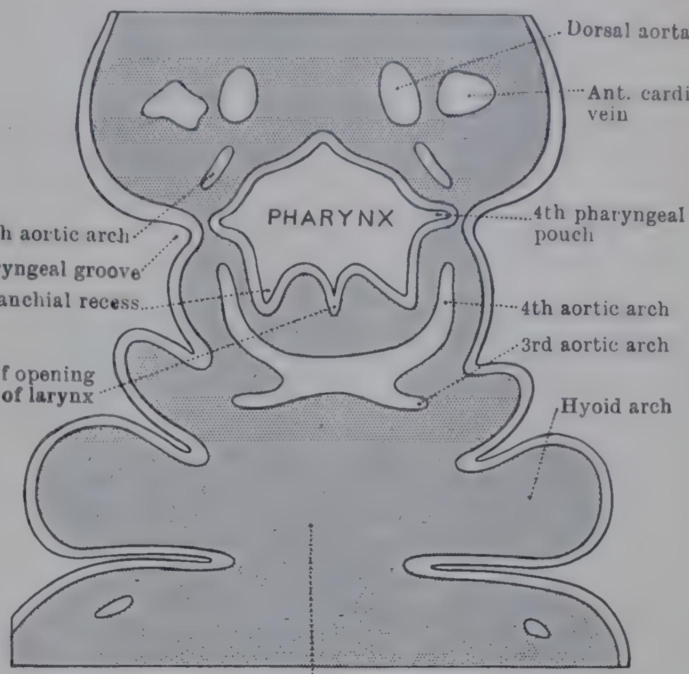

FIG. 691.—SECTION THROUGH PHARYNX OF 4·9 MM. HUMAN EMBRYO, showing the Fourth Pharyngeal Pouch and the Ultimo-Branchial Recess. (After Norris, 1938.)

In embryos of 6 mm. length the second or hyoid arch is already becoming more prominent externally than the third arch. It gradually overlaps this arch and the pharyngeal wall behind it, so as to enclose a deep external recess—the *cervical sinus*—which communicates with the exterior only by a small opening (Fig. 81). Eventually this opening becomes closed and a small cavity, derived from the cervical sinus and therefore lined with ectoderm, remains embedded in the wall of the pharynx; it is known as the *cervical vesicle*. The vesicle is situated opposite the third pharyngeal pouch, but for a short time a narrow passage or "branchial duct" leads forwards from this vesicle to the second separating membrane. The epithelial cells of the vesicle later acquire an intimate relation with the epithelium of the third pharyngeal pouch, forming with it the primordium of the thymus (Norris, 1938). Portions of the cervical sinus may occasionally persist in the form of a slender tubular channel (branchial fistula) which opens to the exterior on the lower part of the neck, or a portion may be closed off within the neck to form a "branchial cyst".

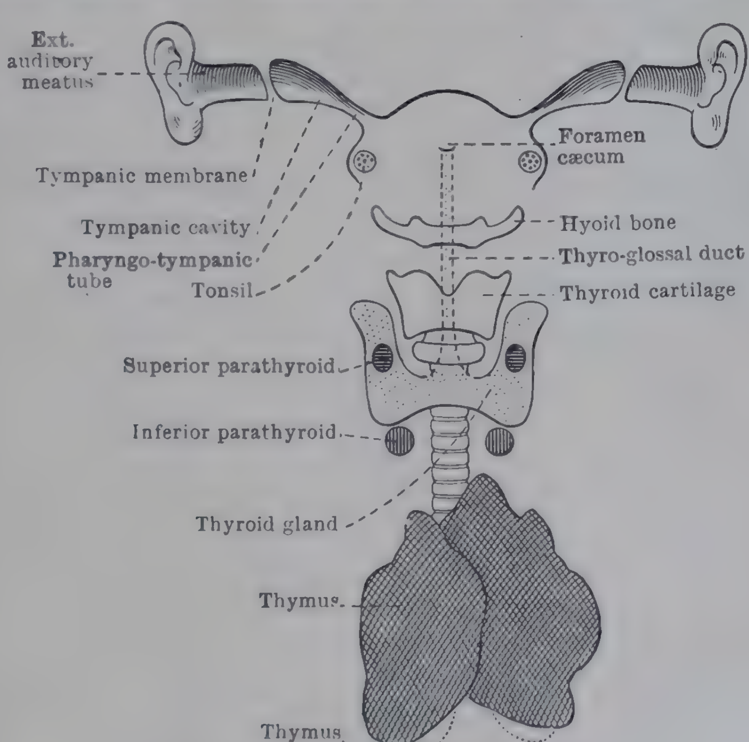

FIG. 692.—SCHEMA SHOWING SOME OF THE DERIVATIVES OF THE PHARYNGEAL POUCHES, AND THE THYRO-GLOSSAL DUCT.

Fate of Pharyngeal Pouches (Fig. 692).—The **first** and **second pharyngeal pouches** are concerned in the development of the *tympanum* and the *pharyngo-tympanic tube* (p. 67).

The third and fourth pouches, in embryos 10 mm. in length, have become small cavities connected to the pharynx only by narrow canals (Fig. 696); shortly afterwards the stalks of connexion are interrupted, leaving small balls of cells (of entodermal origin) embedded in the pharyngeal wall. At the time of its isolation from the pharyngeal wall the **third pouch** consists of (1) a small, hollow, dorsal diverticulum, from which a *parathyroid gland* develops, and (2) a caudally directed cylinder of cells which grow from its ventral

side and are destined to contribute to the formation of the *thymus* (p. 821). The cervical vesicle, which is closely applied to this thymic diverticulum (as described above), probably also contributes to the thymus.

The **fourth pharyngeal pouch** (with the ultimo-branchial body) of each side forms a small, hollow mass at the time of its separation from the pharynx. This becomes differentiated into two parts—a dorsal portion from which a *parathyroid gland* is developed (p. 817), and a ventral portion which is believed to contribute to the *thyroid gland* (p. 814).

Floor of Pharynx.—At a stage when the cephalic part of the fore-gut is still cut off from the exterior by the bucco-pharyngeal membrane, there is to be seen a minute diverticulum in its floor, known as the **median thyroid diverticulum** (Fig. 75). The margins of the opening become raised up to form a swelling called the *tuberculum impar* (pp. 70 and 814)—a mass of tissue which is eventually incorporated in the tongue. The original site of formation of the median thryroid diverticulum is marked permanently by the foramen cæcum.

THYROID GLAND

The **thyroid gland** is situated in the lower part of the front of the neck, and is enclosed in a fascial compartment formed by the sheath of pretracheal fascia which fixes it firmly to the trachea and larynx. The thyroid is an endocrine gland which produces a hormone of the greatest importance for the proper growth and function of most of the tissues in the body. This hormone is known as *thyroxin*. Characteristic of this organ is the storage of its secretion within small closed cavities—the vesicles of the thyroid. It is an organ of very ancient history, yet one that exhibits remarkably little evolutionary change, for its histology and endocrine action are similar throughout the whole series of vertebrates. The gland is yellowish red, soft, and extremely vascular; in this last respect it surpasses all other organs in the body excepting possibly the suprarenal glands. It varies in size with age, sex, and general nutrition, being relatively large in youth, in women, and in the well nourished. In women it increases temporarily with menstruation and pregnancy. Its average dimensions are: height 5 cm., breadth 6 cm., thickness of each lobe 1-2 cm.; and its weight is 18-31 gm. (Nolan, 1938). The maximum weight is attained in the young adult, apart from abnormal enlargements.

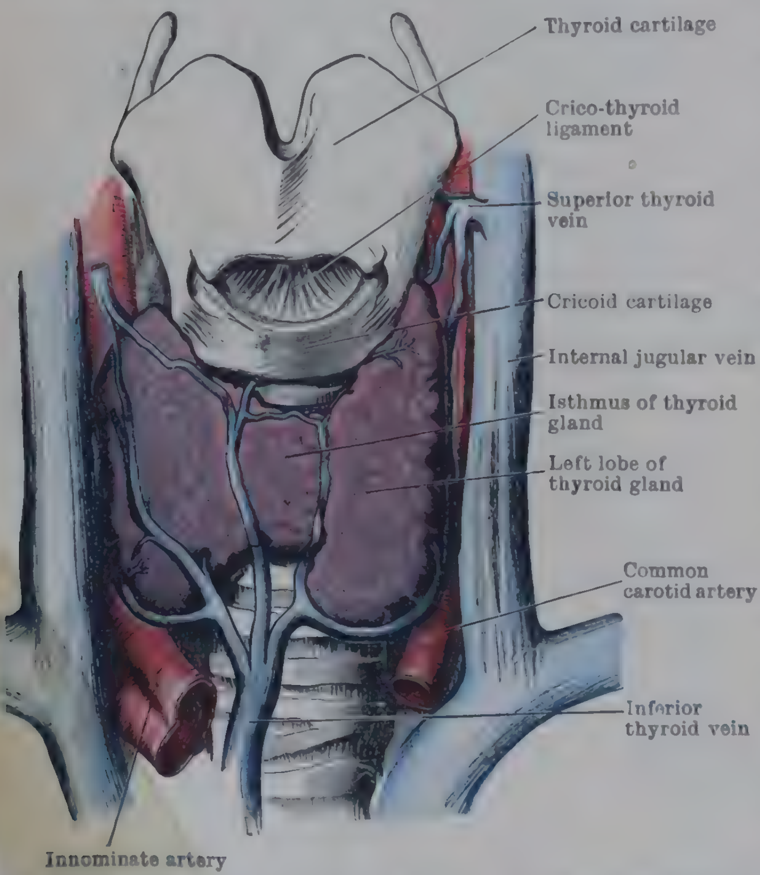

FIG. 693.—DISSECTION OF THYROID GLAND AND OF STRUCTURES IN IMMEDIATE RELATION TO IT.

Usually the thyroid gland consists of a pair of conical **lobes** united across the median plane by a short band of gland-tissue called the **isthmus**. But to many thyroid glands this description is inapplicable. In men and thin elderly women the gland is not uncommonly horseshoe-shaped; in young well-nourished women and during pregnancy its general contour is more rounded, deeply notched above to accommodate the larynx and deeply grooved behind for the trachea and œsophagus. Rarely, the gland is in two separate parts. Not infrequently, it is asymmetrical. In about 40 per cent of specimens, a process of gland-tissue called the **pyramidal lobe** extends upwards from the upper border

of the isthmus, in front of the cricoid and thyroid cartilages, towards the hyoid bone. That process is seldom median, lying more often on the left than on the right ; in rare cases, it is double ; less rarely, it is double below and single above ; sometimes it is represented by a strip of fibrous tissue or a narrow muscle (m. levator glandulæ thyreoideæ). The muscle may, however, be present independently of the pyramidal lobe (see Development, p. 815).

Small oval accessory thyroid glands are common in the region of the hyoid bone, and are occasionally met with in relation to the right and left lobes. They may occur also in the superior mediastinum of the thorax.

Relations.—The gland itself has an external layer of fibrous tissue—the fibrous capsule—which is loosely connected by areolar tissue to the fascial sheath ; the gland with its capsule is thus readily taken out of its sheath of pretracheal fascia. It is under cover of the sterno-thyroid, sterno-hyoid, and omo-hyoid muscles, and, more laterally, it is overlapped by the sterno-mastoid (Fig. 380). The isthmus is, however, comparatively superficial between the margins of the sterno-thyroid muscles a short distance above the suprasternal notch. The isthmus usually lies on the front of the 2nd, 3rd, and 4th rings of the trachea ; but occasionally it lies as high as the cricoid cartilage or as low as the 4th, 5th, and 6th rings of the trachea. The lobes extend down to the level of the 6th ring of the trachea or even lower, and up as far as the middle of the thyroid cartilage. Superficially they are covered by the muscles mentioned, along with twigs of the ansa hypoglossi and the anterior jugular vein. The upper part of each lobe is moulded medially on the thyroid and cricoid cartilages together with the crico-thyroid and inferior constrictor muscles ; the external laryngeal nerve passes across the surface of the constrictor. The lower part is moulded on the sides of the trachea and œsophagus and thus comes into close relation with the recurrent laryngeal nerve.

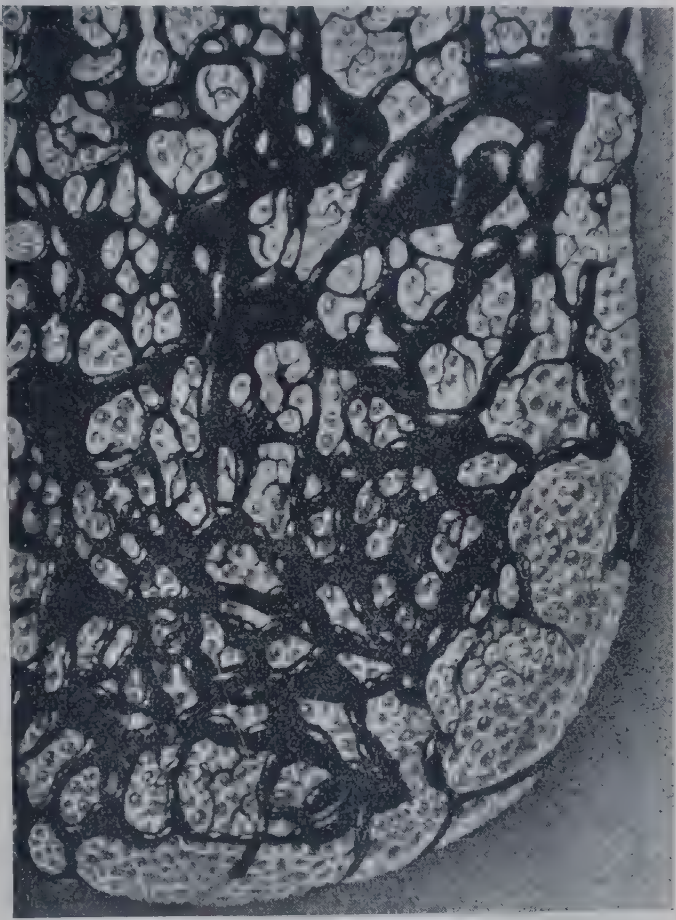

Fig. 694.—Surface View of Dog's Thyroid Gland (slightly magnified) showing individual vesicles and the injected extraglandular plexus of lymph-vessels. (Rienhoff, 1931.)

The posterior surface of each lobe is variable in width. It is in relation to the longus cervicis muscle, and more laterally to the carotid sheath, which becomes displaced in a postero-lateral direction by simple enlargements of the gland. The inferior end of the left lobe approaches or even makes contact with the thoracic duct. Closely applied to the posterior surface, within the fibrous capsule, are the two pairs of parathyroid glands ; they may even be embedded within the substance of the thyroid.

Vessels and Nerves.—The extraordinarily rich **arterial supply** is effected through the *superior* and *inferior thyroid arteries*. Occasionally (10 per cent. of cases) **a** fifth artery—the *thyroidea ima*, normally present in the embryo—persists in the adult. It is usually a branch of the innominate. The pyramidal lobe, if well developed, receives a special branch from one of the superior thyroid arteries, usually the left. The arteries are remarkable for their large size and for the frequency and freedom of their anastomoses. An anastomosing trunk courses up over the back of each lobe within the fascial sheath and unites the inferior and superior thyroid arteries ; it is of interest in connection with the identification of the parathyroid glands (q.v.). Typically, three pairs of **veins** drain the gland. The upper two pairs—the *superior* and *middle thyroid veins*—join the internal jugular veins ; the lower pair—the *inferior thyroid veins*—join the innominate veins. The veins take origin from the venous plexus on the surface of the gland or, in the case of the inferior, from a downward extension of the plexus in front of the trachea. When the gland is very large, accessory veins are present, sometimes in considerable

numbers. Most of them pass to the internal jugular veins. A free, transverse, venous anastomosis is effected along the borders of the isthmus through superior and inferior communicating veins.

The **lymph-vessels** pass directly from the subcapsular plexus to the *deep cervical lymph-glands*; a few descend in front of the trachea to the *pretracheal lymph-glands*, through which they are connected with *innominate glands* behind the manubrium sterni.

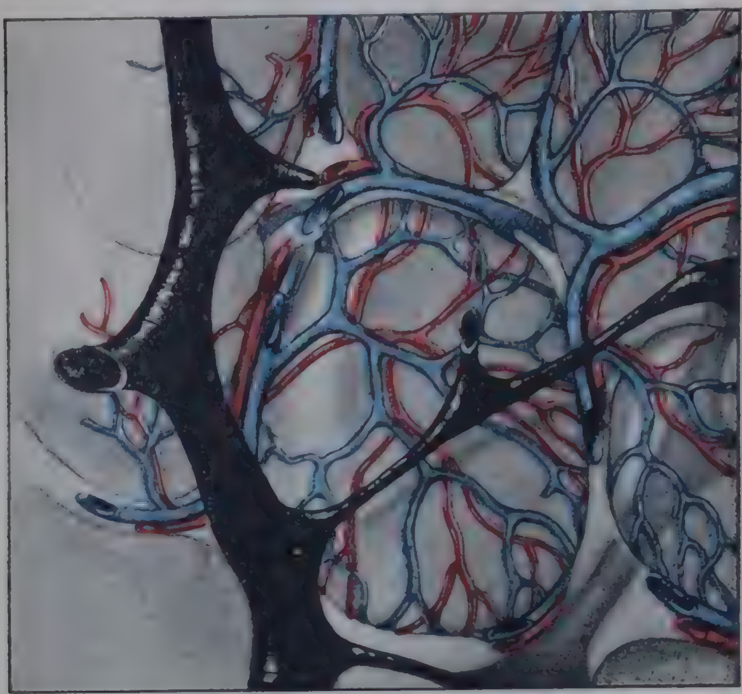

FIG. 695.—INJECTED SPECIMEN OF DOG'S THYROID GLAND. Enlarged drawing demonstrating the relative size of the lymph-plexus and blood-capillary plexus and their relation to the individual vesicles. Note that the lymphatic plexus (black) lies external and in less intimate contact with the individual vesicles than the blood-capillary plexus, which is specific for each vesicle. (Rienhoff, 1931.)

The **nerves** are non-medullated post-ganglionic fibres which come from the *superior* and *middle cervical sympathetic ganglia*. They reach the gland by way of the cardiac and the superior and recurrent laryngeal nerves, and along the superior and inferior thyroid arteries. Some of the nerve-fibres are vasomotor, and others end in close relation with the epithelial cells of the vesicles of the gland—though as yet they have not been shown to be secretory in function.

Structure.—The gland consists of a mass of minute, rounded vesicles, of various sizes and commonly about 300 μ in diameter (Figs. 694, 701). Each vesicle consists of a layer of epithelial cells enclosing a mass of colloid. Microscopic study of living cells has shown that the epithelial cells produce cytoplasmic processes which extend into the lumen of the vesicle, a process which is associated with the addition of colloid to the lumen (Williams, 1941; see also de Robertis, 1942). They are embedded in a framework or stroma of fibrous tissue which is continuous externally with the capsule. Numerous lymph-vessels, arteries, veins, and nerves course in the stroma. The lymph-vessels appear to be mainly concerned in the drainage of the intervesicular tissue (Figs. 694, 695); the larger trunks pass to a dense plexus on the surface of the gland.

Development.—The thyroid gland is developed from a median ventral diverticulum of the floor of the pharynx (p. 812 and Fig. 75); a contribution is possibly derived also from the caudal pharyngeal complex (ultimo-branchial recess, p. 811). According to Weller (1933) the median diverticulum forms the isthmus and a small part only of each lobe. It appears in embryos less than 2 mm. in length (possessing about six mesodermal somites) as a small out-pocketing of the pharyngeal floor. The tuberculum impar (p. 812) at first surrounds the opening of the diverticulum but later is entirely anterior to it. The diverticulum by rapid downgrowth soon forms a plate-like structure ventral to the trachea, connected by a narrow tube called the *thyro-glossal duct* with the pharyngeal floor.

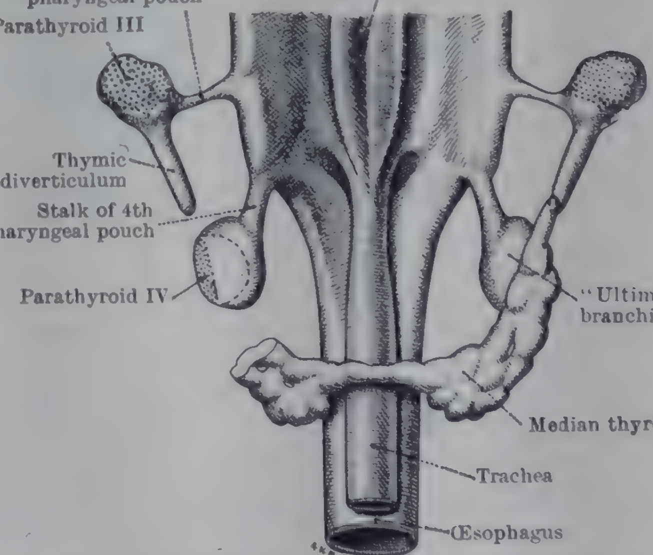

FIG. 696.—DIAGRAMMATIC VENTRAL VIEW OF WALL OF PRIMITIVE PHARYNX, SHOWING THE "PHARYNGEAL DERIVATIVES" IN AN EMBRYO OF THE SIXTH WEEK.

This duct disappears normally in embryos of six weeks, but a vestige of its original opening into the pharynx persists in the adult as the foramen cæcum of the tongue (p. 575). In the sixth week the fourth pharyngeal pouch, with its ventral diverticulum, is still connected by a narrow tubular stalk with the pharynx. At this stage the caudal pharyngeal complex becomes closely applied to the lateral portion of the thyroid gland. Weller (1933) and Norris (1937) confirm the view that it makes a contribution of thyroid tissue to the definitive gland. Even when, as occasionally happens, the median thyroid diver-

ticulum is defective in its development and fails to extend down the neck, there are nevertheless small portions of thyroid tissue formed in the neck, possibly derived from the ultimo-branchial recess.

Histological differentiation of the gland proceeds by the arrangement of the embryonic epithelial cells in two sheets, with disappearance of the original lumen of the diverticular primordium; this stage is followed by the formation of definite follicles in the 50 mm. foetus, which later become vesicular. Colloid material is present in the vesicles, and the lining cells are apparently active, in the foetus of eleven weeks. The median portion of the gland passes through the earlier stages of histological differentiation before the lateral portions, which, as stated above, are believed by some to arise from the caudal pharyngeal complex. Additional 'secondary' follicles are added throughout fœtal life but the process slows down before birth and probably ceases about puberty. Postnatal growth of the gland consists mainly in an increase in size of the vesicles.

The developmental history of the gland affords a ready explanation of its variations in the adult. Thus, the development of a pyramidal lobe and its variations, partial and complete duplication, are due to the development of gland-tissue from that part of the thyro-glossal duct which has a double lumen and the more or less complete fusion or separation of the masses thus formed. *Accessory thyroid glands* near the hyoid bone are the result of development of gland-tissue from isolated remnants of the duct. Their occurrence behind the sternum above the arch of the aorta is probably due to a downward displacement of thyroid tissue along with that vessel, with which the median thyroid diverticulum is in close relation at an early stage.

The occurrence in the adult of a duct that leads from the foramen cæcum to, or towards, the hyoid bone (*lingual duct*) is due to a persistence of the upper part of the thyro-glossal duct. Similarly, *thyro-glossal cysts* are due to the persistence of short segments of the duct. The thyro-glossal duct may be continuous with the pyramidal lobe (p. 812). It usually passes behind the hyoid bone although it is initially anterior to the second pharyngeal arch of the embryo; the change of relation is due to extension and growth of the primordium of the hyoid. A cyst-like derivative of the ultimo-branchial diverticulum is sometimes found in the adult in close relation with the lower pole of the lateral lobe of the gland.

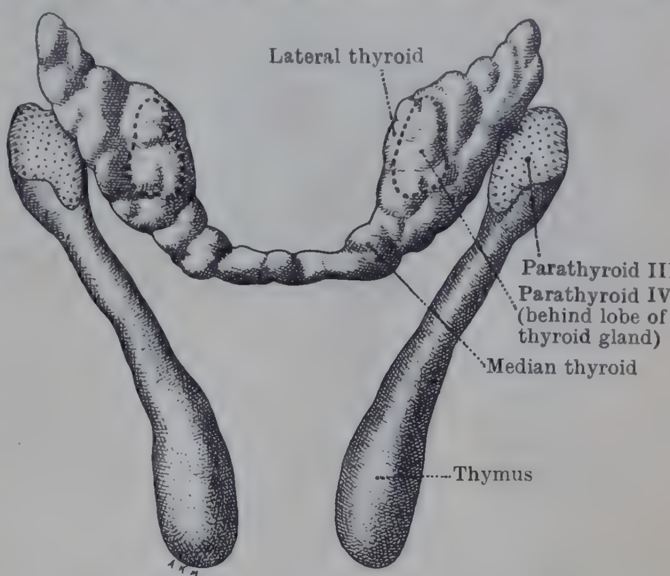

Fig. 697.—Thymus, Thyroid and Parathyroid Glands in an Embryo of the Seventh Week.

Comparative Anatomy.—A thyroid gland similar in structure and probably also in function to that of Man and other mammals is found throughout the vertebrates. In Cyclostomata (p. 809) it is isolated from the pharyngeal epithelium only in the adult; in the larval stage the specific thyroid tissue is situated at the sides of a diverticulum which has an opening on the floor of the pharynx. This diverticulum is elsewhere lined with ciliated epithelium and it appears to be representative of the same organ as the endostyle of the subvertebrate *Amphioxus*. The thyroid gland consists of two separate structures, right and left, in certain fish, amphibia, birds, and mammals. When this arrangement occurs in a mammal (as usually in the dog) it is probably the result of atrophy of the isthmus. It is uncertain whether any part of the thyroid is developed from a median pharyngeal diverticulum in submammalian vertebrates as it is in Man. Structures which appear to correspond to the human ultimo-branchial bodies are seen in vertebrates generally, forming in many of them small isolated **suprapericardial bodies** close to the pericardium.

Methods of Clinical Anatomical Examination.—The lateral lobe of the thyroid gland is felt indistinctly as a soft mass at the anterior border of the sterno-mastoid muscle on the side of the posterior part of the cricoid cartilage and of the adjacent part of the thyroid cartilage. The isthmus also can be felt as a soft swelling over a small part of the front of the trachea a short distance below the cricoid cartilage. When the larynx and trachea are pulled up in the movement of swallowing, the thyroid gland accompanies them. The gland is often large enough to produce an evident fullness of the neck; the sterno-mastoid can then be felt to lie superficial to the postero-inferior part of the lateral lobe.

PARATHYROID GLANDS

The **parathyroid glands** are two pairs of small glands closely applied to the back of the thyroid gland within its fibrous capsule (Fig. 698). They are distinguished as the superior and inferior parathyroid glands; but in reference to their developmental origin (q.v.), the upper pair are known also as the parathyroids IV and the lower pair as the parathyroids III.

The parathyroid glands produce a hormone which plays a part in maintaining the relation between the blood and the skeletal calcium. Possibly they produce another hormone. Extirpation of all four of the glands in a mammal causes death within a few days, but such is the margin of safety that removal of two of them produces no obvious effect. Parathyroids, unlike most glands, become enlarged as a result of underfeeding.

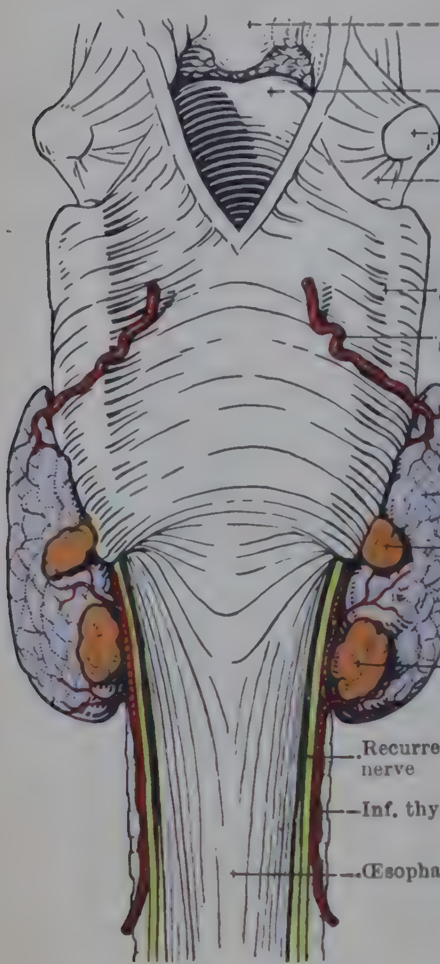

Fig. 698.—Dissection showing Thyroid and Parathyroids of Adult from Behind.

The parathyroid glands are yellowish-brown, ovoid or lentiform structures, varying in size between extremes of 1 to 20 mm. in their long (generally vertical) diameter. Most commonly they are from 5 to 7 mm. in length, 3 to 4 mm. in width, and 1 to 2 mm. in thickness. Their individual weights vary within wide limits. The total amount of parathyroid gland-tissue has been stated to show a mean variation from 0·8 to 1·2 gm.

The normal number of parathyroids may be diminished to three, two, or even one. In some such cases, however, it is not easy to be certain that a minute ectopic gland may not have escaped notice. On the other hand the number may be increased, probably as a result of division of the original primordia. Thus five to eight—even in an extreme case as many as twelve—have been recorded: the distinguishing numerals are then applied to the gland-groups attributed to the respective pouches. Six per cent of subjects have only three parathyroid glands, and in 6 per cent also there are five (Gilmour, 1938).

The **superior parathyroid gland** is usually embedded in the capsule of the thyroid gland at the back of the corresponding lobe, about its middle. The **inferior parathyroid gland** is similarly embedded on the back of the lower end of the lobe (Welsh, 1898). As a rule the anastomosing arterial channel which connects the inferior and superior thyroid arteries passes near both parathyroids and furnishes the best guide to them; but the range of exceptional positions which the glands may occupy is wide. Thus, the superior parathyroid may be found (1) behind the pharynx or œsophagus, (2) in the fibrous tissue at the side of the larynx, above the level of the thyroid gland, (3) behind any part of the corresponding lobe of the thyroid gland (Fig. 699) or even embedded in the thyroid substance ("internal parathyroid")

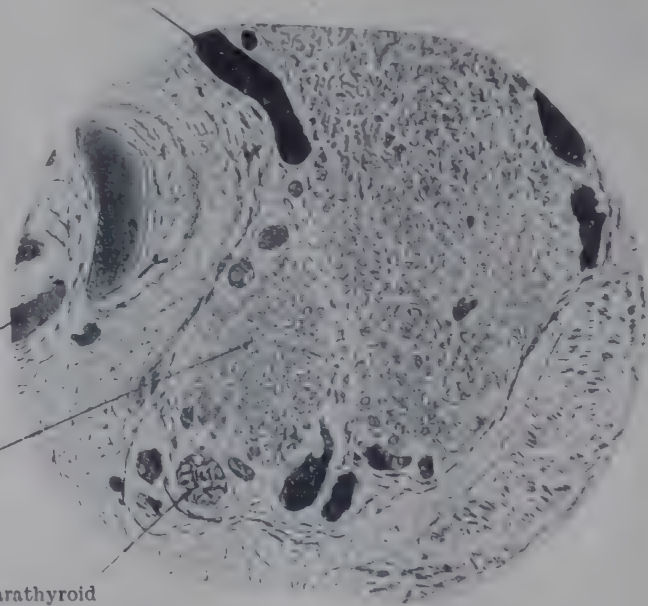

Fig. 699.—Oblique Section through Part of Trachea and Right Lobe of Thyroid Gland of Human Fœtus 60 mm. long, showing a Parathyroid embedded in the Capsule of the Thyroid Gland.

(Fig. 700); whereas the inferior parathyroid may be found (1) near the bifurcation of the common carotid artery, (2) behind any part of the corresponding lobe of the thyroid gland, (3) on the sides of the trachea, or (4) in the thorax close to the thymus. This wide range of variation in position is explicable by the close association of the inferior parathyroid with the main thymus element in development (see below).

Fig. 700.—Oblique Section through Part of Trachea and Left Lobe of Thyroid Gland of Human Fœtus 60 mm. long, showing a Parathyroid embedded in the Thyroid Gland.

Vessels and Nerves.—The **artery** to each parathyroid may spring from any branch of the *inferior* or *superior thyroid arteries*, but most commonly is a branch of the large anastomosing vessel between them. The **lymph-vessels** drain with those of the thyroid gland. The **nerve-supply** is abundant and comes from the plexus surrounding the thyroid gland (*v. supra*). The parathyroids produce their hormone after transplantation; the nerves are apparently vasomotor and not secretory.

Structure. — The parathyroids are built up of interconnected trabeculæ of epithelial cells with only a little vascular tissue between them. Sometimes the cellular arrangement is of a more compact character, or again, some of the cells may be arranged in follicle-like clumps enclosing a colloid material (devoid of iodine). The "principal" cells, which contribute the majority, are large and clear; but, after the age of eight or nine, some of the cells contain acidiphil granules and are believed to be degenerating principal cells (Morgan, 1936).

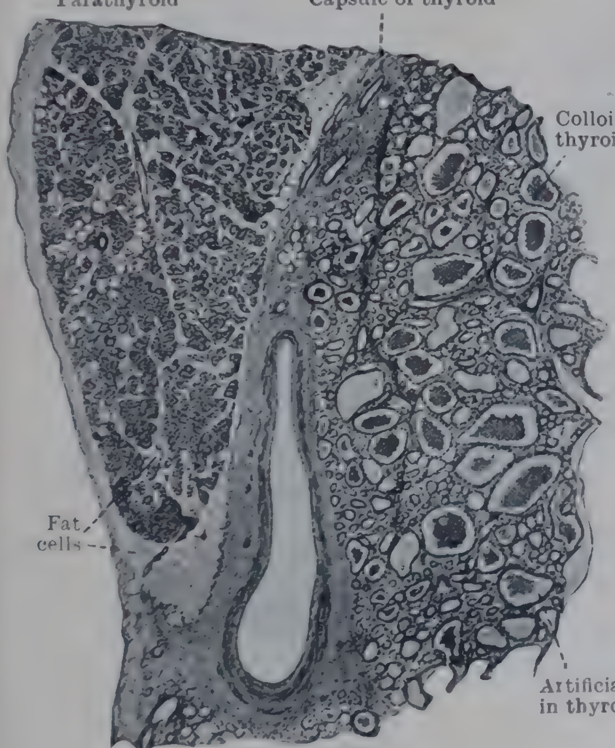

Fig. 701.—Section through Thyroid and Parathyroid Glands (Maximow and Bloom, *Text Book of Histology*, after Braus).

Development. — The parathyroid glands develop from the dorsal diverticula of the third and fourth pharyngeal pouches (Fig. 696). The first indication of their development is a proliferation and thickening of the epithelium on the cephalic and lateral aspects of the diverticula. This thickening may be seen as early as the 10 mm. stage. Its cells are vacuolated, difficult to stain, and indistinct in outline. Cords of cells grow out from the thickening, and fibrous tissue penetrates between the outgrowing cords, which soon lose their connexion with the pharynx.

Parathyroid III—the inferior parathyroid of the adult—is normally drawn by the thymus, as it migrates, caudal to parathyroid IV. As a rule it halts at the level of the lower end of the lobe of the thyroid gland, but may continue its descent into the thorax. On the other hand it may not descend at all. In the latter case it remains near the bifurcation of the common carotid artery, where it is liable to be mistaken for the carotid body. (For details of development, consult Norris, 1937.)

Comparative Anatomy.—Parathyroid glands occur throughout the Tetrapoda (p. 810). In some reptiles they are stated to develop from the second pharyngeal pouch as well as from the third and fourth. In certain mammals, *e.g.*, the mole, only those which are formed from the third pouches are developed.

History.—The parathyroid glands are notable historically as the last of the essential organs of the higher vertebrates to be described. They were discovered in 1877 by Ivar Sandstrom,

then a student of Medicine in Upsala. He published his account in 1880 (when he was Prosector in the Department of Anatomy at Upsala) with illustrations of the glands in the dog, cat, ox, horse, rabbit, and Man.

THYMUS

The **thymus** is situated in the superior mediastinum between the sternum and the great vessels; and it usually extends down for a short distance into the anterior mediastinum in front of the pericardium. In the new-born child (in which it is relatively much larger than in the adolescent or adult) it commonly extends laterally between the thoracic wall and the anterior borders of the pleuræ and lungs (Fig. 702).

The thymus is essentially an organ of the growth-period of life. In the course of a few years after birth it shows a rapid diminution in the rate of its growth; but it continues to grow until puberty, and it is only after that period of life that it undergoes a gradual diminution in size (Young & Turnbull, 1931).

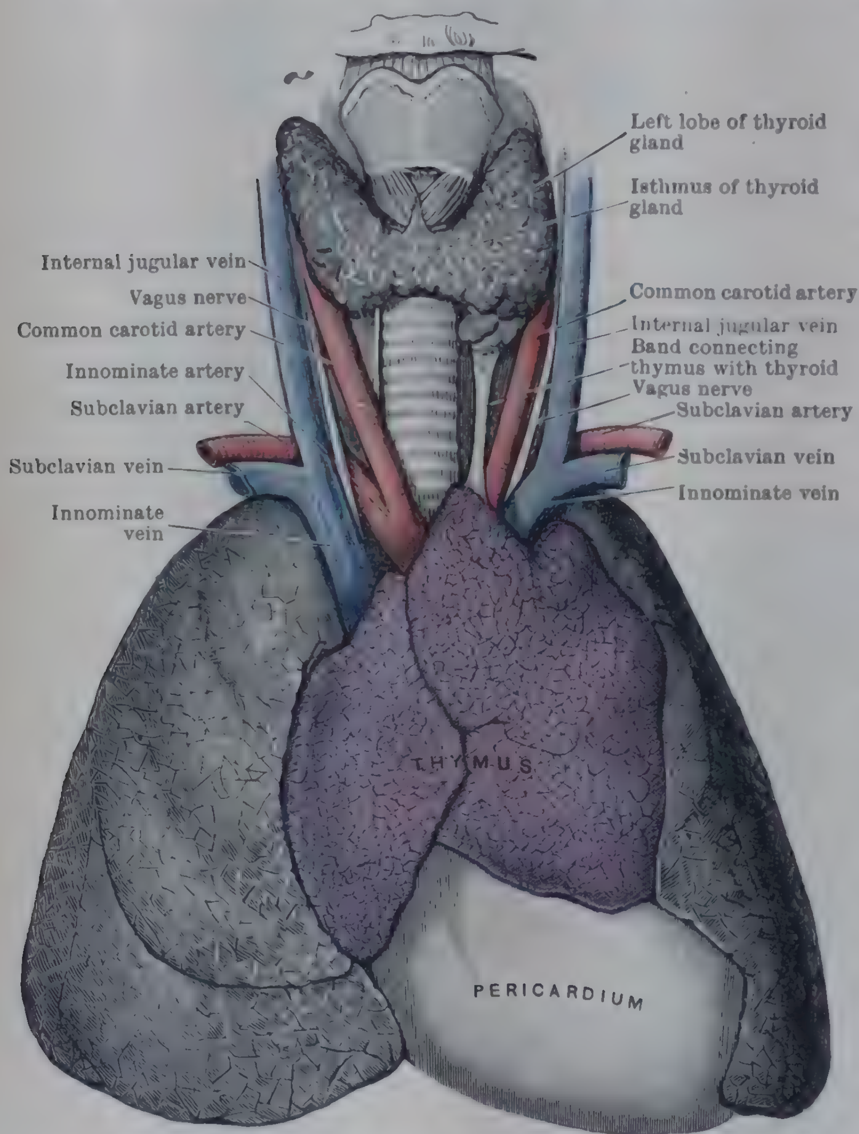

Fig. 702.—Thymus and Thyroid Gland in a Full-Time Fœtus hardened by Formalin Injection.

During the period of its fuller development the thymus appears as a pinkish mass (yellower in later life), consisting of a pair of laterally compressed, more or less pyramidal, asymmetrical lobes. The lobes are connected with each other, not by any bridge of glandular tissue but by areolar tissue.

The surface of the organ, in the young, more actively glandular condition, is finely lobulated.

The thymus is soft in consistence, and the details of its shape are determined by its size and by the structures upon which it is moulded, namely, the pericardium and the great vessels of the superior mediastinum and the root of the neck. Its shape varies with its size and the age of the individual. In infants (with short thoraces) it is broad and squat; in adults (with long thoraces) it is drawn out into two irregular but more or less flattened bands (Fig. 703).

It is in relation posteriorly from below upwards with the pericardium, ascending aorta, left innominate vein and the trachea with inferior thyroid veins. Anteriorly it is related to the sternum and the lower ends of the sterno-thyroid muscles. In the young child the lateral margin is insinuated between the pleura and the upper costal cartilages, intercostal spaces and internal mammary artery.

There is great individual variation in its size at any given age. Thus, at birth it ranges in weight from 2 to 17 gm. with an average of about 13 gm. At puberty the thymus is usually at the height of its development with an average weight of 37 gm.; but sometimes it has already undergone considerable retrogression. In the young adult the average weight is reduced to about 25 gm. even at the age of 30, but the organ is occasionally still quite large.

In old age it commonly weighs only about 10 gm. These age-changes point to some relationship with growth and the attainment of maturity (see Structure, p. 820).

Variations of the form as well as in the size of the thymus sometimes occur,

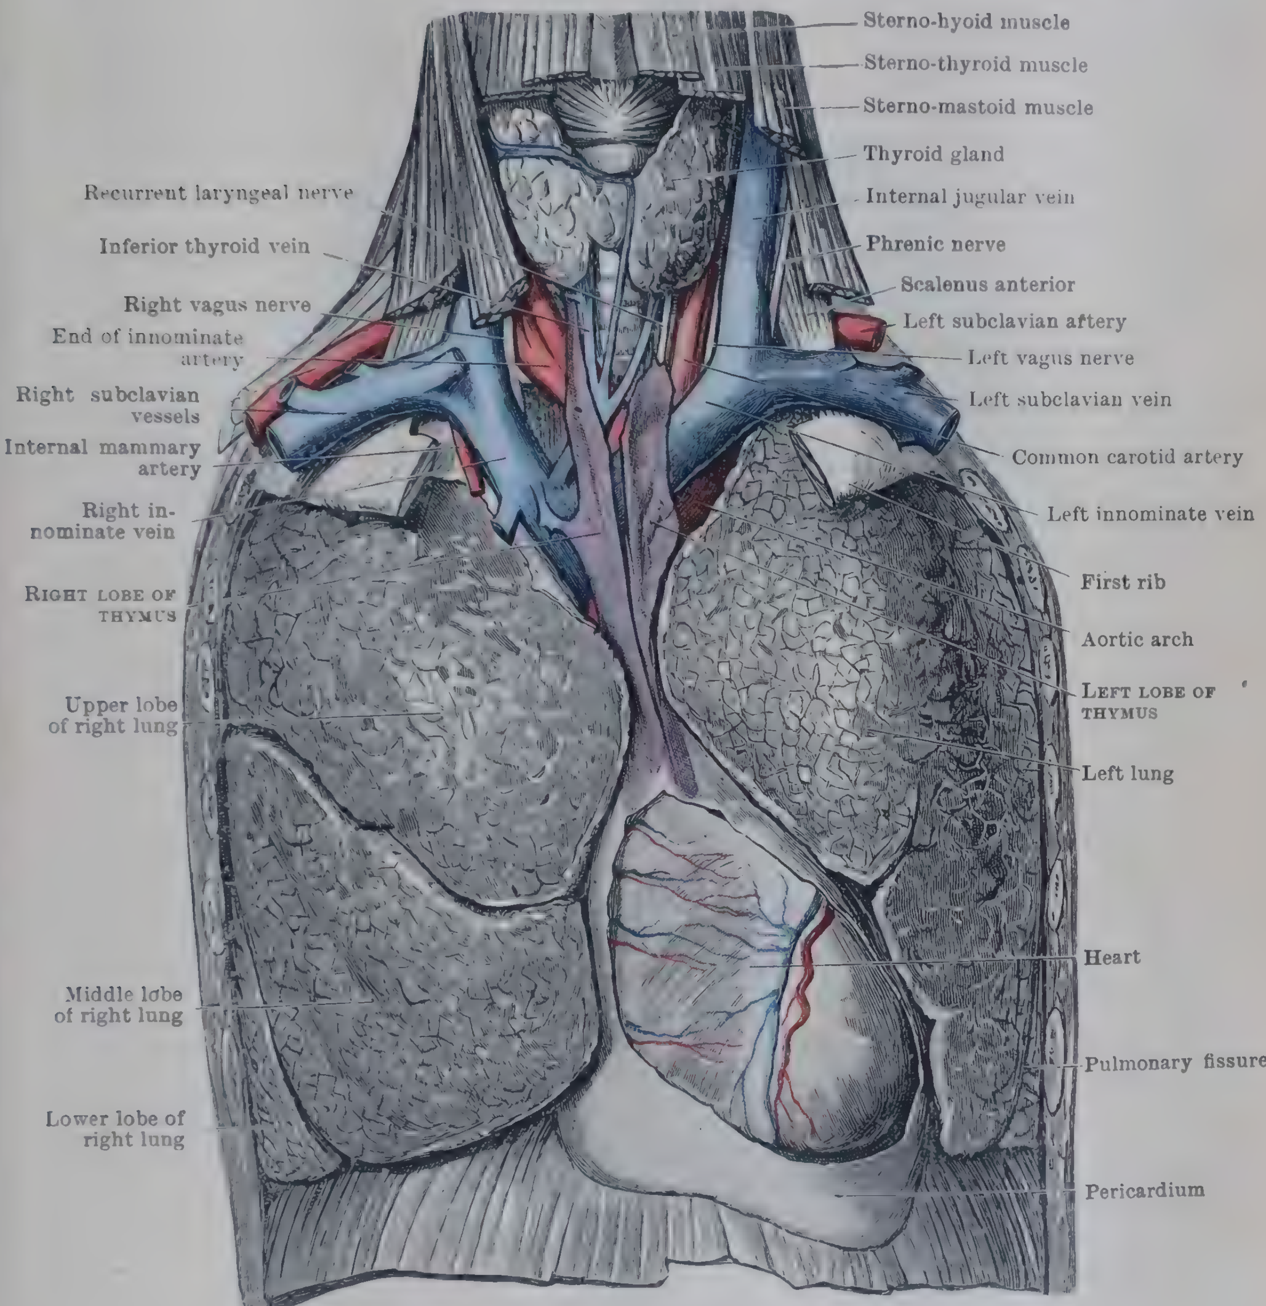

FIG. 703.—DISSECTION TO SHOW THYMUS IN AN ADULT FEMALE.

attributable to a partial persistence of the slender stalks by which at first the developing thymus remains attached to the third pharyngeal pouches. Thus, the thymus may exhibit slender prolongations into the neck on each side, antero-lateral to the trachea. These processes may be connected to the lower parathyroid glands by strands of fibrous tissue (Fig. 705); or again, the whole of the cervical processes may be represented by fibrous strands (atrophic cervical thymus). An isolated portion of thymus tissue may persist in close relation with the lower parathyroid (accessory cervical thymus III).

Vessels and Nerves.—The **arterial** supply of the thymus is effected through inconstant branches, chiefly of the *internal mammary arteries* and their branches. Its **veins** are irregular and mostly join the internal mammary and left innominate veins. Its **lymph-vessels** are abundant. Although they are not related to the organ in the same manner as in a lymph-gland,

they have been found filled with lymphoid corpuscles presumably derived from the gland. They enter the *innominate lymph-glands.*

Its **nerves** are minute and are derived from the vagus and the sympathetic. The branches of the *vagus* descend directly to the thymus from about the level of the thyroid cartilage; the *sympathetic* fibres run with the blood-vessels. The fibrous capsule of the thymus receives small irregular branches from the phrenic nerves, but they do not supply the gland-tissue.

Structure.—The thymus is invested by a fibrous capsule which sends septa into its substance between its constituent lobules. The two "lobes", though really independent paired glands, are also bound together more or less intimately by their capsular investments. If the young gland is dissected so as to liberate its *lobules* from the fibro-areolar tissue between them it will be found to consist of an elongated series of lobules, each connected with a central parenchymatous cord along which they are arranged in irregular necklace fashion. The cord, mainly

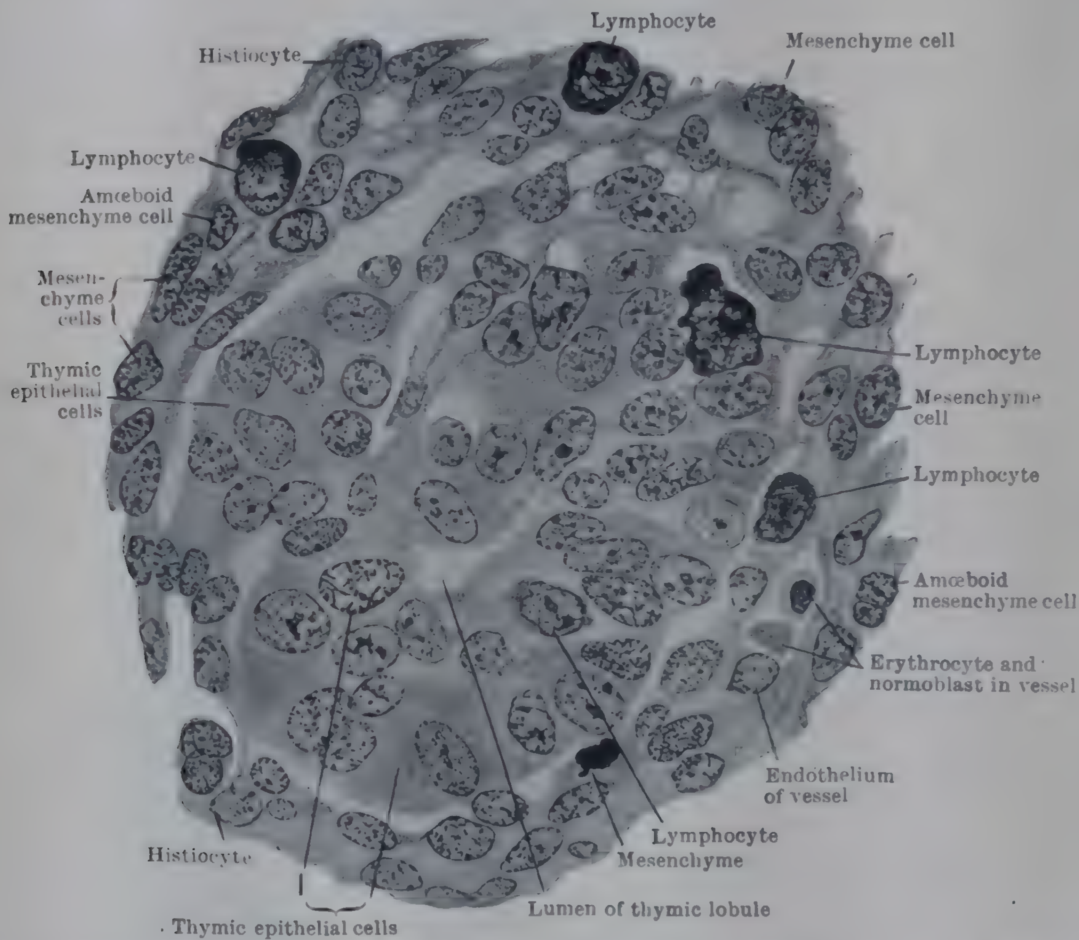

FIG. 704.—SECTION OF EMBRYONIC THYMUS OF RABBIT. (Maximow and Bloom, *Text Book of Histology.*) A hollow lobule is surrounded by mesenchyme in which some histiocytes of the reticulo-endothelial system are seen. Lymphocytes are present both around and among the thymic epithelial cells.

of medullary substance, represents the original thymic diverticulum of which the lobular masses are secondary derivatives.

The lobules of the thymus are further subdivided into *secondary lobules* which average a little over a millimetre in diameter. They are imperfectly separated from one another by delicate areolar tissue. These are the units of thymic structure: each shows a cortex and a medulla. The *cortex* consists of closely packed lymph-cells ("thymocytes") embedded in a delicate fibrous reticulum. It contains no lymph-vessels. The cortex completely surrounds the medulla, which is continuous with that of adjacent lobules and, through the lobular stem, with the central cord of the gland.

In its intimate structure the *medulla* differs from the cortex in the presence of many reticular cells and fibres but only few lymphocytes. The medulla, further, contains the so-called "corpuscles of Hassall", which are concentrically arranged nests of epithelioid cells varying in size from about 25 to 75 μ in diameter. The central cells often show granular degeneration. They vary in number not only in different individuals but also at different periods of life. In a general way the structure of the thymus follicle resembles that of a lymph-gland, but there are neither lymph-sinuses nor germinal centres. The vascular tissue elements and some associated areolar tissue are derived from invading mesenchyme during the course of development.

The thymus appears, then, to have some special relation with the cellular constituents of the vascular system. It has been claimed that it has an endocrine function with an influence on the growth of the gonads; and there is little doubt that it plays a part in regulating the growth of the body as a whole (Rowntree *et al.*, 1935). The process of involution, by which there comes

about a great reduction in the size of the gland after puberty, is influenced by the secretions of various endocrine glands. A persistently enlarged thymus is associated with delayed sex-development and obesity.

Development.—As has been stated, there are in reality two organs. The paired thymus glands, or "lobes", right and left, arise from the ventral diverticula of the third pharyngeal pouches and the adjacent cervical sinus (p. 811). The first indication of the thymus is seen in the 9 mm. embryo, when the third pouch has developed a caudally-directed cylindrical elongation. At this stage the part of the cervical sinus adjacent to the pouch remains connected to the exterior by a narrow stalk only, which is immediately afterwards interrupted, leaving a "cervical vesicle" adjacent to the pouch.

The pharyngeal pouch at the 9 mm. stage displays a differentiation of the cells in its dorsal wall—the primordium of the parathyroid (III) gland. The remainder of the pouch-wall shows no specific histological differentiation. For a considerable time the only further sign of thymic development is seen in an extension of the area of contact of ectodermal cells of the cervical vesicle with the entodermal cells of the pharyngeal pouch.

The elongated thymic portion of the third pouch migrates tailwards to reach the pericardium at the 15 mm. stage. As a result of the migration the upper part becomes drawn out and normally disappears. It is in that process that parathyroid III is involved; it is attached to the upper part of the migrating thymus—the part which disappears (Fig. 697). The relative time of the disappearance determines the permanent level of parathyroid III, for until it happens that gland is dragged in the wake of the thymus (see p. 817). Sometimes a small detached mass of formative tissue of the thymus may persist beside parathyroid III, and may differentiate to form an Accessory Cervical Thymus III (Fig. 705).

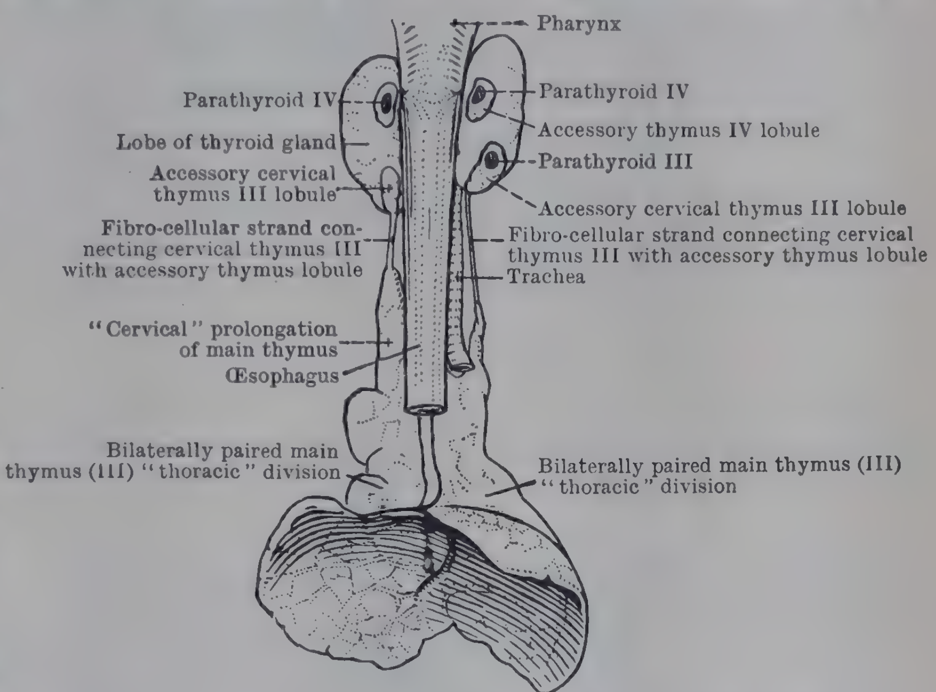

FIG. 705.—ILLUSTRATING ACCESSORY THYMUS LOBULES DESCRIBED BY GROSCHUFF (1900).

The thymus soon becomes isolated from the parathyroid (22 mm. embryo) and becomes a closely packed cellular mass. The mass of cells is penetrated shortly afterwards by mesenchyme and blood-vessels; and reticular fibres, apparently derived from the blood-vessels, make their appearance between endodermal cells (Norris, 1938). Thymocytes appear in the 8th week, probably derived from the invading mesenchyme. The differentiation of cortex and medulla is visible soon afterwards. The concentric corpuscles are derived from the endoderm of the pharyngeal pouch.

The growth of the thymus and its involution after puberty have been described above (p. 818).

THYMUS IV VESTIGES (*vide* Fig. 705).

Small accessory masses of thymus tissue are, in very rare instances, found in close relation to parathyroids IV. They are developed from the ventral diverticula of the fourth pharyngeal pouches in a manner generally similar to that in which the main thymus gland develops from the third. Although extremely rare in Man, such accessory thymic derivatives from the fourth pharyngeal pouch are not uncommonly met with in other mammals. They must not be confused with the accessory thymic lobules referred to in the preceding paragraph, which are to be regarded as detached portions of the cervical part of the main thymus. The accessory thymus IV may, as in some animals (*e.g.*, the cat), be enclosed, along with an "internal" parathyroid IV, in the substance of the thyroid gland, thus forming a so-called "internal thymus".

Methods of Clinical Anatomical Examination.—In children the apex of the thymus extends above the level of the manubrium sterni; but it is only occasionally recognizable on palpation as a soft mass situated in front of the trachea slightly to the left of the median line and behind the infrahyoid muscles.

HYPOPHYSIS CEREBRI

The **hypophysis cerebri** is a small gland of duplex origin. It forms a median basal appendage of the hypothalamns, behind and below the optic chiasma

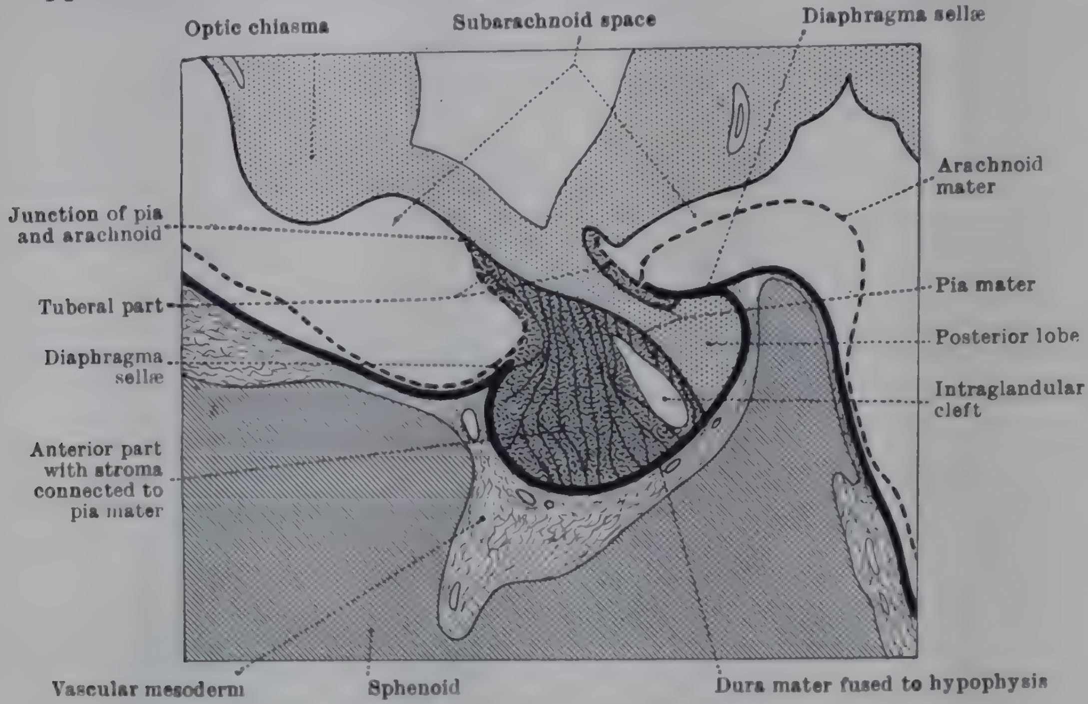

FIG. 706.—DIAGRAM OF RELATION OF MENINGES TO HYPOPHYSIS IN 160 MM. HUMAN FŒTUS. (After Wislocki, 1937.)

(Figs. 707, 708). It is lodged in the hypophysial fossa, between the cavernous sinuses and above the hinder part of the sphenoidal air-sinuses. It was formerly known as the *pituitary body* from an old notion that it secreted the nasal mucus.

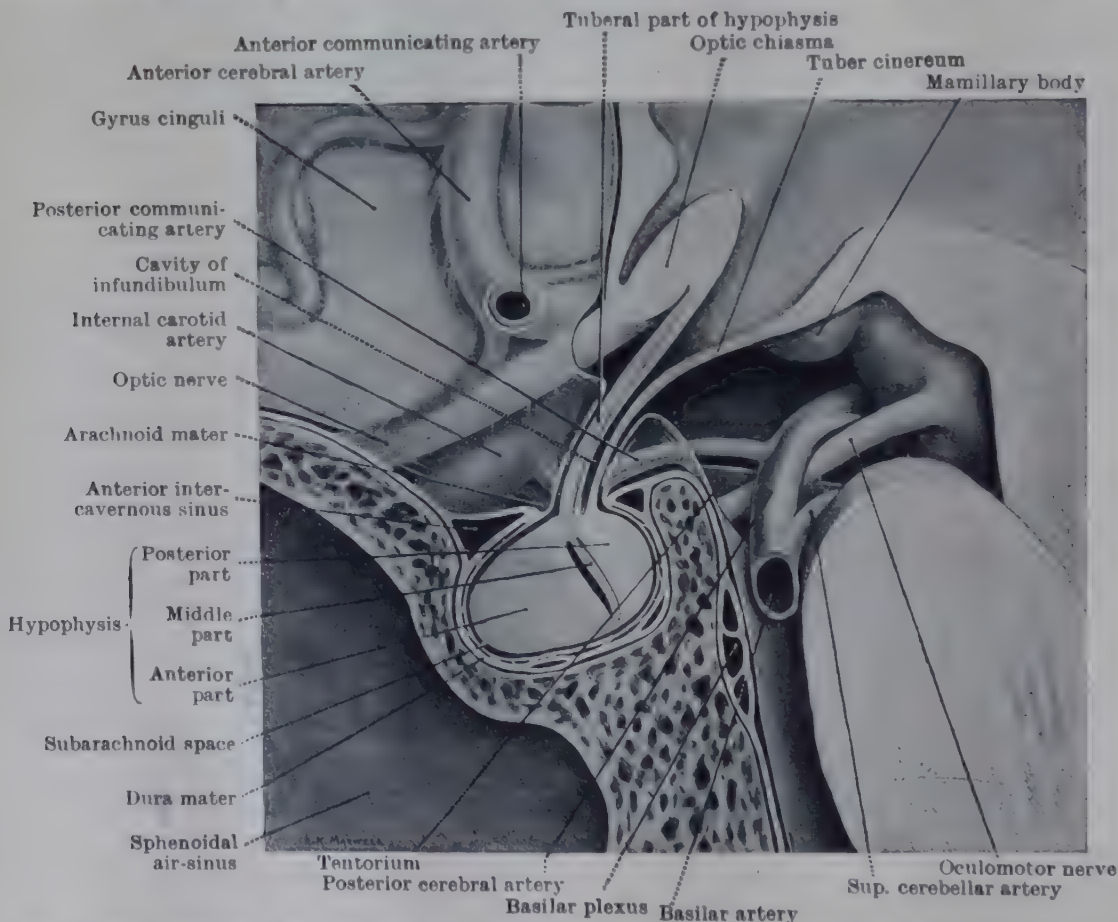

FIG. 707.—DIAGRAMMATIC MEDIAN SECTION OF HYPOPHYSIS *IN SITU*, SHOWING THE PARTS OF THE ORGAN AND ITS RELATIONS TO ADJACENT STRUCTURES. (The existence of a subarachnoid space around the gland in the hypophysial fossa is doubtful, cf. Fig. 706.)

Relations.—It occupies the hypophysial fossa (Pl. LXXIII, p. 944) between the dorsum sellæ behind, and the tuberculum sellæ in front. This cavity is lined with dura mater and roofed over by the diaphragma sellæ. According to Wislocki (1937), no separate arachnoid or pial covering is formed around the hypophysis (Fig. 706) below the level of the diaphragma sellæ (see Development, p. 827). Through a small aperture in the diaphragma sellæ, the infundibulum connects the main portion of the hypophysis with the tuber cinereum of the floor of the third ventricle. The cavernous sinus is lateral to the hypophysis, and the intercavernous sinuses pass below, behind, and in front of it. The internal carotid artery, in the cavernous sinus, is a fairly close lateral relation to the hypophysis, and more distantly, to the lateral side, are situated the oculomotor, trochlear, and abducent nerves and the ophthalmic division of the trigeminal nerve. The anterior part of the diaphragma sellæ intervenes between the anterior part of the hypophysis and the optic chiasma, which, however, is about one-third of an inch above the diaphragma. The interpeduncular cistern, with the contained circulus arteriosus, surrounds the infundibulum above the diaphragma sellæ. The sphenoidal air-sinus is situated below and in front of the hypophysial fossa, separated merely by a thin wall of bone; if small, it is an antero-inferior relation only. The close proximity of important structures to the hypophysis accounts for various symptoms associated with pathological enlargement of the gland (as in acromegaly). Enlargement of the anterior part of the hypophysis tends to thrust the forepart of the diaphragma sellæ upwards and to cause bitemporal hemianopsia through pressure on the more anterior fibres in the optic chiasma. An enlarged hypophysis sometimes also gives rise to symptoms which are due to encroachment upon the roof of the sphenoidal air-sinus or to pressure upon the cavernous sinus and the oculomotor and abducent nerves. Enlargement may be recognized radiographically through the expansion of the hypophysial fossa produced by it.

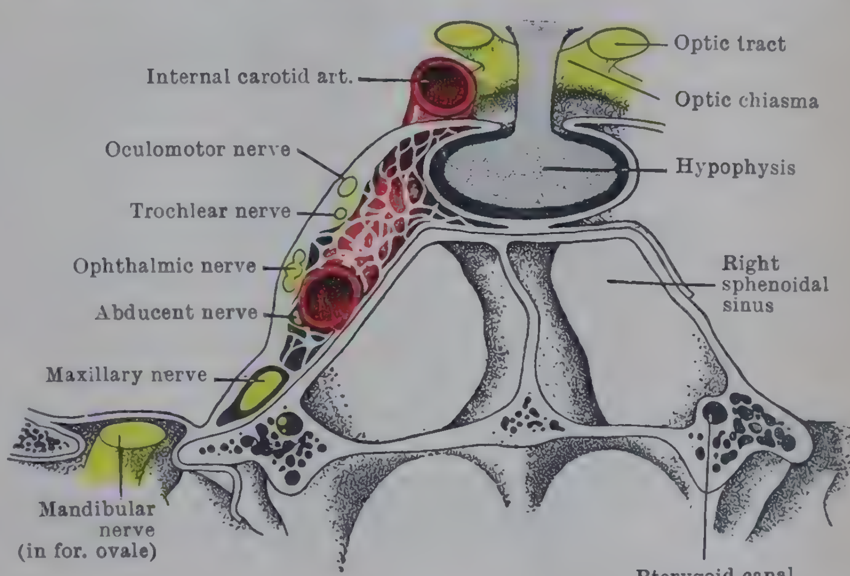

Fig. 708.—Diagrammatic Coronal Section through Cavernous Sinus showing the Relations of the Hypophysis. (Beesly and Johnston's *Manual of Surgical Anatomy*.)

The hypophysis is a rounded structure with the following average dimensions: 14 mm. transversely, 9 mm. antero-posteriorly, and 6 mm. vertically. It usually weighs a little over half a gramme. It undergoes some enlargement during pregnancy.

The following parts are distinguished (Figs. 707, 711):—

ANTERIOR LOBE: (1) Anterior part; (2) Tuberal part; (3) Middle part.

POSTERIOR LOBE: (4) Posterior or "nervous" part.

The **anterior part** of the anterior lobe forms the greater part of the entire gland and comprises its anterior and lateral portions (Fig. 712). It is separated (at any rate until middle age) by a cleft from the **middle part**, which is a very thin layer of tissue applied to the surface of the **posterior lobe** (Fig. 707). The **tuberal part** is a thin layer of tissue which encircles the front of the infundibulum, and extends as far as the tuber cinereum. When the infundibulum is cut across in the removal of the brain, most of the tuberal part usually remains adherent to the tuber cinereum. The weight of the middle part ranges

from $\frac{1}{2000}$ to $\frac{1}{50}$ gm. The anterior part weighs over half a gramme, and slightly more in women; it is five times as large as the posterior part, which contributes most of the remainder of the entire organ.

The hypophysis comprises two parts of different developmental origin, distinguished as the anterior lobe and the posterior lobe (Fig. 710). The anterior lobe is derived from Rathke's pouch, a diverticulum of the oral (stomodæal) pit (p. 63), the posterior lobe from a diverticulum of the floor of the diencephalon. The two parts are different in structure and function, but the line of demarcation between them becomes obscured by their very intimate union, and the infiltration of the part of neural origin by cells derived from the part of oral origin (Fig. 713). The hypophysis occupies a position of pre-eminence in the endocrine system in virtue of the control it exerts over most of the other endocrine glands by means of the various hormones it produces. For this reason it has been termed the " Master Gland ".

Vessels and Nerves.—The anterior and tuberal parts of the gland have an abundant **arterial supply**; that of the middle and posterior parts is relatively poor. A branch of the *internal carotid* artery enters the gland on each side at the junction of anterior and posterior lobes, and is distributed to both lobes. Other small arteries arise from the circulus arteriosus and reach the gland by passing down the surface of the infundibular stalk. Blood leaves the gland by means of **veins**

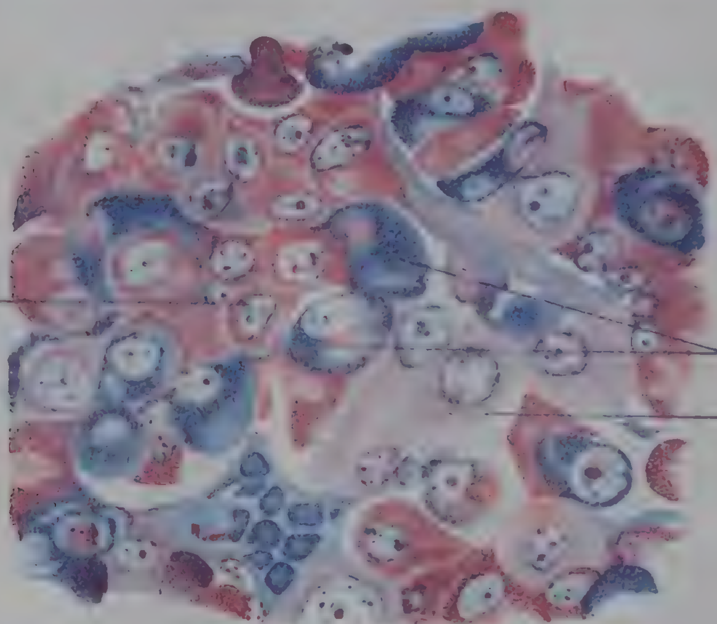

FIG. 709.—SECTION OF ANTERIOR PART OF PIG'S HYPOPHYSIS, stained with safranin-acid violet to show the three principal kinds of cell. (Maurer & Lewis, 1922.)

which pass into the *cavernous* and *intercavernous sinuses.* There is a series of fine channels in the walls of the infundibular stalk in which small particles of colloid are sometimes seen. According to Popa & Fielding (1930, 1933) these constitute a " portal " blood-system which conveys blood from the vessels of the hypophysis to a system of capillaries in the hypothalamus. Wislocki & King (1936), however, have adduced evidence which indicates that the flow of blood is in the reverse direction, viz., from the infundibular venules to the tributaries of the cavernous sinus; and this view has been confirmed by Harris (1947). **Lymph-vessels** have not been demonstrated in the gland.

The **nerves** of the anterior part are a rich supply of non-medullated fibres from the carotid plexus. While many of these are vasomotor in function, there are some nerve-fibres which have terminals in intimate relation with the epithelial cells and may be secretory in function. That the nervous connexions are not essential to all its endocrine functions is shown by the fact that grafts of the gland produce active secretions. The posterior lobe receives fibres from the supra-optic nucleus (Cajal) and from the paraventricular nucleus by a well-marked tract which runs along the infundibulum. The fibres end by forming a dense network around the small cells of the posterior lobe (see p. 825). Functionally there is a close connexion between the hypophysis and the hypothalamus (p. 948).

Structure and Function.—The *anterior part* of the **anterior lobe** is composed in the adult mainly of columns of epithelial cells supported by areolar tissue. In the central part of each half there is a vascular pocket of areolar tissue which contains vessels of considerable size. Capillaries pass from these vessels into intimate relation with the epithelial cells, and they eventually reach a vascular plexus on the periphery of the anterior part. The tubular arrangement of the epithelial cells seen in fœtal life disappears before birth. Vesicles of colloid

material are to be seen at all ages from the fourth month of intra-uterine life; colloid also appears in the intraglandular cleft.

Three principal kinds of cells are recognized: *Chromophobe, Acidiphil, Basiphil.* The chromophobe cells form about half the total number (Fig. 709); most of the remainder are acidiphils, basiphils forming only about one-tenth of the total.

The anterior part is known to produce numerous distinct hormones, several of which influence the activity of other endocrine glands. Since there are only three principal types of cell it is evident that one or more of them must produce more than one hormone. The growth-hormone appears to be derived from the acidiphil cells, and the hormone which influences the sex-glands from the basiphil. The precise source of the others is not known. The unequal distribution of basiphils and acidiphils in the anterior part (the former mainly peripherally and near the cleft) assists the comparative study of experimental injuries. Tumours consisting of the different types of cell produce different effects—basiphil ones causing obesity and various other changes, known collectively as Cushing's syndrome, acidiphil ones causing acromegaly. Various conditions have been recognized which appear to depend on hyposecretion, *e.g.*, the types of infantilism described by Simmonds and Lorain. A relation to periods of the œstrous cycle is indicated by the cyclic variations of cell-type in guinea-pigs. The condition of diabetes insipidus is thought to be due to a lesion of the posterior lobe or of the hypothalamus or of both.

Absence of the acidiphils is found to be related in mice to defect in respect of a certain gene; the effect on the sex-glands is then found to be present but not the growth-stimulating effect.

The *middle part* is almost avascular. It appears to be the least specialized portion of the hypophysis; it grows less, shows an accumulation of colloid, and occasionally has ciliated cells. No acidiphil cells are differentiated; chromophobes and basiphils are present. In the fœtus gland-tubules are present and open into the cleft, which is a vestige of the lumen of the buccal diverticulum (Rathke's pouch). These gland-tubules subsequently extend into the posterior lobe (Fig. 713); and basiphil cells also migrate from the middle part into the posterior lobe (Lewis & Lee, 1927).

The *tuberal part* consists mainly of small basiphil cells with small accumulations of colloid.

The **posterior lobe** or "nervous part" consists of a mass of neuroglia, and of small cells that resemble neuroglial cells. The invasion of this part by gland-tubules and basiphil cells from the middle part of the anterior lobe has been mentioned above. Thousands of nerve-fibres enter it from the hypothalamus; interruption of continuity gives rise to diabetes insipidus (p. 948). Small hyaline bodies described by Herring (1908), are found among these fibres (see Development, p. 827). Potent hormones are produced in the posterior lobe; *vasopressin* raises the blood-pressure and *oxytocin* causes uterine muscle to contract. It is not known whether the immigrant basiphil cells have the same function as those of the anterior lobe.

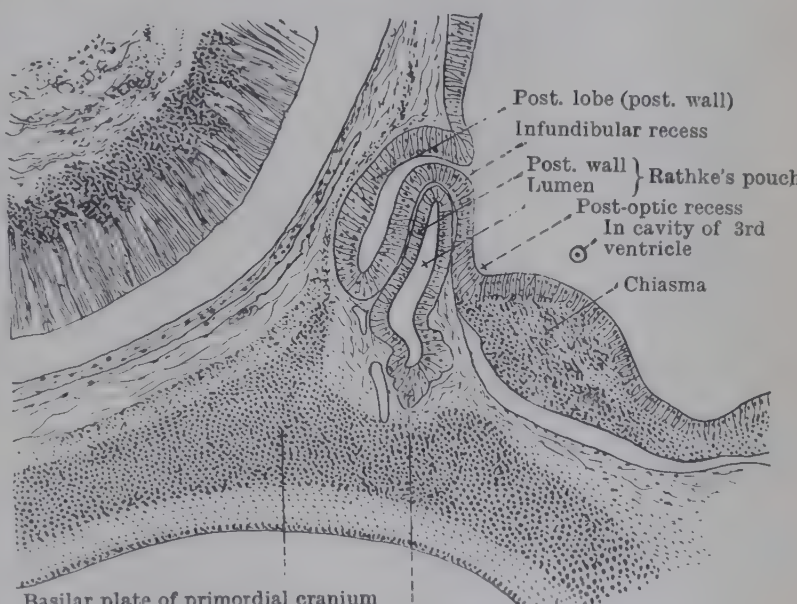

Fig. 710.—Paramedian Sagittal Section of Hypophysial Region of a Human Embryo (20 mm. CR Length).

Development.—As already mentioned, the hypophysis originates from two entirely distinct rudiments. Both of these are hollow ectodermal diverticula, one neuro-ectodermal, derived from the floor of the primary fore-brain, the other from the ectodermal lining of the primitive mouth-cavity. The buccal diverticulum, known as "Rathke's pouch", gives origin to the whole of the anterior lobe. The other diverticulum gives origin to the posterior lobe and the infundibulum.

The first indication of the appearance of the hypophysis is met with in embryos of 2-3 mm. in the shape of an angular depression at the bottom of the oral pit (p. 63) immediately in front of the dorsal attachment of the bucco-pharyngeal membrane. It deepens progressively, and in the 7 mm. embryo it has become a deep and wide saccular diverticulum, compressed antero-posteriorly, and opening by an aperture of equal width into the primitive mouth-cavity. The earliest indication of the appearance of the posterior lobe is a slight funnel-like depression in the floor of the fore-brain vesicle (Fig. 87, p. 71) in the 4-5 mm. embryo. At the 10-12 mm. stage the recess has become deeper and more sharply marked, and its anterior wall is already in close apposition with the fundus of the saccular anterior lobe. After the 12 mm. stage the portion of the buccal diverticulum nearest its mouth rapidly narrows and elongates to form a slender tubular stalk. By the stage of the 20 mm. embryo this stalk has become interrupted,

separating the embryonic anterior lobe from its original connexion with the epithelium of the mouth. Remnants of the obliterated stalk persist, not only at that stage but up to much later periods of intra-uterine life, and may sometimes be detected in the postnatal period. In some cases the basilar plate remains incomplete immediately around the stem of the hypophysis, so that a cranio-pharyngeal canal may be found later in the osseous cranial base and sometimes even containing vestiges of the epithelial tissue of the stalk.

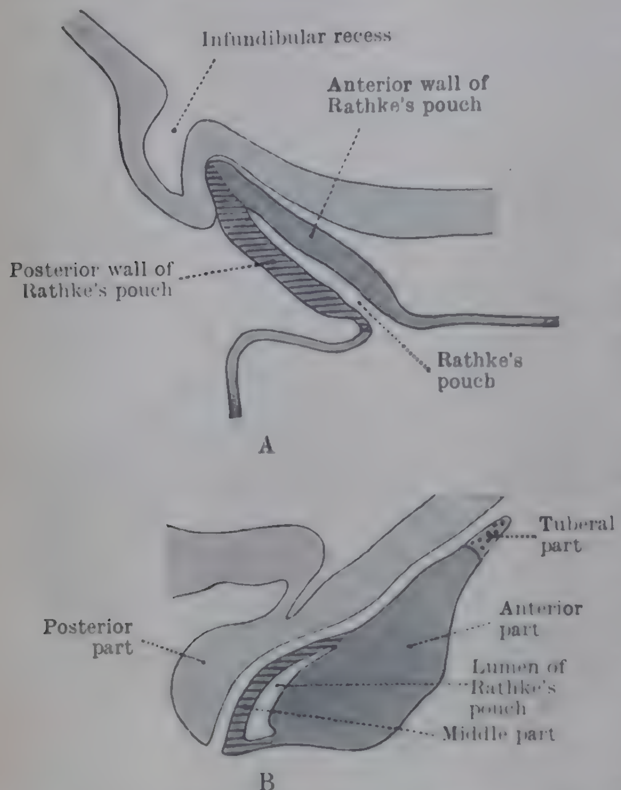

FIG. 711.—DIAGRAMMATIC MEDIAN SECTIONS OF HYPOPHYSIS IN EARLY STAGES OF DEVELOPMENT, showing (A) approximation of the infundibular recess to Rathke's pouch, and (B) the origin of the various parts of the organ. The posterior wall of Rathke's pouch develops into the middle part of the hypophysis, its anterior wall into the anterior and tuberal parts.

At the end of the second month the anterior lobe is a broad compressed sac, deeply notched for the reception of the posterior lobe. On each side of that notch the fundus of the sac is prolonged backwards in the form of paired hollow cornual extensions of the anterior lobe at the sides of the neck of the posterior lobe (they are already conspicuous in that situation in transverse sections as early as the 14 mm. stage). At the two-months period the original anterior surface of the sac has become secondarily cupped, its concavity now looking towards the floor of the brain in front of the infundibular region. The concavity is partially divided by a prominence in the middle into two fossæ which are occupied by tissue continuous with the surrounding mesoderm. These fossæ are presently invaded by the proliferating glandular cell-cords of the anterior wall of the sac during the process of formation of the anterior part of the organ. The bilateral pockets of areolar tissue, representing these mesodermal accumulations, were noted on p. 824 in the course of the description of the anterior part of the adult gland.

The recurved margin of the anterior lobe extends forwards and upwards towards the brain and eventually reaches the tuberal region of the floor of the diencephalon, where it spreads out to a greater or lesser extent as the tuberal part.

Up to about the 20 mm. stage the wall of the anterior lobe preserves its simple epithelial character. Already, however, it has begun to show indications of a process of proliferative budding (Fig. 710) and in this manner the cell-cords become intermingled with highly vascular mesenchyme which will form the sinusoidal stroma of the fully developed anterior part. In a fœtus of the third month (Fig. 712) the epithelial posterior wall of the anterior lobe is closely applied to the anterior surface of the posterior lobe and shows very little, if any, proliferative increase in thickness. It is this epithelial lamina which forms the middle part of the anterior lobe. In front of it the lumen of the anterior lobe of the hypophysis is still quite roomy. Later, it undergoes reduction and at least partial obliteration, for the "intraglandular cleft" or clefts which represent it become occupied by globules and irregular masses of colloid. The lumen shown in Fig. 712 does not, however, represent the whole of the earlier cavity of the anterior lobe, for portions of the sac become involved in the proliferative activity that produces the solid tissue of the anterior part.

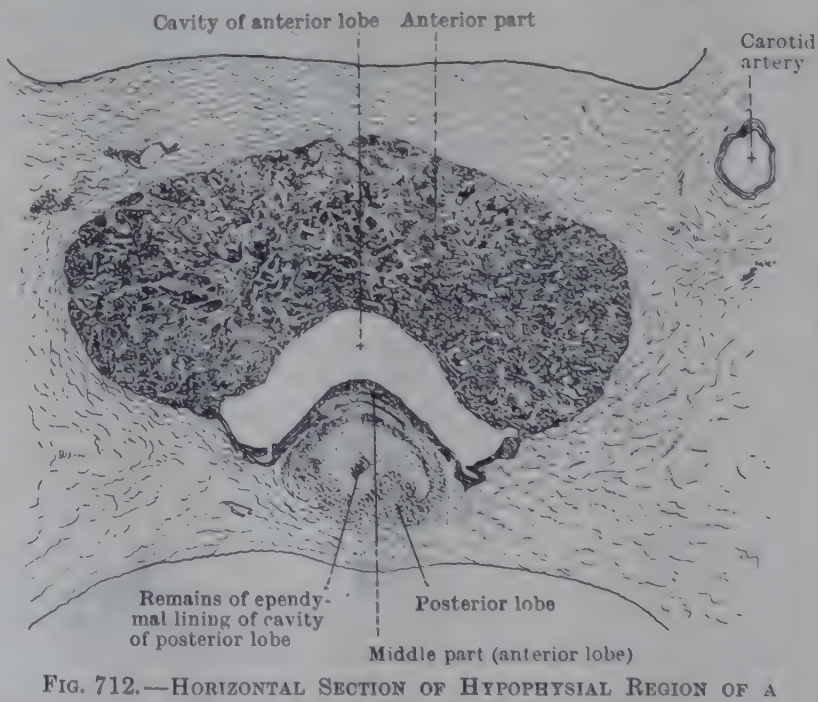

FIG. 712.—HORIZONTAL SECTION OF HYPOPHYSIAL REGION OF A HUMAN FŒTUS (71 MM. CR LENGTH).

During the course of development from the 20 mm. stage onwards the cavity of the posterior lobe in the human hypophysis tends to become obliterated, and finally the lobe becomes solid,

as does the infundibular stalk also. The lumen persists in the root of the stalk as the infundibular recess of the third ventricle.

In the later stages of antenatal growth there is a progressive invasion of the posterior lobe by glands and by basiphil cells that belong to the middle part of the anterior lobe, *i.e.*, to the posterior wall of the original buccal diverticulum. These glands undergo atrophy in the adult. The basiphil cells give rise to colloid and the hyaline bodies of Herring (1908), which have been supposed to consist of the same material in a different state. Replacement of worn-out cells is apparently not a feature of the adult hypophysis, for cell-division and degeneration of cells are seldom seen. The intraglandular cleft, commonly filled with colloid in the child, becomes obliterated in many adults, though in others it persists as a space still filled with colloid.

In the 20 mm. embryo the two lobes of the hypophysis are surrounded by mesenchyme, except where the infundibulum remains connected to the brain. This mesenchyme eventually differentiates into a lamina of dura mater which is firmly united both to the hypophysis and to the hypophysial fossa (Fig. 706).

Comparative Anatomy.—The hypophysis cerebri is an organ possessed of a very ancient history (de Beer, 1926). Its essential features are similar throughout the vertebrates, even those most primitive of all surviving vertebrates—the Agnatha (the class to which the Cyclostomata (p. 809) belong). An anterior lobe and a posterior lobe, developed in a manner similar to that described for Man, and with similar cellular constituents, are found in all of them. It has been settled experimentally that in the lower Tetrapoda (p. 810), *e.g.*, Amphibia, the hypophysis is an endocrine organ which produces hormones like some of those described in Man. The anterior lobe appears to have been originally an exocrine gland. Its essential cells are always developed from the epithelial wall of Rathke's pouch. In the Agnatha, as indeed in the modern fish *Polypterus* and probably also in various fossil ones, it remains in communication with the exterior throughout life, but the presence of masses of acidiphil and basiphil cells along the dorsal wall of the blunt end of the hypophysial sac suggests that already it possesses typical endocrine functions.

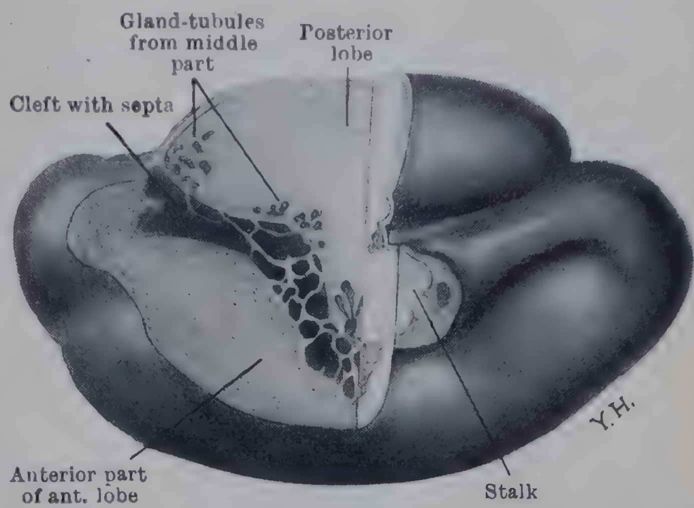

FIG. 713.—HYPOPHYSIS OF A CHILD, aged one year, with part removed to show the stalk and glandular tubules projecting from middle part of anterior lobe into posterior lobe (pars nervosa). (Lewis & Lee, 1927.)

This exocrine gland of the pre-vertebrates is perhaps represented by the ciliated organ of Müller in *Amphioxus*. To this organ endocrine functions were added in the evolution of the vertebrates, and an intimate relationship was established with the *neural hypophysis* or infundibulum, with the formation of the compound hypophysis characteristic of the vertebrates.

The actual orientation acquired by various parts of the hypophysis differs considerably in the various vertebrates. Thus, the anterior lobe of Reptilia acquires a position caudal and ventral to the middle part and posterior lobe. Amphibia exhibit a similar orientation of parts. In various Mammalia the hypophysis retains features which are lost in the course of human development. Thus, in the cat the posterior lobe remains patent and is lined with ependyma, and its cavity communicates with the third ventricle through a tubular infundibulum. Mammals differ greatly in the size and form of the middle part of the anterior lobe. It may, as in Man, form merely a thin sheet of tissue behind the intraglandular cleft. On the other hand, it may enclose the posterior lobe almost completely, as in the cat. Or it may be extremely thick, as in the ox.

PINEAL BODY

The **pineal body** is a small oval or cone-shaped structure, attached by a short, hollow stalk to the hinder end of the roof of the diencephalon, between the habenular and posterior commissures (p. 945 and Figs. 714, 764). It is moderately firm in consistence, reddish-brown in colour, and measures 5-10 mm. anteroposteriorly, 3-7 mm. in its other diameters. It weighs about one-fifth of a gramme. Much discussion has centred around its supposed endocrine function. There is, however, no definite evidence that it has any internal secretion; it appears to be a vestigial structure (see Comparative Anatomy). It commonly becomes calcified in middle age (see below).

Relations.—It is covered with pia mater, and it lies in the sulcus between the superior corpora quadrigemina. It is below the splenium of the corpus callosum,

from which it is separated by the great cerebral vein. Its posterior end is free, and is a short distance in front of the vermis of the cerebellum and the free edge of the tentorium (Fig. 827, p. 945).

The cavity of the stalk is the pineal recess of the third ventricle. On the dorsal lip of this recess is the habenular commissure. Immediately above the habenular commissure and the stalk of the pineal body is another and larger recess of the third ventricle called the suprapineal recess.

Structure.—The pineal body consists mainly of a mass of distinctive cells (the pineal parenchyma) interspersed with neuroglial cells. This tissue becomes divided into lobules by the ingrowth of septa of fibrous tissue from the pia mater—a process which takes place mostly during childhood. Vascularized fibrous tissue invades the organ during early intra-uterine life. The characteristic parenchyma-cells have long processes which end in bulbous extremities, some of which are on the surfaces of the lobules next to the intervening fibrous septa, and others within the lobule on the fibrous tissues which enclose the blood-vessels.

The body of each cell is rounded and has a large round nucleus and granular cytoplasm. They offer a marked contrast with nerve-cells—which are wanting in the pineal body except close to the habenular commissure. The granules of the cytoplasm have been claimed as being secretory in character, but they show no variation in number at different ages, nor does the pineal body display any differences in appearance under different physiological conditions. There is no evidence of histological change at puberty. Evidence in support of a suggested endocrine function is lacking. The non-medullated nerves which are found in the organ appear to be distributed to the blood-vessels. Calcareous deposits usually make their appearance in the organ from adolescence onwards, and the pineal body thus becomes visible in radiographs (Pls. LXXIII, p. 944, and LXXIV, p. 945).

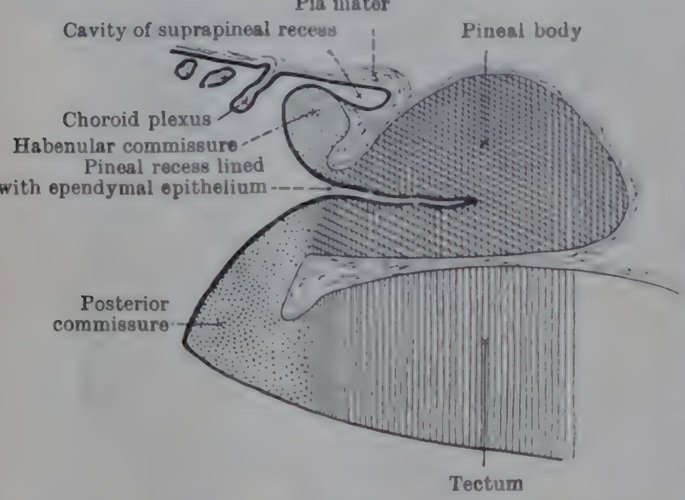

FIG. 714.—DIAGRAM OF MEDIAN SAGITTAL SECTION THROUGH PINEAL BODY AND ITS IMMEDIATE ATTACHMENTS.

Development.—The pineal body develops as a pouch-like evagination of the hinder part of the roof of the diencephalon, separated from the mid-brain by the posterior commissure only. Its epithelial wall becomes thickened, with restriction of the lumen to the stalk of attachment. Later, this epithelial mass is invaded by cellular sprouts from the ependyma around the cavity; these form the characteristic pineal parenchyma. Blood-vessels also invade the organ. The development of the septa takes place actively in early postnatal life.

Comparative Anatomy.—A pineal structure is present throughout the vertebrates. In certain groups (*e.g.*, Agnatha and certain Reptilia) it takes the form of a "pineal eye" or parietal organ. This organ may have a gland-like structure at its base similar to the mammalian pineal body. The pineal body of man is similar to that of other mammals. The reptilian forerunners of mammals also appear (from a study of their skulls) to have possessed a well-developed parietal organ.

The suprapineal recess is the vestige of a similar structure ("parapineal eye") which is situated in front of the parietal organ in certain vertebrates. There are grounds for believing that the parapineal and parietal organs were originally the left and right members respectively of a pair of organs, visual in function, in the pre-vertebrates. This view finds support in the nerve-connexions of the two organs. Further, certain fossil remains of the dermal roofing bones of primitive vertebrates show a pair of depressions which are believed to represent the position of these organs. (For further details, see the monograph by Gladstone & Wakeley, 1940.)

SPLEEN

The **spleen** (**lien**) (Fig. 715) is a soft, contractile organ of purplish colour. It is freely movable, situated far back in the upper part of the abdominal cavity on the left side, behind the stomach and in close relation with the diaphragm.

The spleen is the headquarters of the reticulo-endothelial cells or macrophages —that great system of scavengers that cleanse the blood. It acts as a great blood-filter in which a slowly moving stream of blood is brought into an intimate relation of unique character with tissue-cells and tissue-fluids, for the endothelial barrier between blood and tissue-fluid is here incomplete. Lymphoid tissue is present, but differs from that of the lymph-glands and lymphatic nodules

inasmuch as it is interposed in the arterial system and is not drained by lymph-vessels. The spleen serves also as a blood-reservoir on account of the large amount of blood it accommodates when expanded and the very material contribution it is capable of making to the amount of blood in the general circulation when it contracts. If removed from the living subject after ligation of its vessels it is found to be about three or four times as heavy as the spleen of the cadaver. The average weight after sudden death in the healthy subject (as after accidents) is about 150 grammes.

Form and Relations.—The form and position of the spleen are influenced largely by changes in adjacent structures. The stomach and colon show great variations of size, with corresponding effects upon its form; and the descent of the diaphragm during inspiration results in a downward displacement of the spleen. Notches are developed on the upper border, sometimes also on the lower border when the spleen is shrunken to a small size as in the cadaver: fissures, indeed, may extend across the diaphragmatic surface from the one border to the other. Two principal **surfaces** are recognized—the diaphragmatic and the visceral. The *diaphragmatic surface* is closely related to the under surface of the diaphragm. It is separated by upper and lower **borders** from the visceral surface. The *visceral surface* exhibits renal and gastric impressions separated by a more or less distinct but blunt border. The spleen has *medial* and *lateral* **ends**: the lateral end shows a flattening of varying extent—the colic impression — for the left flexure of the colon (Fig. 715). When the stomach is distended and the colon relaxed the spleen is similar in form to a segment of an orange, while distension of the colon causes it to assume an irregular tetrahedral form owing to the flattening of the lateral end. A *hilum* is recognized at the junction of the gastric, renal, and colic impressions. It is here that branches of the splenic artery enter the gland, and tributaries of the splenic vein leave it. At the hilum the spleen is moored by its peritoneum and its vessels to the fold of peritoneum which originally formed the dorsal mesogastrium; this constitutes its sole attachment. Elsewhere than at the hilum the spleen is completely invested with peritoneum which is firmly adherent to its capsule. The portion of the dorsal mesogastrium which is behind this attachment of the spleen is the lieno-renal ligament; the part in front is the gastro-splenic ligament. Exceptionally, the lieno-renal ligament is opened up so that the lower part of the renal impression comes into direct contact with the kidney. The tail of the pancreas makes contact with the spleen immediately below the lateral part of the hilum.

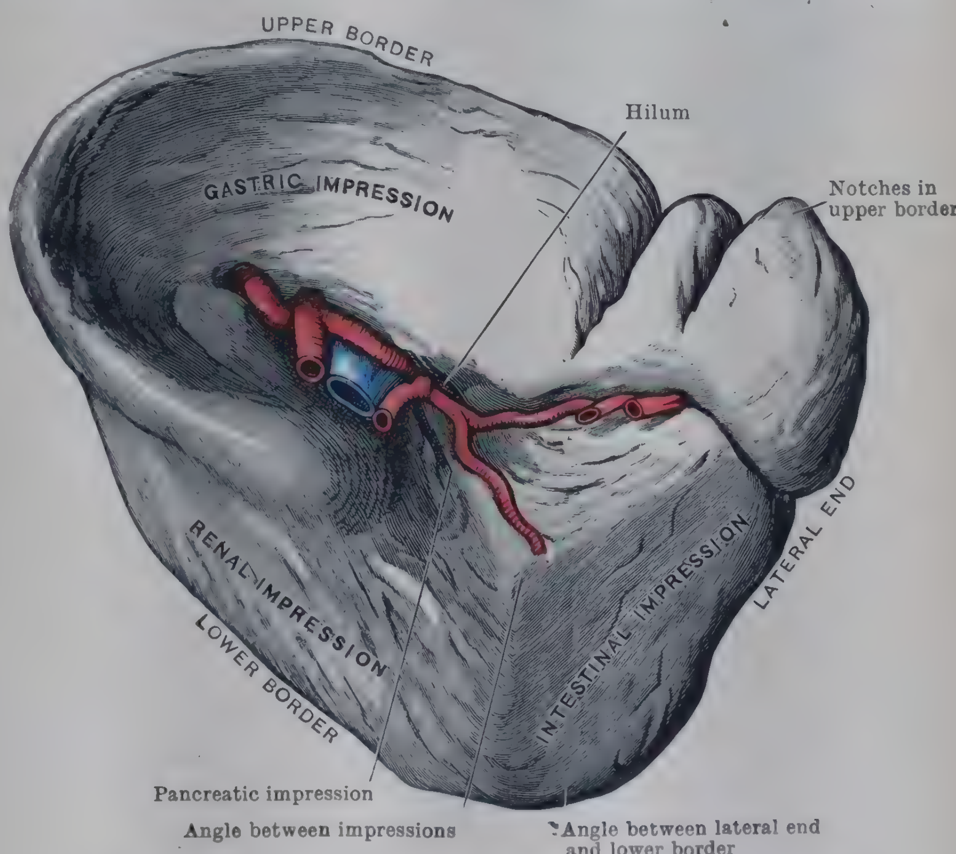

Fig. 715.—The Spleen—Visceral Aspect, Tetrahedral Form.

The *gastric impression* of the spleen lies against the upper part of the posterior

surface of the *stomach*, separated from it by the gastro-splenic ligament; the *renal impression* against the upper lateral part of the left kidney. In the young child the spleen touches the left suprarenal gland also. The *colic impression* rests upon the left flexure of the colon and the phrenico-colic ligament. The diaphragmatic surface is separated by the diaphragm from the pleura and the lower border of the lung. The medial end of the spleen is situated about one and a half inches from the median plane, at the level of the tenth thoracic spine in the cadaver and somewhat lower in full inspiration. The lateral end is just above the costal margin immediately behind the mid-axillary line. The long axis of the spleen is opposite the tenth rib (separated from it by diaphragm and pleura) when the body is in a supine posture, but in the erect attitude the long axis of the spleen tends to be more vertical, especially in women.

Fig. 716. — Sectional Surface of Adult Human Spleen, from which the Pulp had been removed by washing with Water so as to show the Arrangement of the Trabecular and Main Vascular Structures.

The size of the spleen is subject to great changes in life. It is a storehouse for blood and can expel its contents by the action of the muscle in its trabeculæ; it thus plays a part in the adjustment of circulating hæmoglobin to the needs of the body. Observation on the "exteriorized" spleen of the dog has shown that it exhibits reflex contraction in response to various stimuli. After a meal the spleen slowly increases in size for some hours and then gradually shrinks. Exercise diminishes the size. The living spleen exhibits slow rhythmic contractions, and it has been stated that these take place even when the nerve-supply is interrupted, as in the excised and perfused spleen.

Small rounded *accessory spleens* are often present, attached like the spleen to the dorsal mesogastrium, usually on the gastro-splenic ligament.

Radiographic Examination of Spleen.—The normal spleen may be visible radiographically if there are large amounts of gas in both the stomach and the left flexure of the colon. The spleen, like the liver, may also be made semi-opaque to the passage of X-rays by the injection of "thorotrast" into the circulation; but this is a very dangerous procedure and is rarely used clinically (see Appendix on Radiographic Anatomy).

Enlargement of the spleen may be diagnosed by downward displacement of the left flexure of the colon, and in such cases its outline may be seen in the radiograph.

Vessels and Nerves.—The spleen receives its blood from the **splenic artery**, which reaches it through the lieno-renal ligament. At the hilum the artery breaks up into six or more branches which enter independently. The **splenic vein** is formed within the lieno-renal ligament by the union of several tributaries which emerge from the hilum. By the splenic vein the blood is carried to the portal vein. The **lymph-vessels** also leave the spleen at the hilum. They are small and come only from the capsule and trabeculæ, not from the gland substance, which is devoid of lymph-vessels. They drain into the *splenic lymph-glands* placed near the hilum and into the *left suprapancreatic* glands.

The **nerves** are almost entirely non-medullated. They come through the cœliac plexus from the *greater splanchnic nerve* and possibly from the lesser splanchnic nerve. Some of these nerves are vasomotor in function; others supply the plain muscle of the organ. It is probable that *afferent* nerves pass from the spleen into the greater splanchnic nerve. The contractions of the spleen are in some circumstances brought about through the nervous system, but they take place also without its intervention, *e.g.*, the slow, rhythmic contractions. The strong contraction which takes place on stimulation of the greater splanchnic nerve is due in part to the action of the adrenalin liberated from the suprarenal glands.

Structure.—There is an elastic contractile framework of trabeculæ which radiate from the hilum to the surfaces, where they become continuous with the fibrous capsule (tunica albuginea). The trabeculæ contain plain muscle-fibres; and the larger arteries and veins pass along them from the hilum. The peritoneal covering (serous coat) covers almost the

whole organ and is firmly bound to the underlying tunica albuginea. The essential substance of the spleen is a spongy network of tissue together with small vessels. The ultimate subdivisions of the trabecular framework outline small areas of splenic pulp (lobules of Mall) (Fig. 717) which are most evident on and near the surface of the organ. These are about 1 mm. in diameter, irregular in shape and at best very imperfectly circumscribed. Each splenic lobule comprises a central *lymphatic nodule*—an irregularly ovoid mass, the "white pulp", and a surrounding marginal zone or "red pulp" which contains capillaries and a peripheral zone of venous sinuses. The lymphatic nodules vary in size from 0·2 to 0·7 mm., and they undergo individual alterations of size. Some atrophy takes place in middle age as in the lymphatic nodules elsewhere in the body.

Vascular pattern (Fig. 718).—*Arterial.* The lymphatic nodule is supplied by an artery which reaches it from the trabecular framework. It can contract sufficiently to obliterate its lumen. After giving rise to capillaries in the nodule it divides into branches which leave the nodule, and each branch divides into a few parallel "penicillate" vessels. These soon acquire

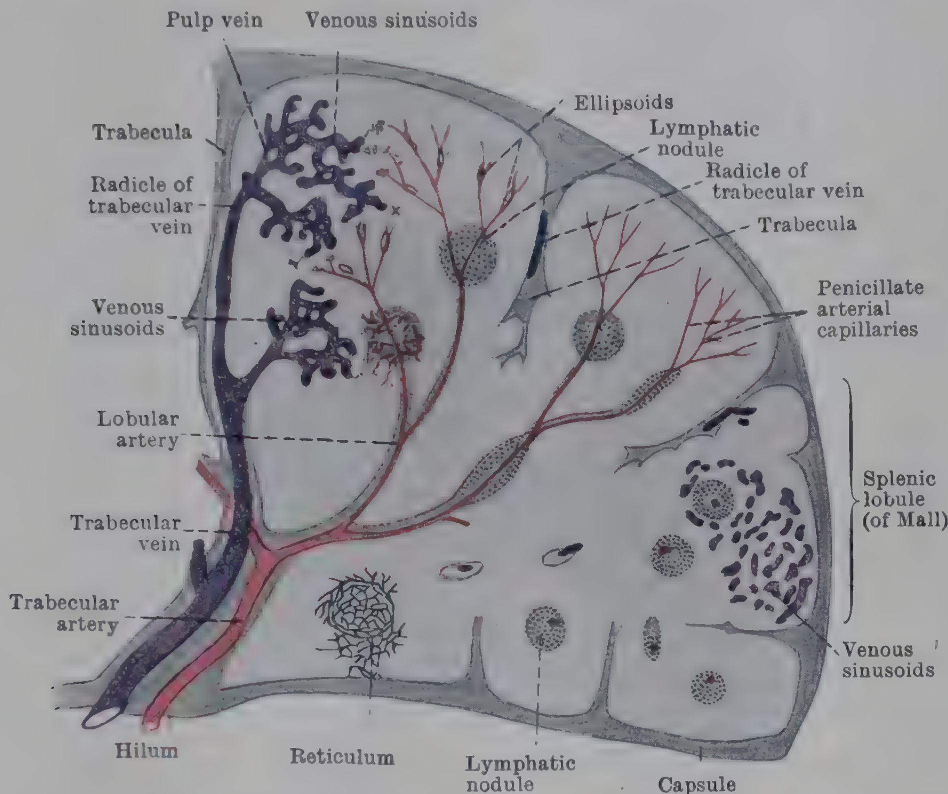

FIG. 717.—SCHEMATIC REPRESENTATION OF SPLENIC STRUCTURE, MUCH SIMPLIFIED BY THE SUPPRESSION OF RAMIFICATIONS OF THE TRABECULÆ AND VASCULAR TREE. (After Stöhr, *Lehrbuch der Histologie*, Fischer.)

NOTE.—Both the pulp-reticulum and the system of venous sinusoids supported by it must be understood as pervading the entire extent of the area figured except the trabeculæ and the splenic nodules; and, further, that the meshes of the reticulum itself are occupied by a varying content of red blood-corpuscles, together with various types of splenic cells.

thickened walls and have been termed "sheathed" arteries. A capillary network extends between capillary branches of the penicillate vessels and the capillaries of the lobule.

Venous. The sheathed arteries end in arterial capillaries. These are connected to the larger trabecular veins either (1) by means of long fine capillaries or (2) by bulbous venous sinuses, according to Knisely (1936) who has observed the circulation in the living spleen. He has described sphincter mechanisms in the sheathed arteries, and at the entrances and exits of the venous sinuses.

The venous sinuses may be expanded or narrowed and the spleen accordingly varies in size while the venous sinuses serve alternately as storage or as conducting structures. Red corpuscles pass through the walls of the venous sinuses into the intervening tissue (sometimes known as "pulp-cords"), and are thus "filtered" from the trabecular plasma. According to Knisely there is a complete endothelial lining to the vascular system of the spleen.

No special cells are found in the spleen which are not found elsewhere. The distinctive feature of the spleen is the large number of reticulo-endothelial cells (macrophages). The red pulp contains abundant red corpuscles, monocytes (often called splenocytes) and macrophages which are to be seen ingesting fragments of red corpuscles. Lymphocytes are formed in the lymphatic nodules, whence they migrate into the red pulp and finally reach the venous sinuses. The blood of the splenic vein contains many macrophages and is richer in lymphocytes than that of the splenic artery.

Reticulo-endothelial cells are found in the blood; they form the wall of blood-vessels in certain parts of the body; and they are found in the loose areolar tissues. They show great

differences of form in various places, and at different times; one morphological type will at times change into another type. They act as the scavengers of the body. They are engaged in the destruction of blood-cells, in bile-pigment production, in the metabolism of iron, fats, and proteins, in the elaboration of antibodies, and in the clearing of the body of bacteria, protozoa, and non-living bodies. In the blood they are represented by the lymphocytes and by the monocytes, which are perhaps derived from the lymphocytes. In the walls of blood-vessels, as *specific endothelial* or *reticular cells*, they lie in wait for foreign bodies where the blood-stream is slowed, as in the spleen, the lymph-glands and the sinuses of the liver (where they are known as the "stellate" cells of von Kupffer). Such endothelial cells are distinguished from ordinary endothelial cells in their phagocytic properties, and in the avidity with which they take up trypan-blue dye—a property in which they are like other reticulo-endothelial cells. Endothelial cells intermediate in properties between those of ordinary and "specific" endothelia also occur. Under certain conditions, indeed, ordinary endothelium acquires phagocytic properties. The distinction between the ordinary and specific endothelia is therefore not a hard-and-fast one.

Cells which belong to the reticulo-endothelial system are to be found also in the loose areolar tissues in the form of "histiocytes" or "resting wandering cells". These are the last to be mobilized when foreign matter in the circulation has to be dealt with; they may then migrate into the blood-stream.

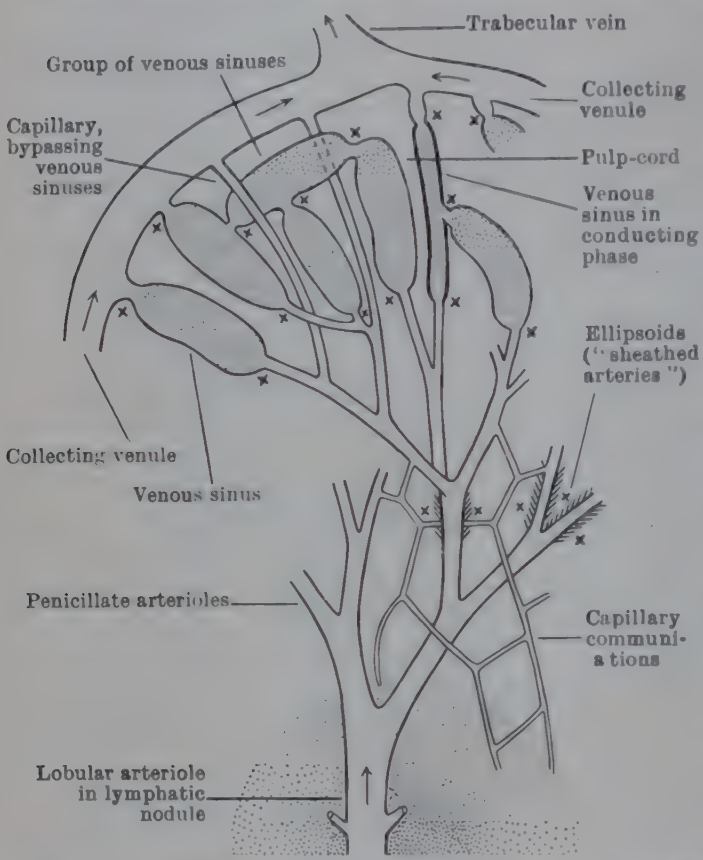

FIG. 718.—DIAGRAM OF THE TYPES OF VASCULAR CONNEXIONS THAT HAVE BEEN OBSERVED IN THE SPLEEN. × Sphincters. (After Knisely, 1936.)

Development. — The spleen is developed in the dorsal mesogastrium. The first indication is a thickening of this mesogastrium in embryos of about five weeks. In embryos of 10-12 mm. in length, there is a temporary thickening of the cœlomic epithelium over the swelling with several layers of cells, but the deeper layers are soon transformed into mesenchyme. The mesenchymal rudiment at first shows no division into lobules; a capillary network is present which forms the basis of the final vascular pattern. With the formation of the trabecular fibrous tissues along the course of the main vessels the future lobules become mapped out. Continued differentiation of the terminations of the arterial capillaries in the lobules leads eventually to the establishment of the characteristic capillary systems of the adult organ opening into wide venous capillaries. This arterio-venous capillary bed forms the rudiment of the adult splenic pulp. In it, giant cells and erythroblasts make their appearance, and blood-formation is active from about the fourth month of intra-uterine life. The lymphatic nodules arise as clumps of lymphocytic tissue in the adventitia of the arterial capillaries, during the middle and later periods of intra-uterine development, by infiltration of the walls of the vessels with lymphocytes.

Comparative Anatomy.—The spleen is found throughout the vertebrates, with the exception of the Agnatha (*e.g.*, the lamprey). Its structure is similar in fish, amphibia, reptiles, birds, and mammals; and it is in all instances developed in the dorsal mesentery of the gut. Its situation, however, relative to the alimentary canal, varies considerably; in some amphibia and reptiles, the spleen is opposite the intestines, in others opposite the stomach Certain fish normally possess several spleen-like structures.

Methods of Clinical Anatomical Examination.—The normal spleen cannot be felt by palpation of the abdominal wall. If it is enlarged or displaced, however, its lower part can be felt below the tenth costal cartilage during a movement of deep inspiration or sometimes even without such movement. Its position can be recognized by percussion; resonance is impaired over it. Anteriorly the zone of impaired resonance is limited by the area of resonance of the stomach, about the mid-axillary line; but the splenic and stomach areas may be separated by an intervening zone of resonance which is due to gas in the left flexure of the colon. Posteriorly, the upper border of the splenic zone of impaired resonance abuts on the area of lung resonance. Inferiorly, the splenic dullness merges with the zone of impaired resonance produced by the kidney, but there is a resonant angular region, below the spleen and lateral to the kidney, where resonance can be obtained from the descending colon.

CENTRAL NERVOUS SYSTEM

by W. E. Le Gros Clark, D.Sc., M.A., F.R.C.S., F.R.S.
Professor of Anatomy, University of Oxford

ELEMENTS OF THE CENTRAL NERVOUS SYSTEM

Every type of nervous system with which we are acquainted, from the most primitive to the most complex, is composed essentially of three categories of elements. These are (1) **sensory cells**, so situated and so specialized in structure as to be capable of being affected by changes in the animal's environment, and of transmitting the effects of such stimulation, directly or indirectly, to (2) **efferent nerve-cells**, which influence the muscles and other active tissues, so that the stimulation may find expression in some appropriate action; and (3) **intercalated nerve-cells**, which regulate such responsive behaviour by bringing it under the influence of other sensory impressions and of the state and activities of the body as a whole.

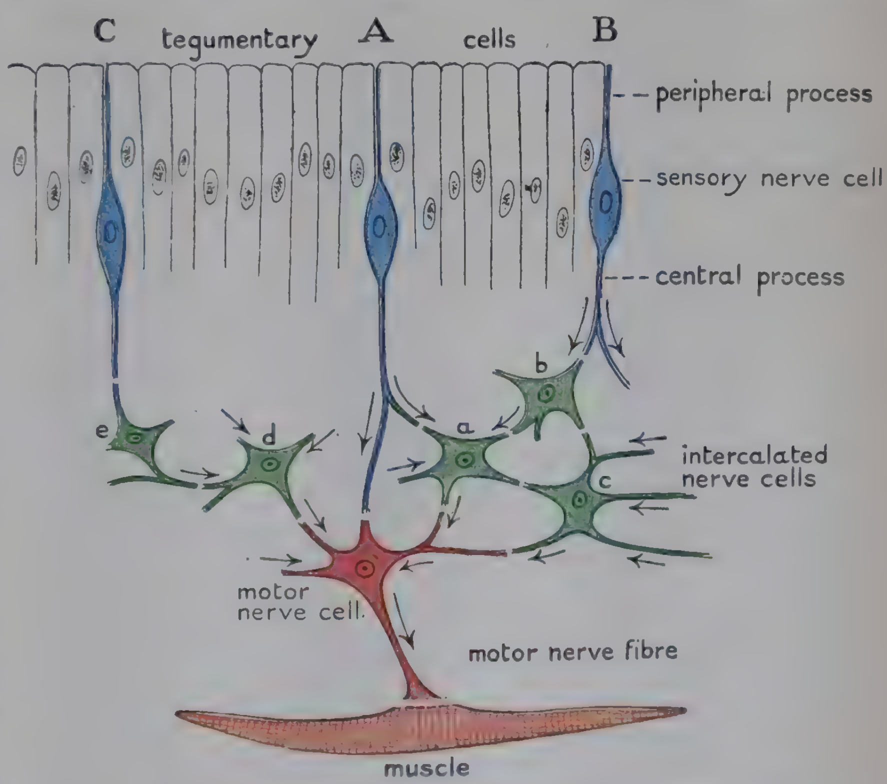

Fig. 719.—Diagram representing Essential Features in the Arrangement of the most primitive Type of Nervous System.

The study of a simple scheme representing the relationship that obtains among the three classes of elements in a primitive cœlenterate organism (Fig. 719) will make these fundamental facts plain. Changes in the animal's environment affect the extremities of the **peripheral processes** of the sensory cells (*A*, *B*, and *C*), which in such a primitive invertebrate are situated amongst the ordinary tegumentary cells: the effect is transmitted by the **central processes** of such cells (*A*, for example), either directly to the efferent cell, represented in the diagram by a **motor nerve-cell**, or more usually to an intercalated nerve-cell (*a*, *b*, or *e*). Into the cell (*a*) impulses stream from other intercalated cells (*b* and *c*), bringing the impulse from the sensory cell *A* under the influence of those coming from *B* and from more distant parts of the body through the intermediation of the intercalated cell *c*. The cells *a*, *c*, and *d* are connected with the motor nerve-cell. Thus, there is provided a mechanism whereby the conditions affecting

other regions of the body, B and C, may influence the nature of the response which the stimulation of A evokes—either increasing or diminishing its effect or perhaps altering its character.

In this way the intercalated nerve-cells form a great co-ordinating mechanism, linking together all parts of the body in such a way that the activity of any part of the organism may be influenced by the rest, and thus be enabled to act in the interest of the whole.

Throughout the whole course of its subsequent evolution the nervous system is formed of the same three kinds of elements; and the essential feature in its elaboration and increasing complexity is the multiplication of the intercalated cells, and their concentration, together with the motor nerve-cells, to form a definite organ which we call the **central nervous system.**

During the process of development of the more complex forms of nervous system, most of the sensory nerve-cells migrate from their primitive positions in or near the skin (Fig. 719); and, as the free extremity of the peripheral process retains its primitive relationship to the skin, such migration of the cell-bodies necessitates a great elongation of their peripheral processes. Although the sensory cells thus move inwards into the deeper tissues of the body, the great majority of them do not become incorporated in the central nervous system, but become collected into groups which form the **ganglia** of the sensory nerves.

In addition to its primary functions of (*a*) providing the means whereby the organism can be brought under the influence of its surroundings, and (*b*) co-ordinating the activities of the whole body, the nervous system comes also to perform other functions of wider significance.

In the course of its evolution the co-ordinating mechanism formed by the intercalated cells becomes so disposed in each animal that an appropriate stimulus applied to the sensory nerves can evoke a definite response—often of great complexity and apparent purposiveness. The nervous system thus becomes the repository of those inherited dispositions of its constituent parts which determine instinctive behaviour: and in the course of time it eventually provides also the apparatus by which individual experience and the effects of education can be brought to bear upon and modify such automatic reactions. In other words, the instrument of intelligence is formed from the nervous system; and the relatively great bulk and extreme complexity of this instrument—the brain—in Man are in a sense the physical expression of human intellectual pre-eminence.

In conformity with its primary function of affording a means of communication with the outside world, the neural elements of the whole of the nervous system in the human embryo, as in other animals, are developed from the ectoderm, as has already been explained in the chapter dealing with General Embryology. In the most primitive Metazoa the sensory nerve-cells remain in or close to the ectoderm (Fig. 719), while other ectodermal cells become converted into motor nerve-cells and intercalated nerve-cells which are found in the underlying tissues (Fig. 720). In the vertebrate embryo there is an analogous process of development, but with the important difference that the various nervous elements do not wander into the mesoderm individually. A definite patch of ectoderm is set apart to produce the greater part of the nervous tissues for the whole body; and all except the margins of that area sinks into the body *en masse.*

In one part of this ectodermal patch, many of the motor nerve-cells develop (Fig. 720, *d*), in another (*c*) only intercalated nerve-cells, in yet another (*b*) the sensory cells originate. With our knowledge of the fact (from the evolutionary point of view) that the sensory cells were originally distributed throughout the skin (Fig. 719), the idea naturally suggests itself that in man also the units of the sensory ganglia might be formed *in situ* in the ectoderm, and that the collection of sensory cells in the ganglia might possibly be brought about by the migration of such sensory cells inwards, while their peripheral processes elongate to permit such migration of the cell-bodies without disturbing their original endings in the skin. But there is no evidence to show, or even to suggest, that such a process takes place in the human embryo. The facts at our disposal show that the sensory nerve-cells are derived from sharply circumscribed patches of ectoderm,

and that the peripheral processes of these cells are distributed, by a process of outgrowth, to the outlying area of ectoderm beyond them from which the epidermis is eventually formed (Fig. 720).

At the beginning of the second week the nervous system of the human embryo is represented by a thickened plate of ectoderm lying along the median axis of the embryonic area (Fig. 721). This is the *neural plate*, and it is grooved in the median line by a shallow furrow—the *neural groove.*

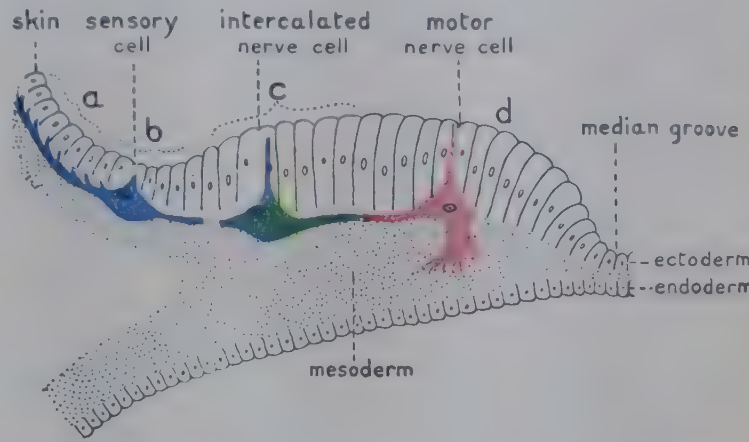

FIG. 720.—DIAGRAM REPRESENTING (IN BLACK) LEFT HALF OF TRANVERSE SECTION OF 2 MM. HUMAN EMBRYO. Superimposed upon it there is shown (in colours) the hypothetical primitive arrangement of the nervous elements derived from each part of the ectoderm.

In a diagram (Fig. 720) representing a transverse section through one-half of such an embryo (the uncoloured part), colours corresponding to those employed in Fig. 719 have been placed to indicate the nature of the elements that are known to develop in relation with each area of the ectoderm at a later period in the history of the embryo: *b* represents an area which later will form the **neural crest**, from which the sensory cells will be developed. The peripheral processes of these cells will pass into the skin (*a*) and to sensory endings elsewhere, and their central processes into the area *cd*, which will become part of the neural tube. In the area *c*, intercalated cells will develop

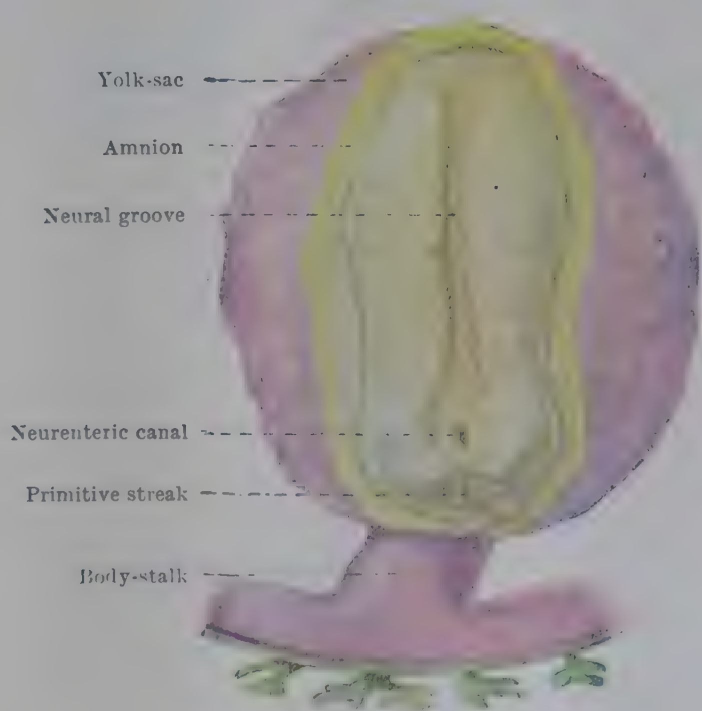

FIG. 721.—DORSAL SURFACE OF HUMAN EMBRYO 1·54 MM. LONG. (After von Spee.)

to receive the incoming sensory nerves; and in connexion with the area *d* the motor nerve-cells (as well as other intercalated cells) will be formed.

Early in the second week in the human embryo the axial groove along the median line of the neural plate becomes deepened by the tilting-up of the lateral margins of the plate. This process becomes accentuated during the next day or two until a deep cleft is formed, the walls of which consist of the thickened ectoderm and the floor of the thinner ectoderm of the neural groove

(floor-plate) joining them together. Before the end of the week the dorsal edges of the thickened plates become joined in the region which will develop into the neck; and during the third week the sealing of the lips of the neural groove extends headwards and tailwards, so that the neural tube becomes completely closed by the end of that week. The head and tail ends of the tube are the last parts to close, the latter being, as a rule, a little later than the former. When the tube is in the stage of being patent only at its two ends, the openings are known as the **anterior** and **posterior neuropores.**

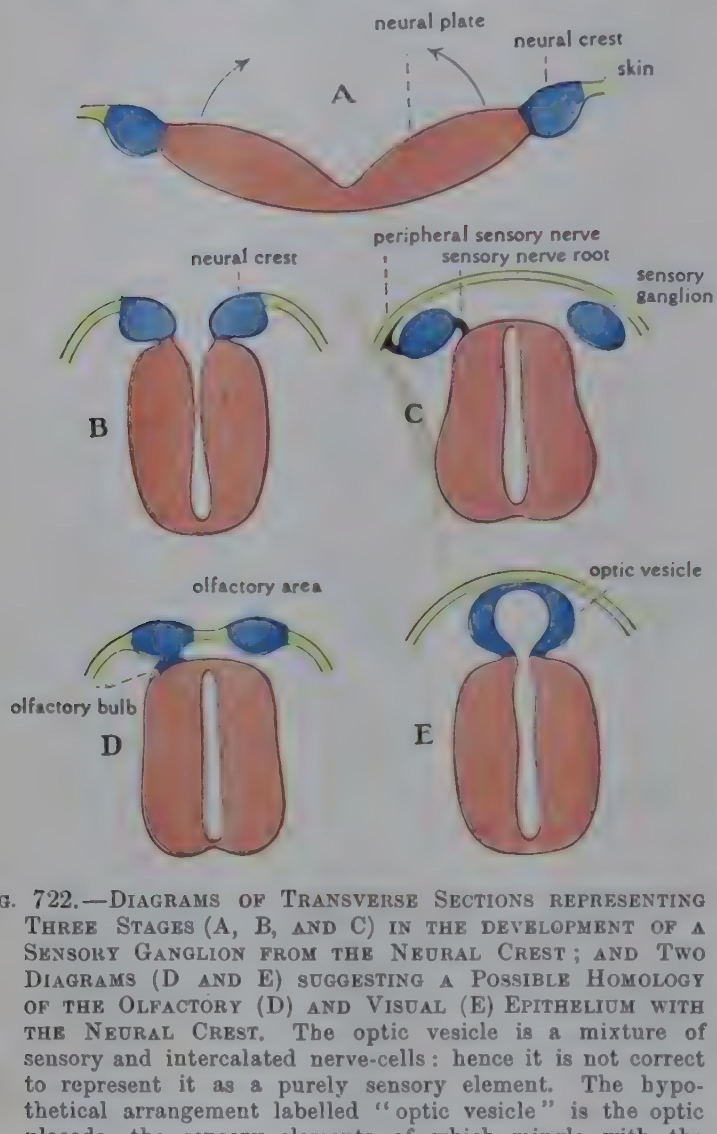

Fig. 722.—Diagrams of Transverse Sections representing Three Stages (A, B, and C) in the development of a Sensory Ganglion from the Neural Crest; and Two Diagrams (D and E) suggesting a Possible Homology of the Olfactory (D) and Visual (E) Epithelium with the Neural Crest. The optic vesicle is a mixture of sensory and intercalated nerve-cells: hence it is not correct to represent it as a purely sensory element. The hypothetical arrangement labelled "optic vesicle" is the optic placode, the sensory elements of which mingle with the neuroblasts of the neural tube; and a mixture of the two elements grows out to form the true optic vesicle.

In the process of closing, the extreme dorsal edges of the neural plate become excluded, in the greater part of its extent, from participation in the constitution either of the neural tube or of the skin, and form on each side a column of cells lying between the two. This is the **neural crest** (Fig. 722, A, B, and C).

The cells of the neural crest provide the basis for the development of the sensory ganglia of the spinal and cranial nerves, and these cells become arranged segmentally along the side of the neural tube. The neural crests, however, do not extend the whole length of the neural tube. Nevertheless, peculiar ectodermal areas, which ultimately give origin to sensory nerves, are found at the junction of the neural plate with the skin in those regions where the neural crest proper is lacking. At the extreme anterior end of the neural tube the margins of the anterior neuropore become thickened to form crest-like patches; but when the tube closes these areas do not separate from the skin (Fig. 722, D), as the rest of the neural crest does. They remain part of the skin and become the olfactory areas, in which sensory cells, very similar to those found in cœlenterate organisms (Fig. 719), develop.

A little farther on the caudal side of the olfactory region a large mass of ectoderm which appears to be homologous with neural crest tissue becomes a constituent part of the neural tube (Fig. 722, E). When the optic diverticulum grows out it carries out to the periphery these sensory cells mixed with intercalated cells of the neural tube to form the composite, sensitive membrane of the eye known as the retina.

In several other regions sensory nerves originate from cells of ectodermal areas which do not form parts of the neural crest, though they are homologous with that tissue. The nerves of hearing and taste are developed in a way that seems at first sight quite abnormal, until it is remembered that they afford examples of very primitive methods of nerve-formation.

The essential part of the organ of hearing is an ectodermal sac (otic vesicle) that develops as a diverticulum on the side of the head from a thickened patch

of ectoderm which is called the *otic placode*. Some of the cells of this area probably become transformed into nerve-cells which migrate into the space between the otic vesicle and the neural tube (Fig. 723) and join elements derived from the acoustico-facial portion of the neural crest to form the sensory neurons (p. 840) of the facial and auditory nerves.

At the upper margins of the branchial clefts a series of thickenings develop, which are known as the **epibranchial placodes**. Comparison with the process of development in fish-embryos suggests that the nerve-cells which give origin to the nerves of taste arise from these placodes as well as from cells of neural crest origin. Fibres of such origin are found in the facial, glosso-pharyngeal and (in some animals) vagus nerves (Fig. 723).

When first formed, the neural tube is compressed from side to side and presents an elliptical outline in transverse section (Fig. 722). The two side-walls are very

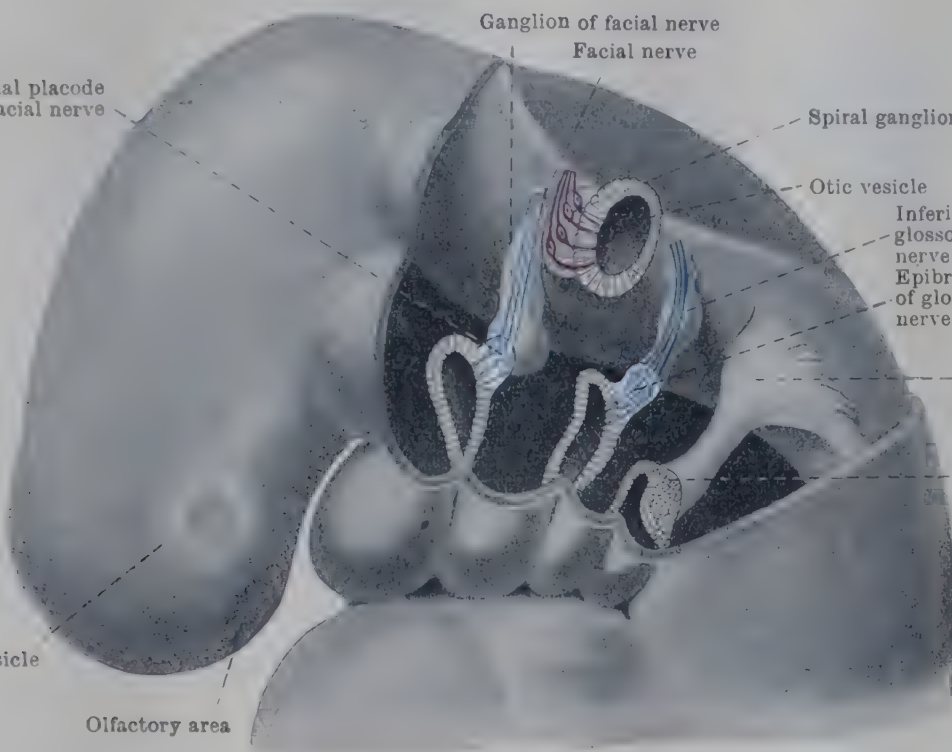

FIG. 723.—RECONSTRUCTION OF THE GANGLIA OF THE FACIAL, COCHLEAR, GLOSSO-PHARYNGEAL, AND VAGUS NERVES OF A HUMAN EMBRYO 5 MM. LONG. (Cf. Fig. 912, p. 1048.)

The epithelium of three pharyngeal grooves and the otic vesicle is represented diagrammatically; and the probable origin of the gustatory nerve-cells (and their fibres) from the epibranchial placodes is indicated in blue, and of those auditory nerve-cells contributed by the otic vesicle in purple.

thick, whilst the dorsal and ventral walls are narrow and thin, and are termed the **roof-plate** and **floor-plate** respectively (Fig. 728). The cavity of the tube in transverse section appears as a narrow slit. The wall of the neural tube consists at first of low columnar epithelium arranged in a fairly regular series, but with a certain number of large, spherical, so-called **germinal cells** scattered between the columns. But this regular disposition as a single layer of cells does not last long. For even by the second week the rapid proliferation of the cells has led to a marked increase in the thickness of the side-wall and a scattering of the more numerous nuclei, apparently irregularly, throughout its substance (Fig. 728). As growth proceeds, the innermost part of the wall of the neural tube becomes condensed to form a delicate membrane, termed the **internal limiting membrane**, which lines the lumen of the tube, whilst its outermost part presents a similar relation to an **external limiting membrane**, which invests the outer surface of the tube. Toward the end of the first month the side-walls of the tube show signs of a differentiation into three layers. Next to the central canal there is an epithelial-like arrangement of the innermost cells that forms the **ependyma.** Then there is an intermediate layer crowded with nuclei and known therefore as the nuclear or **mantle layer**. On the surface there is a layer singularly free from nuclei which is called the **marginal layer**. The

germinal cells are placed in the ependymal layer between its radially arranged cells as they pass in towards the internal limiting membrane.

From the proliferation of the germinal cells, in which mitotic figures can frequently be seen, some cells are formed which become ependymal epithelium, and others which migrate peripherally into the mantle layer. There they undergo further proliferation and some of the resulting cells develop into **spongioblasts**, which constitute the supporting framework or embryonic neuroglia; others become rudimentary nerve-cells or **neuroblasts**; and others again are known as **indifferent cells**, which are destined to undergo further division and to become the parents of more spongioblasts and neuroblasts.

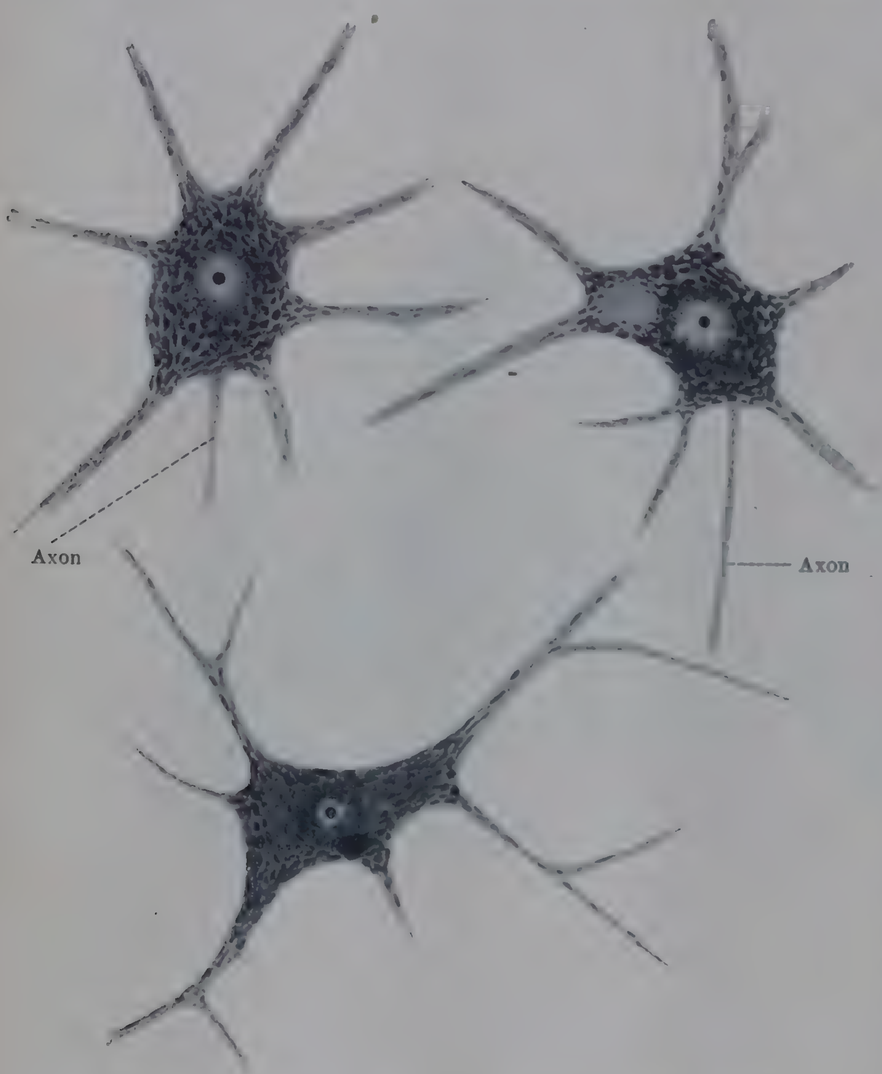

Fig. 724.—Three Nerve-Cells from Anterior Grey Column of Human Spinal Cord.

The neuroblasts are characterized by their early assumption of a piriform shape, due to the incipient outgrowth of a fibre-process. The spongioblasts, on the other hand, develop a series of branching protoplasmic processes which interlace freely to form a closely meshed network. The outermost or marginal zone of the neural tube is at first mainly composed of such a reticulum. It provides a scaffolding for the support of tracts of fibres which later grow up and down the spinal cord, linking up one part with another and connecting its whole length with the brain.

In the development of the spinal cord the three layers of the differentiating neural tube remain fairly distinct. The ependymal layer remains to form the ependymal epithelium which lines the central canal of the mature spinal cord; the mantle layer forms the grey matter of the cord, which contains receptive, motor, and intercalated neurons; and the marginal layer becomes the white matter of the cord and is occupied by tracts of ascending and descending fibres.

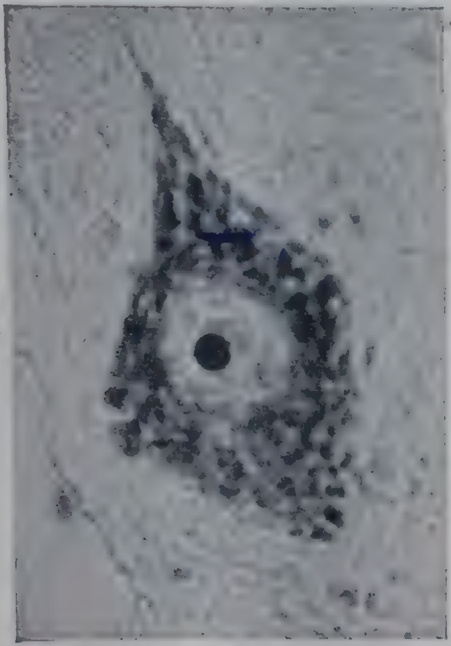
Cellular Elements of Nervous Tissue.—The anatomical unit of the nervous system is the **neuron**—that is to say, the nerve-cell with its processes. The latter are essentially conducting elements along which nervous impulses can be transmitted over considerable distances; and they form fine protoplasmic threads (or nerve-fibres) which may even reach a length of a metre or more. While there is evidence that the transmission of an impulse along a nerve-fibre can occur in the absence of its cell-body, each nerve-fibre depends on the integrity of its cell-body for the maintenance of its nutrition and vitality.

The larger nerve-cells are characterized by the presence in their cytoplasm of granules which stand out conspicuously when stained with a basic dye such as

methylene-blue. These granules are termed **Nissl bodies** or chromophil granules (Fig. 724). Their size and distribution show some variation in different types of nerve-cell; and they are absent altogether in the smallest neurons. They tend to be arranged concentrically around the nucleus and they extend also into the dendrites. They are absent, however, in the axonal process, except occasionally at its origin from the cell-body. It is of considerable importance to note that the Nissl bodies undergo characteristic changes in damaged cells. For example, if the axon is cut, they rapidly break up into a fine granular deposit and eventually disappear altogether. This reaction, which is termed *chromatolysis*, is usually accompanied by other changes such as a swelling of the cell-body and the displacement of the nucleus from a central position to the margin of the cell (Fig. 725). If regeneration occurs, the whole process is reversed and Nissl bodies once more make their appearance in the cytoplasm. The significance of the Nissl granules in the metabolism of nerve-cells remains obscure.

Another characteristic of the cytoplasm of nerve-cells is its fibrillary structure.

A



B

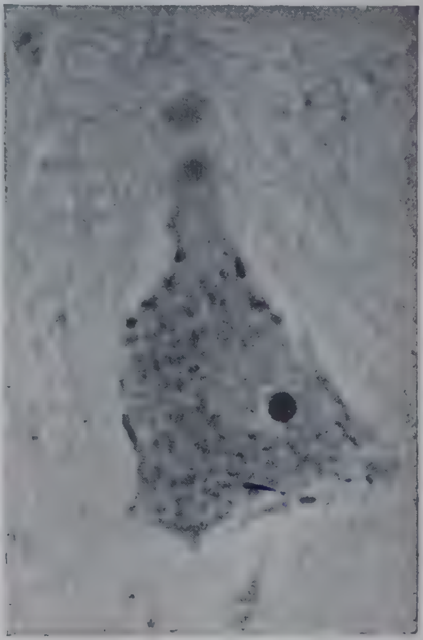


Fig. 725.—Photomicrographs showing (A) a Normal Motor Nerve-Cell of the Spinal Cord, and (B) a Motor Nerve-Cell which has undergone Chromatolysis two weeks after its Axon has been cut. (W. E. Le Gros Clark, *The Tissues of the Body.*) Note that in the degenerated cell the Nissl granules have disappeared or become dispersed in fine particles, and that the nucleus has been displaced to an excentric position. × 700.

Cells which are treated by methods of silver-impregnation show extremely fine fibrils—**neurofibrillæ**—which cross through the cell-body and extend into the axonal and dendritic processes. These neurofibrillæ were at one time regarded as the ultimate conducting elements of the neuron, but it is still disputed how far their appearance in histological preparations reflects the normal condition of the living cytoplasm. They have, however, been observed in fresh unstained nerve-cells.

Nerve-Cells of Brain and Spinal Cord.—The cells in the cerebro-spinal axis are variable both in size and form. Some are relatively large, as, for example, certain of the pyramidal cells of the cerebral cortex and the motor cells in the spinal cord, which almost come within the range of unaided vision; others are exceedingly minute, and require a high power of the microscope to bring them into view. The cell consists of a protoplasmic nucleated body, with which two kinds of processes are connected—the **axon** or emitting process and the **dendrites** or receiving processes (Figs. 726 and 727).

The **axon** presents a uniform diameter and a smooth and even outline. It may give off in its course fine collateral branches, but does not suffer thereby any marked diminution in its girth. The most important point to note in connection with the axon, however, is the fact that it forms the essential conducting element of a peripheral nerve-fibre, where it is commonly termed the *axis-cylinder*, and here it assumes one or two investing sheaths, of which more will be said later.

The axon may run its entire course within the substance of the brain or spinal cord, either for a short or a long distance (intercalated cells), or it may emerge from the brain or spinal cord in one of the cranial or spinal nerves as an efferent nerve-fibre and run a variable distance before it finally reaches the peripheral structure in relation to which it ends (efferent nerve-cells). The axon and its collaterals appear to terminate either in small button-like knobs (end-bulbs), or more frequently in terminal arborizations, the extremities of which seem to be furnished with exceedingly small terminal varicosities. When the axon or its collaterals end within the brain or the spinal cord, some of the terminal arborizations interlace with the dendrites of nerve-cells, and others are twined around the bodies of other cells. In the latter case the interlacement may be so

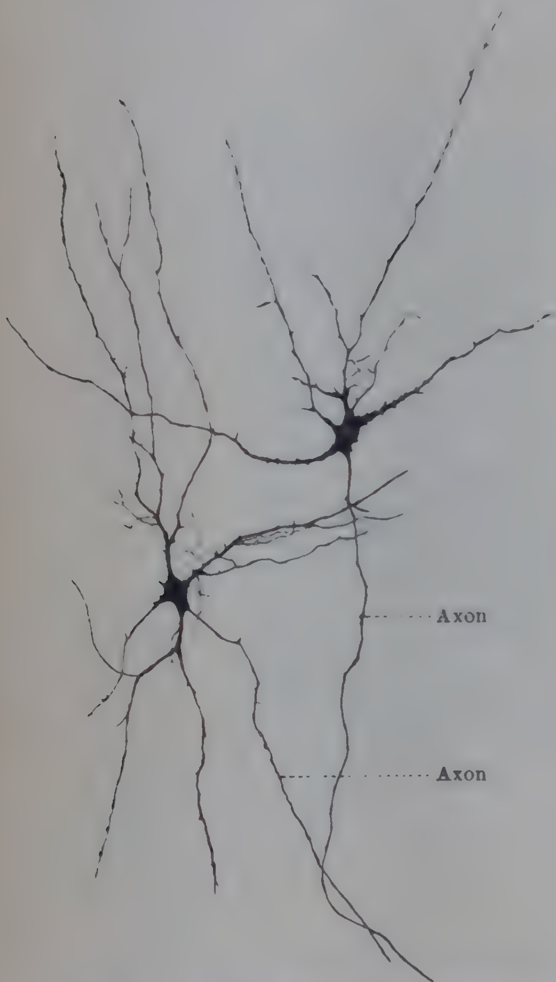

Fig. 726.—Two Multipolar Nerve-Cells. (From a specimen prepared by the Golgi method.)

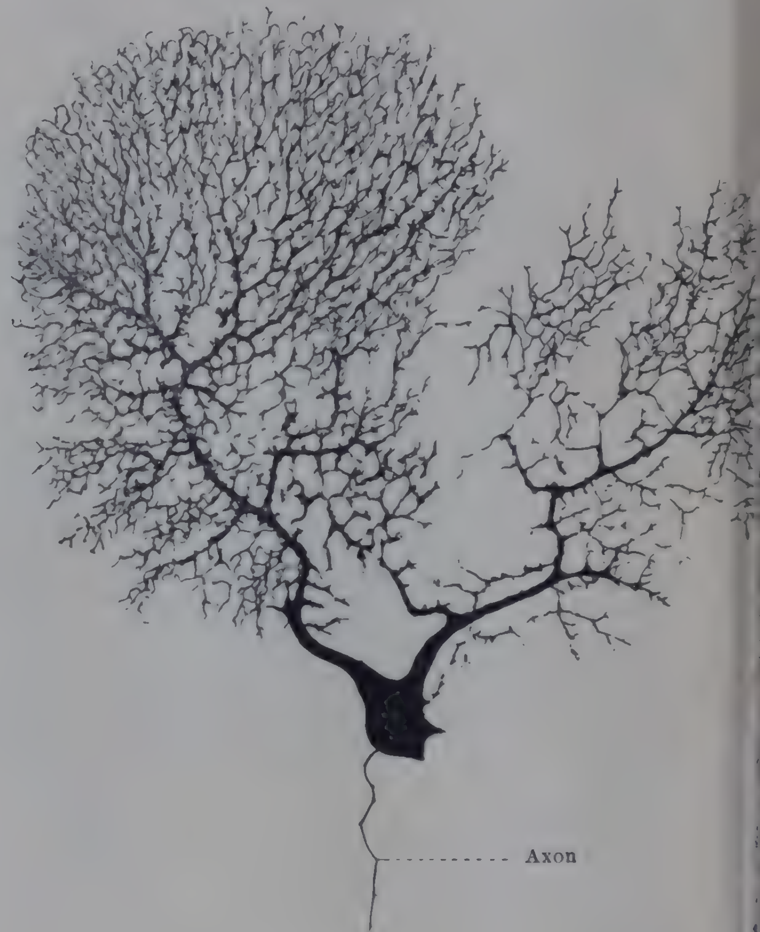

Fig. 727.—Nerve-Cell from Cerebellum (Cell of Purkinje) showing the Branching of the Dendrites. (Symington.)

close and complete that it almost presents the appearance of an enclosing basket-work. When the axon emerges from the cerebro-spinal axis its terminal arborization ends in relation to a muscle-fibre or some other tissue in the manner described below.

The **dendrites** or receiving processes of the nerve-cell are thicker than the axon, and they may present a rough-edged irregular contour. They usually divide into numerous branches, and gradually become more and more attenuated until finally they appear to end in free extremities. The branching of the dendrites sometimes attains a marvellous degree of complexity (Fig. 727), but there is no anastomosis between the dendrites of neighbouring cells, or between the dendrites of the same cell.

Most nerve-cells possess several dendritic processes and one axon, and they are therefore *multipolar* in shape. The processes are formed during development as a series of outgrowths from the cell-body, the axon usually (but not always) being the first to appear (Fig. 732). In some cases, in addition to the axonal

process, one main dendrite only may be developed, leading to the formation of a bipolar nerve-cell. Lastly, attention must be given to the *unipolar* type of cell which is really derived secondarily from a bipolar type (see p. 845). Such unipolar cells are found in the sensory ganglia of the spinal nerves and of some cranial nerves.

Efferent Nerves.—The efferent cells of the neural tube are distinguished by the fact that their axons leave the central nervous system and traverse the mesoderm for a longer or shorter distance to end in relation to a muscle-fibre or some nerve-cell outside the nervous axis. In the course of the growth of the body the various structures supplied by efferent fibres become removed progressively farther

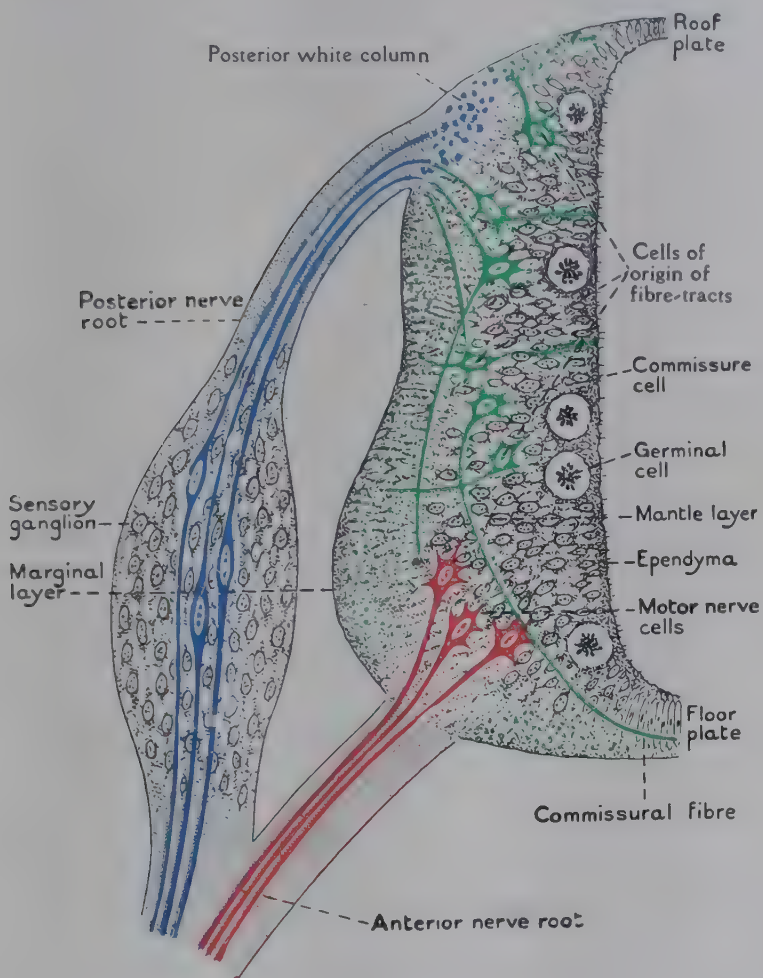

FIG. 728.—DIAGRAM OF TRANSVERSE SECTION OF EARLY NEURAL TUBE.

and farther from the central nervous system; and in that process (Fig. 729) a distinction can be detected in the behaviour of the efferent fibres (*a*) proceeding to the striated or voluntary muscles, and those (*d*) conveying impulses destined for viscera and plain muscle, respectively. The efferent cells (*a*) which innervate voluntary muscles take up their positions in the central nervous system, their axons (motor nerve-fibres) becoming elongated in the ordinary process of growth in proportion to the migration of the muscle from its original situation. But the cells (*c*) which innervate plain muscles and viscera are disposed in a different manner. They lie outside the central nervous system as constituent elements of one of the **autonomic ganglia**. Impulses from the central nervous system are transmitted to such ganglia by means of fibres arising from cells (*d*) within the central organ; and the latter elements are termed **splanchnic efferent cells**. In spite of their morphological homologies, the motor cells of the autonomic ganglia appear not to have their origin in the motor part of the neural tube but to be derived from cells of the neural crest which migrate from their original position on the dorsal aspect of the neural tube. However, this generally accepted thesis may still be regarded as not finally settled, for there is still some support for an earlier conception that the cells of the autonomic ganglia migrate out from the neural tube

along the anterior roots of the spinal nerves. Such a process would be in harmony with purely morphological expectations.

Afferent Nerves.—It has been noted that the sensory ganglia of the cranial and spinal nerves are derived from the neural crest or from ectodermal tissue homologous with it. In the process of development each of the cells of these ganglia sends out (1) a process to the periphery which ultimately forms a sensory receptor ending, and (2) a process which enters the dorsal part of the neural tube. This central process may penetrate directly to the mantle layer to terminate in relation to the neurons in this layer, or it may ascend or descend through the neural tube in the marginal layer for a variable distance before its termination.

Nerve Components.—From the statements in the preceding paragraphs it must be evident that there are several varieties of afferent and efferent nerves that respectively enter and leave the central nervous system. The cells of origin of the efferent nerves collect in the ventral part of the side-wall of the neural tube; and for this reason that part of the wall becomes swollen at an early stage of development (Figs. 729 and 730). It is called the **basal lamina**. Most of the cells that emit afferent fibres are situated in the sensory ganglia outside the central nervous system, and their growth can therefore have no direct influence upon the form of the neural tube; but their central processes become inserted into the dorsal part of the side-wall of the tube, which is called the **alar lamina**; and groups of intercalated cells collect around the entering fibres to form **receptive** or **terminal nuclei**. The growth of the terminal nuclei leads to an expansion of the alar lamina which is analogous to that seen in the basal lamina but is much less extensive. The unequal swelling of the dorsal and ventral parts of each side-wall of the neural tube leads to the development of a longitudinal groove—**sulcus limitans** (Fig. 730)—as a demarcation between the alar and basal laminæ.

The **nuclei of origin** of the efferent fibres, which are found in the basal laminæ, may be divided into two main groups (and, in some regions of the nervous axis, three). There is first the group of large multipolar nerve-cells which emit fibres to innervate the ordinary striated voluntary muscles. This is commonly called the **somatic efferent nucleus**. Then there is a group of small multipolar cells, the axons of which pass out into autonomic ganglia and indirectly control the involuntary plain muscles and other active parts of viscera. Those cells form the **splanchnic efferent nucleus**.

In the upper cervical region of the spinal cord and in the brain-stem a portion of the somatic efferent nucleus is set apart to innervate the striated muscles developed in the pharyngeal arches (Fig. 812). This is termed a *branchial nucleus*, for, although the muscles which it supplies are not distinguishable from ordinary skeletal musculature in their minute structure, they have a different developmental origin, being derived from the mesoderm of the "branchial" arches formed in the wall of the pharynx. It may be noted, too, that the cells of the branchial nuclei are similar to those of the somatic efferent nuclei (see *Nucleus ambiguus*, p. 929).

The alar lamina also can be subdivided into a series of functional areas (Fig. 730). In the dorsal part there is the **somatic afferent terminal nucleus**, which receives impulses coming from somatic structures such as the skin, subcutaneous tissues, muscles, and joints. In the brain-stem a *special somatic afferent nucleus* is developed for the reception of impulses from the cochlea and semicircular canals (Fig. 812). Then there is a group of cells collected around the incoming visceral sensory nerves—the **splanchnic afferent terminal nucleus.** A part of this, again, is specialized in the brain-stem to form a *special splanchnic afferent nucleus* (the gustatory nucleus) which receives impulses from the sense-organs of the tongue (Fig. 812, p. 924).

This analysis of the various functional elements that may enter into the constitution of the various cranial and spinal nerves is made use of in elaborating the **theory of nerve components**, which will help us to understand many features of the structure of the nervous system that otherwise would be unintelligible. It will be noted that primarily the arrangement of nerve-cells in the lateral wall of the neural tube from dorsal to ventral aspect is as follows: somatic sensory, splanchnic sensory, splanchnic motor, and somatic motor (Fig. 730).

This simple arrangement persists in the spinal cord and to some extent also in the brain-stem. Elsewhere it becomes modified and obscured during the process of development of the more specialized parts of the brain.

Ganglia of Sensory Nerves.—The cells found in the ganglia of the cranial nerves and on the posterior roots of the spinal nerves differ in origin from neurons in the grey matter of the brain and spinal cord. As already indicated, the ganglia in question are derived from the neural crest. The cells in these ganglionic masses are at first oval in form, and each extremity or pole becomes drawn out into a process, so that the neurons become bipolar. The processes are distinguished as central and peripheral according to the direction which they take. The central processes penetrate the wall of the neural tube. In the region of the spinal cord they form the fibres of the posterior roots of the spinal nerves. In the substance of the cerebro-spinal axis they give off numerous collaterals, and after a course of varying extent they end, after the manner of an axon, in terminal arborizations which enter into relationships with certain nerve-cells in the cerebro-spinal axis. The peripheral processes extend distally until they finally reach the skin or other sensory surface; for example, many of the fibres which go to the skin break up into fine terminal filaments which end freely between the epithelial cells of the epidermis. The two processes of a ganglion-cell, therefore, form the afferent fibres, and constitute the path along which a nervous impulse initiated by a peripheral

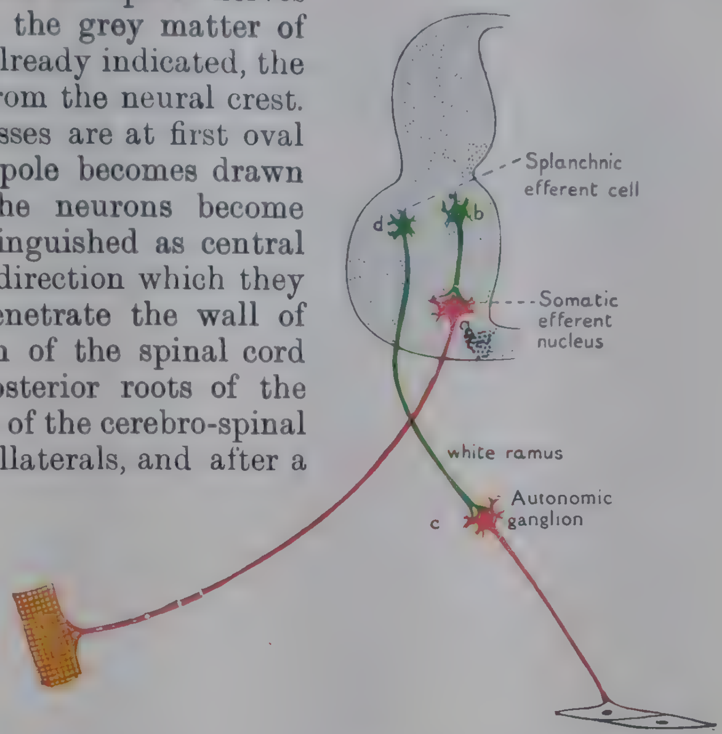

Fig. 729.—Diagram of Transverse Section of Left Half of Neural Tube representing the Arrangement of the Autonomic Nerves, to suggest the Possible Homology of a Sympathetic Ganglion Cell with a Central Motor Cell and of a White Ramus with the Axons of Intercalated Cells.

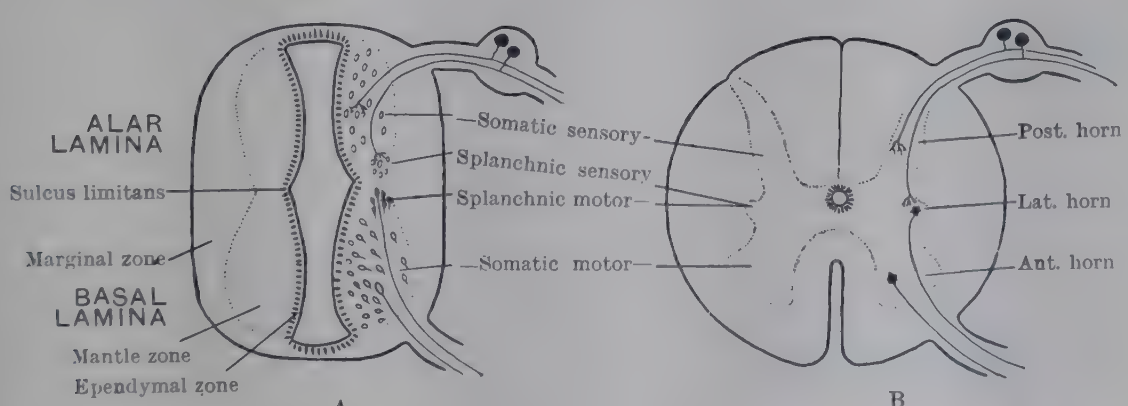

Fig. 730.—Diagrams of Transverse Sections of (A) Embryonic Neural Tube and (B) Spinal Cord showing the Main Categories of Afferent and Efferent Nerve-Components and their Central Nuclei. (W. E. Le Gros Clark, *The Tissues of the Body.*)

stimulus is conducted towards the brain and spinal cord. The body of the cell is, as it were, interposed in the path of such impulses.

But the original bipolar character of these cells, with very few exceptions (ganglia in connexion with the auditory nerve and the bipolar nerve-cells in the olfactory mucous membrane), gradually undergoes a change which ultimately leads to their transformation into unipolar cells. Asymmetrical growth leads to a gradual approximation of the attached ends of the processes, and finally to a condition in which they appear to arise from the extremity of a short common stalk in a

T-shaped manner (Fig. 734). It is interesting to note that in some types of fish the original bipolar condition of the spinal ganglion-cells is retained without change throughout life.

A comparison with more typical nerve-cells suggests that the peripheral process of a unipolar ganglion-cell is really a much elongated dendrite (in spite of its enclosure in a medullary sheath), for it conducts impulses towards the cell-body. In this case the central process is to be regarded as the axon.

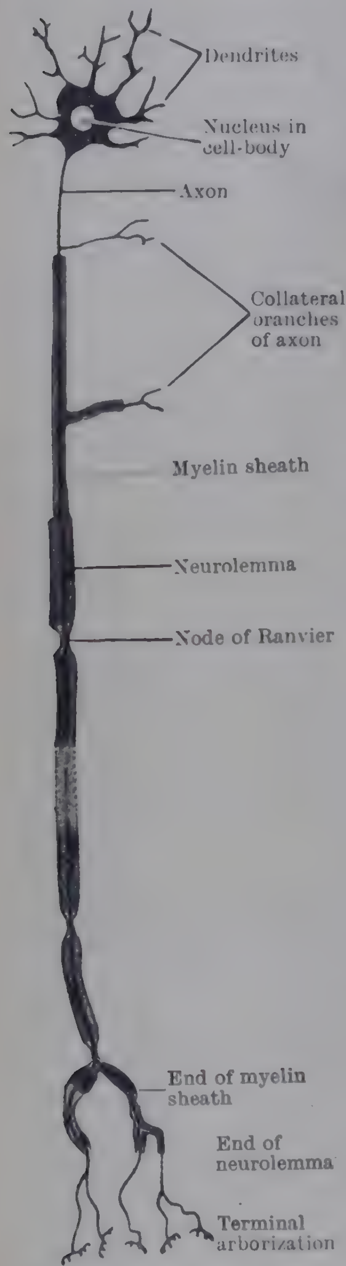

FIG. 731.—DIAGRAM OF A PERIPHERAL MOTOR NEURON SHOWING STRUCTURE OF MEDULLATED NERVE-FIBRE. (Maximow and Bloom, *Text-Book of Histology*.)

The interruption of the fibre by broken lines indicates that it may be relatively very much longer.

The Synapse.—It has been noted that dendrites are the receiving processes of a nerve-cell and that the axon is the emitting process, In other words, the neuron shows a dynamic polarity with respect to its processes, nerve-impulses being directed towards the cell-body by the dendrites and away from the cell-body by the axon. Within the central nervous system, and also in the peripheral course of the autonomic nervous system, nervous impulses may be conducted along relays of neurons, the terminal arborizations of the axon of one neuron effecting a contact with the dendrites or the cell-body of another. Such a connexion is termed a **synapse**, and this part of a nervous circuit is of extreme importance on physiological and pharmacological grounds.

In spite of prolonged controversy in the past, it is now almost universally admitted that at the synapse there is no protoplasmic continuity between one neuron and another—the relation between the processes of the two neurons being one of contact only. Similarly, the connexions of a peripheral nerve-fibre with a muscle-cell or a sensory cell are effected by contiguity and not by protoplasmic continuity. These dispositions, indeed, are implicit in what has been termed the *neuron theory*. This theory (which is now commonly accepted) states that each nerve-cell with its processes is a separate and independent anatomical unit, and that each nerve-fibre is ultimately the protoplasmic process of a nerve-cell. It is not opportune to enter here into a discussion of the neuron theory or to quote the questionable evidence which has been adduced by those who hold that the nervous system is really a syncytium of cellular elements. We may observe, however, that apart from direct histological observations there seems to be overwhelming evidence that each complete neuron is indeed a separate cellular element. Embryological studies, tissue-culture experiments, physiological data on the transmission of the nervous impulses, the degenerative processes which occur after injury to a nerve-cell or section of the axon, and the effects of certain pharmacological agents, all point to this conclusion (Le Gros Clark, 1945).

a, Neuroblast with rudimentary axon, but no dendrites; *b* and *c*, the dendrites beginning to sprout out; *d* and *e*, further development of the dendrites and appearance of collateral branches on the axon.

Nerve-Fibres.—Nerve-fibres, arranged in bundles of greater or less bulk,

form the nerves which pervade every part of the body. They also constitute the greater part of the brain and spinal cord. As already noted, nerve-fibres are the conducting elements of the nervous system; they serve to bring the nerve-cells into relation both with one another and with the various tissues of the body.

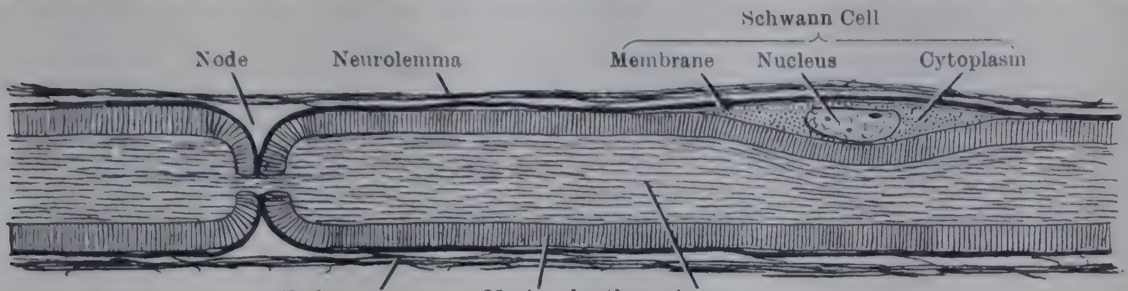

Fig. 733.—Diagram of a Normal Medullated Nerve-Fibre.

The Schwann nucleus lies nearer to the node than it would usually do, but otherwise the proportions are correct. (Holmes & Young, 1942.)

There are different varieties of nerve-fibres, but in all of them the essential constituent is the delicate, thread-like axon. The most obvious difference between individual fibres depends upon the nature of the covering of the axon. When it is coated on the outside by a more or less thick sheath of a fatty substance termed **myelin**, which can be demonstrated by reagents such as osmic acid, it is said to be a myelinated or *medullated fibre* (Fig. 733). When the visible coating of myelin is absent the fibre is termed a non-myelinated or a non-medullated fibre. A second sheath—thin, delicate and membranous, and placed externally—also may be present in each case. It is termed the **neurolemma** (or primitive sheath) and is intimately related to cellular elements called *Schwann cells* which partially invest the axon (or the myelin sheath when this is present). From a structural point of view, therefore, four different forms of nerve-fibre may be recognized :—

Non-medullated—
1. Naked axons.
2. Axons with Schwann cells

Medullated—
3. Schwann cells absent.
4. ,, ,, present.

Fig. 734.—Three Stages in the Development of a Cell in a Spinal Ganglion.

The significance of the medullary sheath and the investing Schwann cells remains obscure. The medullary sheath is commonly believed to subserve insulating functions and it is possible that it is concerned with the nutrition of the axon. It is known also that the thickness of the sheath has some relation to the rate of conduction in a nerve-fibre. The Schwann cells play an important but not an essential part in the regeneration of cut nerve-fibres. The observation that nerve-fibres within the central nervous system do not (in mammals) undergo repair after they have degenerated was at one time attributed to the fact that they have no investment of Schwann cells. This assumption, however, has received no support from recent experimental studies.

Every nerve-fibre near its origin and as it approaches its termination is unprovided with sheaths of any kind, and is simply represented by a non-medullated, naked axon (Fig. 731). The fibres of the olfactory nerves afford us an example of non-medullated fibres furnished with Schwann cells. Similar fibres are abundant in the peripheral distribution of the sympathetic nervous system, and they are found in small numbers also in peripheral nerves of the somatic type.

It is important to note that the distinction between the medullated and non-

medullated fibres is not one which exists throughout all stages of development. As already pointed out, every fibre is the prolongation of a cell, and in the first instance it is not provided with a medullary sheath. Indeed, it is not until about the fifth month of intra-uterine life that those fibres which are to form the white substance of the cerebro-spinal axis begin to acquire their coating of myelin. Further, this coating appears in the fibres of different fasciculi or tracts at different periods, and knowledge of the fact has helped anatomists to follow out the connexions of the tracts of fibres which compose the white matter of the brain and spinal cord.

It has already been explained that fibres which form the nerves may be classified into two sets—afferent and efferent. **Afferent nerve-fibres** conduct impressions from the peripheral organs into the central nervous system; and, as this frequently leads to a conscious awareness of the original stimulus, or, in other words, a sensation, they are often called *sensory fibres*. **Efferent nerve-fibres** carry impulses out from the brain and spinal cord to peripheral organs. The majority of them go to muscles to induce contraction and are termed *motor fibres*; others go to glands to promote secretion and are called *secretory fibres*. (For a discussion on the structure of nerve-fibres, see Young, 1942.)

Neuroglia.—The neuroglia is the supporting tissue of the central nervous system. It may be considered to include two different forms of tissue, viz., the lining ependymal cells and the neuroglia proper. We place these under the one heading, seeing that they have a common developmental origin.

The **ependymal cells** are the columnar epithelial cells which line the central canal of the spinal cord and the cavities of the brain. In the embryonic condition a process from the deep extremity of each cell traverses the entire thickness of the neural wall and reaches the surface. It is not known for certain whether or not this is the case in the adult, but it appears that in most parts of the brain and spinal cord this connexion becomes broken. The ependymal epithelium is characteristically ciliated, but the functional significance of the cilia is obscure, for they have not been observed to show any movement. In the ventricles of the brain a part of the ependymal lining covers invaginated tufts of vascular pial tissue (choroid plexuses) and here it plays the part of a secretory epithelium, for it is concerned in the production of cerebro-spinal fluid (p. 1003).

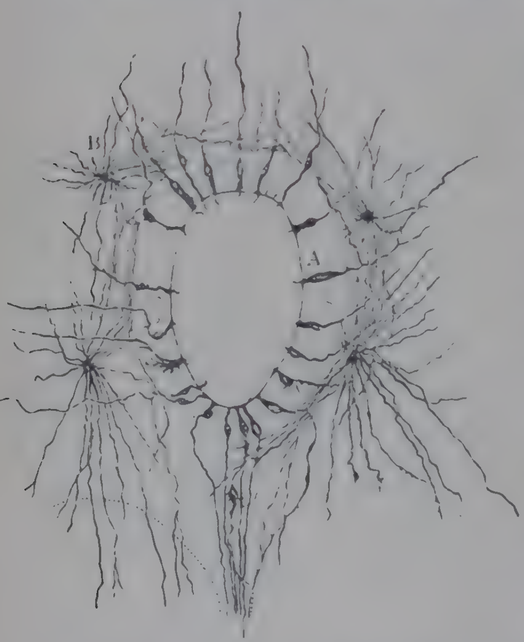

Fig. 735.—Section through Central Canal of Spinal Cord of Human Embryo, showing Ependymal and Neuroglial Cells. (After v. Lenhossek.)

A, Ependymal cell. B, Neuroglial cell.

Note that the dorsal (posterior) aspect is *below*.

The **neuroglia proper** is present in both the white and the grey matter of the cerebro-spinal axis. It constitutes an all-pervading matrix in which the various nerve-elements are embedded in such a way that they are all bound together into a consistent mass and are yet all severally isolated from one another.

Neuroglia is composed of cells in which the cell-body is relatively small and is provided with fine, filamentous processes. The latter may attain to a considerable complexity, and by their interlacements they constitute a feltwork which can be demonstrated microscopically by special methods of silver-impregnation. Whilst the neuroglia is for the most part intimately intermixed with the neuronal elements, there are certain localities, in both the brain and spinal cord, where it is spread out in more or less pure layers. Thus, upon the surface of the brain there is such a layer; likewise beneath the ependymal lining there is a thin stratum of neuroglia. Various types of neuroglial cell are recognized and, although the functional significance of each type is not in every case apparent, their recognition is of considerable practical importance, since they are responsible for forming different kinds of tumours which are met with clinically. Neuroglial tissue in general, like the ependymal epithelium, is

formed embryologically from ectoderm, being derived from the neuro-epithelium of the neural tube. There is one exception, however, in a type of neuroglia called *microglia* (or mesoglia). Microglial cells are mesodermal derivatives and they are distinguished by their high motility and their phagocytic properties. They play the part of macrophage cells in the central nervous system and have important protective functions.

GENERAL PLAN OF CENTRAL NERVOUS SYSTEM

In the foregoing account it has been explained that the nervous system is composed of a series of afferent nerves which bring information from every part of the body into the central nervous system, from which efferent nerves pass out to the muscular and other active parts of the body, providing the means for translating such information into appropriate action. But it has been seen that the essential parts of the central nervous system are the intercalated cells, which provide the means whereby the information brought in by any sensory nerve may be placed at the service of the whole body, and the response which it excites may be controlled and regulated by the condition of the rest of the body. The system of intercalated cells links together into one co-ordinated mechanism the whole nervous system and, through it, every part of the body itself.

In some very primitive and remote ancestor of Man (and in fact of the vast majority of animals) one end of the nervous system became enhanced in importance to form a brain, which assumed a dominant influence over the rest. This was brought about, in the first place, by the fact that in an elongated prone animal moving forwards the front end would naturally come first into relationship with any change in environment, and that earlier acquisition of information concerning the outside world would necessarily give the head-end of the nervous system exceptional opportunities for influencing the rest of the nervous system. This predominance is further accentuated by the development in the head-region of the organs of special sense, which provide mechanisms specially adapted to be influenced by light, sound, and such delicate chemical forms of stimulation as excite in ourselves sensations of smell and taste. As the information conveyed by the special senses, such as the scent of food or the visual impression of some enemy, must be able immediately to influence the movements of the whole body, it follows that a specially abundant system of intercalated elements link the central ends of the nerves of the special senses with the rest of the central nervous system. Moreover, the predominant influence of the head-end of the central nervous system implies that it must be provided with a specially large series of nervous connexions (in the form of fibre-tracts), not only for the purpose of bringing influence to bear upon the rest of the nervous system, but also of being itself brought into intimate relationship with the nervous system as a whole, seeing that sensory impulses are constantly pouring into every part of it.

Thus the head-end of the central nervous system becomes the brain, which is characterized by a series of large irregular swellings, due to (*a*) the development around the termination of each special sensory nerve of a mass, or group of masses, of intercalated cells which will enable the effects of the visual, auditory, olfactory, gustatory, or other sensations to influence the whole nervous system, and (*b*) the evolution of complicated systems of intercalated cells which receive, and in a sense blend, impressions from all parts of the nervous system, and emit fibres which pass, directly or indirectly, to the various groups of motor nerve-cells to control their activities and, through them, the behaviour of the animal.

Development of Brain.—In the development of the human embryo the distinction between the head-end and the rest of the central nervous system is indicated even before the medullary plate is completely folded up to form the neural tube. The widened part represents the rudiment of the brain; and the rest of the tube will become converted into the spinal cord.

If the attempt is made to analyse the meaning of the early broadening of the brain rudiment it will be found to be due in great measure to the fact that there is added to the margins of the medullary plate (see Fig. 722 E, p. 838) the material from which the sensitive part of the eye and the optic nerve are developed; but

soon after the neural tube is closed, irregular swellings make their appearance around the attachments of the nerves of smell, vision, hearing, and taste (Fig. 736), and also of the vagus nerve, which is widely distributed to the viscera of the neck, thorax, and abdomen.

But there are other factors besides the irregularities of growth of its walls which add complexity to the form of the brain in the embryo. In the course of their growth both parts (brain and spinal cord) of the neural tube undergo great extensions in length, breadth, and thickness; but in the case

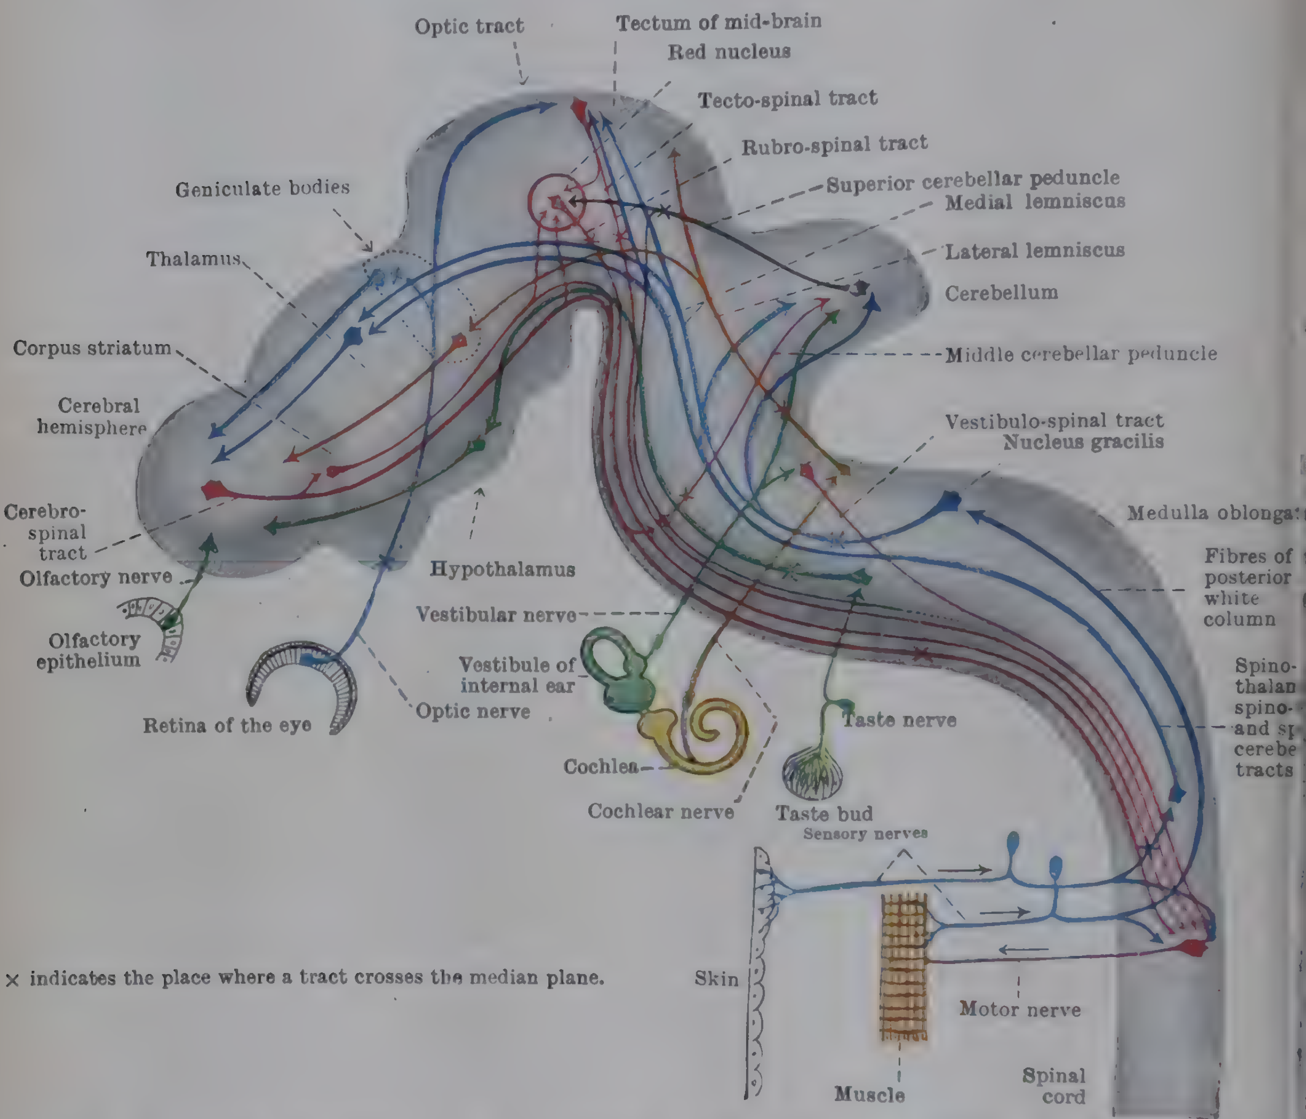

FIG. 736.—DIAGRAM REPRESENTING THE CONNEXIONS OF SOME IMPORTANT SENSORY AND MOTOR TRACTS IN THE BRAIN. Motor paths in red; sensory in other colours. The tracts are represented as projected on to the outline of an embryonic brain which shows the main divisions of the brain in a simplified plan. See also Figs. 758-762.

of the cord it is the increase in length that is most distinctive, whereas in the brain the irregular expansion in breadth and thickness is more striking. Nevertheless, the brain elongates more rapidly than that part of its mesodermal capsule which ultimately becomes the brain-case; hence it becomes bent, apparently to permit of its being packed in the limited length of the cranial cavity. But if it is admitted that these mechanical considerations are in a measure responsible for the three bends which develop in the embryonic brain, their situation and the forms they assume are determined by the irregularities of growth inherent in the brain itself (p. 61).

Even at a time, about the end of the third week, when the anterior (head) end of the neural tube is still open (anterior neuropore), a right-angled bend has already developed in the rudiment of the brain (**cerebral vesicle**). Slightly less than half of the length of the vesicle has projected beyond the headward end of the notochord and become flexed ventrally round it (Fig. 737).

This bend is known as the **cephalic flexure**. The region of the brain vesicle in which it develops will later on become the **mid-brain** or **mesencephalon**; and even at the early stage of development now under consideration (Fig. 737) there is a slight narrowing of the tube (**isthmus**) that marks the boundary between the mid-brain and the **hind-brain** or **rhombencephalon**. Immediately beyond the end of the notochord there is an even fainter trace of a constriction that indicates the line of demarcation between the mid-brain and the **fore-brain** or **prosencephalon**.

Shortly after the appearance of the cephalic flexure a similar bending occurs in the region where the brain becomes continuous with the spinal cord (Fig. 738 A). It is called the **cervical flexure**.

But at that stage, or even earlier (Fig. 737), there has been developing a third bend which produces effects that differ from those just mentioned. At the end of the fourth week a slight bulging can be detected on the ventral side of the hind-brain (Fig. 738): during the next four weeks it steadily becomes accentuated and forms the **pontine flexure**. The convexity of the bend is directed ventrally, differing in this respect from both of the other flexures. The difference in direction has a profound influence upon the form which the hind-brain assumes. If a plastic tube is bent, a strain is thrown upon the wall in the concavity of the flexure. If the wall is strong and resisting, like the floor-plate of the neural tube (in the cases of the cephalic and cervical flexures), the bending does not affect the outline of the tube (in section) very materially. But when the strain is thrown upon the thin roof-plate during the development of the pontine flexure it is not strong enough to resist; it becomes stretched and allows the side-walls of the neural tube to splay laterally in precisely the same manner as occurs when a rubber tube is bent towards a side which has been split (or weakened) longitudinally (Fig. 738). This mechanical factor seems to determine the form assumed by the hind-brain at the end of the first month; and gives its cavity—the fourth ventricle—a lozenge or rhomboid form when seen from its dorsal aspect through the thin translucent roof. For this reason the hind-brain is known as the **rhombencephalon**.

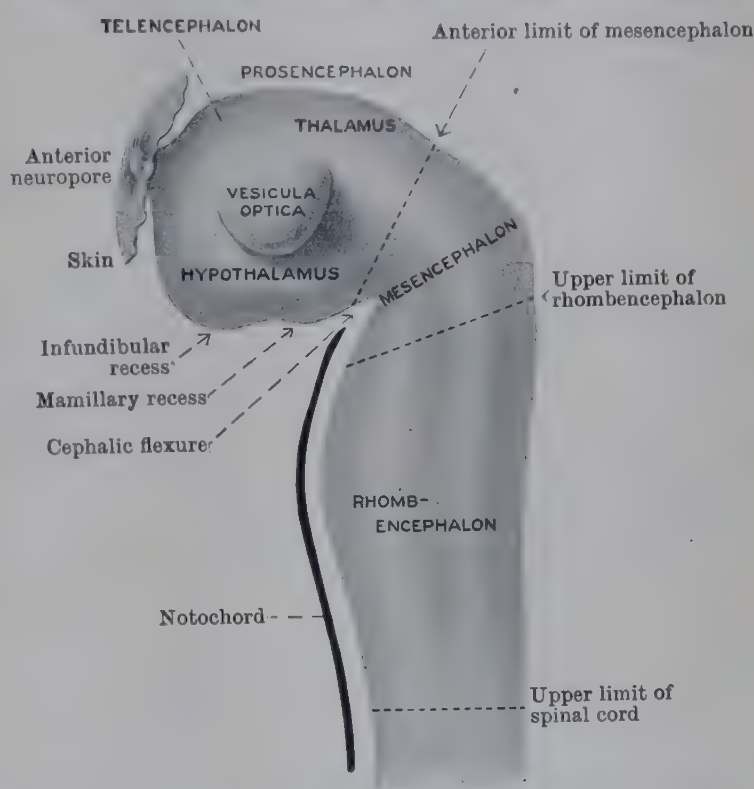

FIG. 737.—LEFT SIDE OF BRAIN OF HUMAN EMBRYO ABOUT THREE WEEKS OLD. (After a model by His, 1904.)

The rhombencephalon forms at first more than half of the brain, and, as it expands, it appears to become marked off from the rest by a constriction called the **isthmus rhombencephali**.

The development of the pontine flexure subdivides the rhombencephalon into two parts—the **myelencephalon**, joined to the spinal cord, and the **metencephalon**, joined to the rest of the brain.

The myelencephalon is known as the **medulla oblongata**, and important nuclei develop in it. These include the nuclei of the nerves which are concerned in the regulation of the activities of the heart, lungs, and a considerable part of the alimentary canal, and also the receptive nuclei of the nerves of taste.

The insertion of the auditory nerve in the neighbourhood of the outsplayed, lateral angle of the rhombencephalon leads to the profound transformation of the metencephalon. The auditory nerve conveys into the hind-brain impulses which

are stimulated by movements of fluid in the closed sac developed from the otic vesicle (Fig. 812, p. 924). The truly auditory function of the apparatus is called

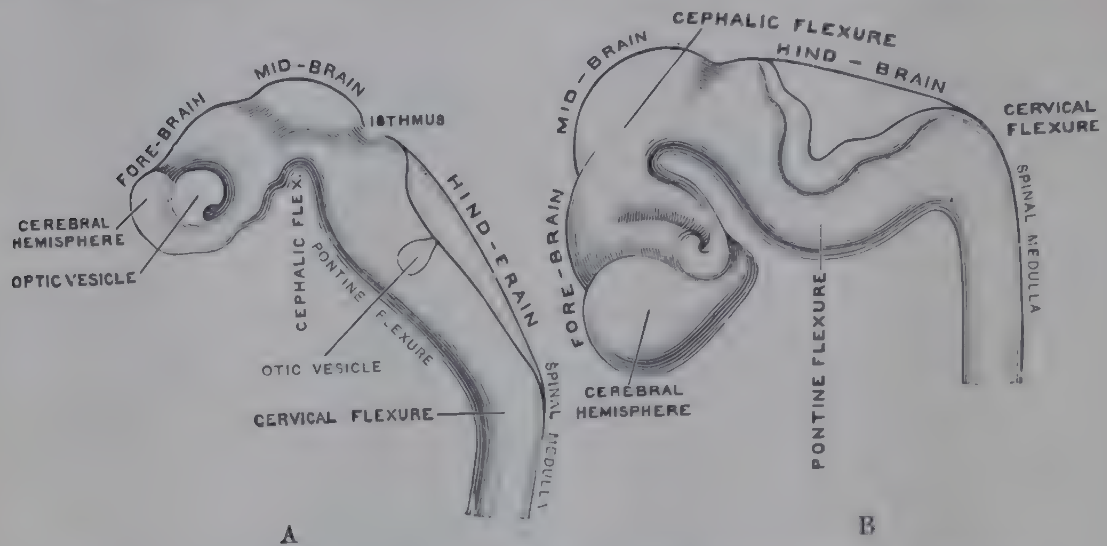

FIG. 738.—TWO STAGES IN THE DEVELOPMENT OF THE HUMAN BRAIN. (After His.)
A, Brain of embryo of the fifth week. B, Brain of embryo of six weeks.

into activity when the movements of the fluid are caused by waves of sound transmitted to it from the outside world. But it is obvious that motion may also be set up in the fluid by changes in position of the body itself; in other words, movements in the fluid of the otic vesicle may stimulate nerves to convey to the brain information concerning the position and movements of the body itself. There are separate fibre-bundles in the auditory nerve to serve each of these functions, and they are referred to as the cochlear and vestibular divisions of the nerve. A great mass of nerve-cells develops around the termination of that part of the auditory nerve which is called vestibular to make use of the information for the regulation of the movements of the body in balancing or equilibration. To enable the terminal vestibular nucleus the better to perform its function of equilibration, depending as it does upon the co-operation and adjustment of the movements of vast numbers of widely separated muscles, nerve-tracts coming from muscles

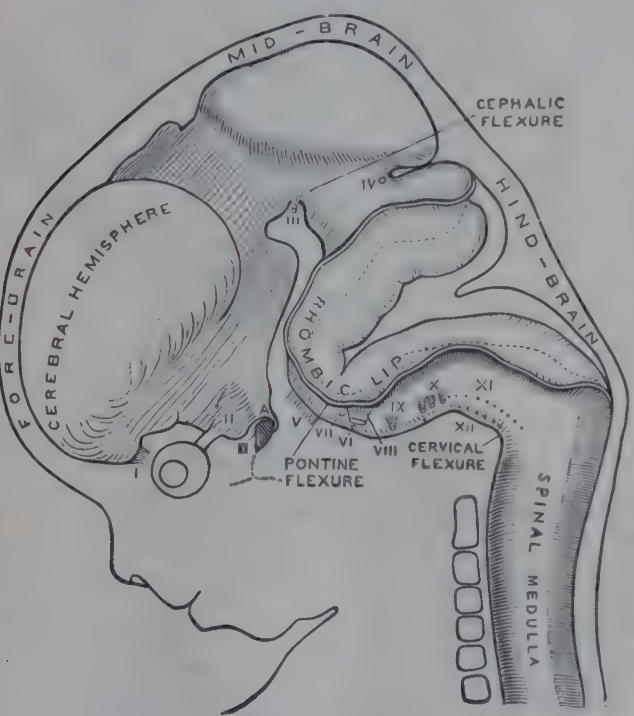

FIG. 739.—PROFILE VIEW OF BRAIN OF HUMAN FŒTUS OF TEN WEEKS. (After His.)

and skin-areas of all parts of the body make their way into the vestibular nucleus; and it expands and forms a great excrescence known as the **cerebellum**. As the cerebellum has to adjust the activities of all the muscles of the body it necessarily becomes the great organ of muscular co-ordination, and as such it is made use of by those parts of the brain which have to initiate and control complex actions such as skilled movements. It will be shown in the subsequent account how the cerebellum becomes linked to the mid-brain to co-ordinate the movements of the body which are excited by this part of the brain; and, later, how it becomes associated with the fore-brain, when the latter becomes responsible for the initiation and control of the most highly

skilled actions. For the latter purpose the cerebellum emits a system of fibres that convey impulses which are eventually relayed to the cerebral hemispheres. Moreover, a great pathway of efferent nerve-fibres is laid down to connect the fore-brain with the cerebellum: the terminal pathway of this connexion is situated on the ventral (anterior) aspect of the metencephalon in the form of a great mass of transverse fibres. At one time these strands of nerve-fibres were looked upon as a bridge between the two hemispheres of the cerebellum: hence the name **pons** was applied to them. This term is now applied not only to the fibres themselves, but also to the upward prolongation of the medulla oblongata, to the surface of which they are related.

The division of the rest of the brain into **mesencephalon** and **prosencephalon** develops later and is less fundamental than the primary demarcation of the rhombencephalon.

The visual apparatus is connected with both the mid-brain and the fore-brain, to both of which also nerve-pathways are established to convey sensory impressions of touch and sound from the spinal cord and medulla oblongata. From the alar laminæ of the mesencephalon the **tectum** or dorsal part of the mid-brain is formed, and in it there are developed four little hillocks—**corpora quadrigemina**—to receive these varied impressions and to enable them to influence the actions of the whole body. Special nerve-paths, called the **tecto-spinal tracts**, are laid down from the corpora quadrigemina (Fig. 736) to the spinal cord to enable the mid-brain to control the motor nuclei of the muscles of the trunk and limbs. A group of intercalated cells known as the **red nucleus** develops in each half of the mid-brain for the purpose of establishing connexions between the cerebellum and the mid-brain. When an impulse passes out of the mid-brain by the tecto-spinal tract to excite some movement of the body, the red nucleus provides the link by which the cerebellum can co-ordinate the actions of the muscles involved. By means of a **rubro-spinal tract** it can bring its influence to bear directly upon the nuclei of motor nerves in the brain and spinal cord (Fig. 736). While, however, the rubro-spinal tract is an important tract in lower mammals, it becomes relatively insignificant in the human brain, where the motor functions of the central nervous system are dominated by the elaborately developed fore-brain.

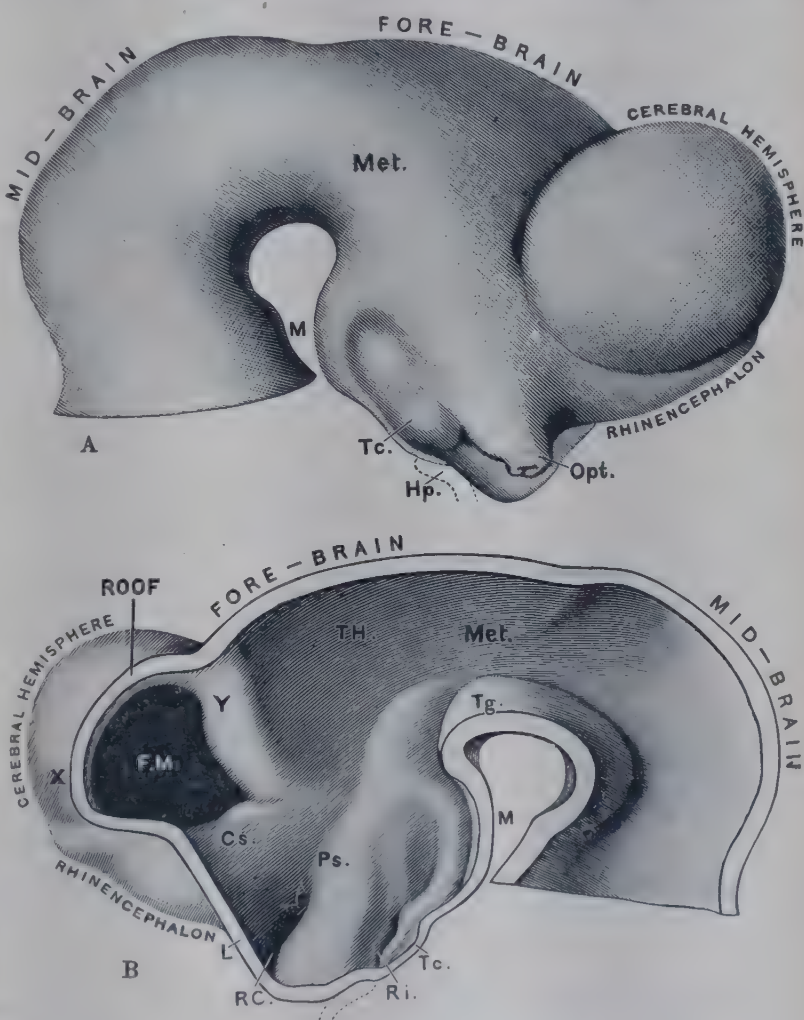

FIG. 740.—BRAIN OF HUMAN EMBRYO IN SEVENTH WEEK. (His, 1904.)

The prosencephalon is at first, and in some of the lower fishes remains, the most insignificant of the three brain vesicles, but in the human brain (as also in

that of most other vertebrates, though in varying degrees) a pair of enormous excrescences—the **cerebral hemispheres**—are budded off from it; and they become the dominant part of the nervous system (Fig. 740). The median, unpaired part of the prosencephalon contains the cavity of the third ventricle, and this part of the brain is termed the *diencephalon*. The cerebral diverticula are hollowed out by the lateral ventricles, and together they comprise the *telencephalon* or "end-brain".

Each hemisphere is formed, however, from a relatively small part of the side-wall of the prosencephalon, the rest of which goes to form the optic diverticula, the thalamus, and the hypothalamus, among other structures. The cerebral hemisphere is at first pre-eminently olfactory in function, the nerves of smell being inserted directly into it. But impressions of the associated sense of taste make their way into the cerebral hemisphere in the most primitive vertebrates: the gustatory nerves are inserted into the medulla oblongata, but fibre-paths are laid down to establish connexions which (by paths not yet definitely established) reach the cerebral hemisphere (Fig. 736). Other types of sensory impulse reach the cerebral hemispheres by passing through a mass of nervous tissue which is developed in the wall of the third ventricle—the **thalamus**. The thalamus is developed as a greatly swollen part of the prosencephalic wall adjoining the mesencephalon. Its main part receives sensory impressions brought up from the spinal cord and the terminal nuclei of the sensory cranial nerves and transmits them to the corresponding cerebral hemisphere. Its caudal portion becomes specialized as special receptive nuclei for visual and auditory impressions for transmission to the cerebral hemisphere. These terminal nuclei are called the **geniculate bodies**. Thus, the cerebral hemisphere, from being essentially a receptive organ for smell impressions, ultimately becomes the terminus of all the sensory paths, and the structure that is concerned with the consciousness of all kinds of sensations. It also controls the voluntary movements of the opposite half of the body and emits a great strand of fibres—the **cerebral peduncle**—to establish relations with the cerebellum and all the motor nuclei on the other side of the brain and spinal cord (Fig. 736).

The most primitive part of the prosencephalon (but of extreme functional importance for the very reason that it *is* a primitive and fundamental component of the fore-brain) is the **hypothalamus**. This is a mass of nervous tissue which forms the floor of the third ventricle and is intimately related to the attachment of the hypophysis cerebri. It is to be regarded as a central mechanism for the regulation of the visceral activities of the body, and, as such, it plays an important part in metabolic functions and emotional reactions.

SPINAL CORD

The **spinal cord** is the part of the central nervous system which occupies the upper two-thirds of the vertebral canal. It is an elongated cylindrical structure, slightly flattened in front and behind, and extends from the foramen magnum to the lower border of the body of the first lumbar vertebra or to the upper border of the second. Its average length is 45 cm. in men and 43 cm. in women.

The level of the lower end of the cord varies from the middle of the last thoracic vertebra to the upper border of the third lumbar and is said to be slightly lower in women than in men. It varies also in the fœtus and infant at different periods of development. Up to the third month of intra-uterine life the spinal cord occupies the entire length of the vertebral canal. But from that time onwards, the vertebral column lengthens at a more rapid rate than the cord. The spinal cord, therefore, has the appearance of shrinking in an upward direction within its canal, and at birth the lower end usually is opposite the body of the third lumbar vertebra. The attitude of the body affects to a small degree the position of the lower end of the cord. When the trunk is bent well forwards, the terminal part of the cord rises slightly.

At the foramen magnum the spinal cord becomes continuous with the medulla oblongata, whilst its lower end tapers rapidly to a point and forms a conical extremity termed the **conus medullaris**. From the end of the conus medullaris a slender glistening thread is prolonged downwards within the vertebral

canal, and finally anchors the cord to the back of the coccyx. The prolongation receives the name of the **filum terminale**.

The diameter of the cord is very much smaller than that of the vertebral canal The wide interval left between it and the walls of its canal is clearly a provision for allowing free movement of the vertebral column without producing any jarring contact between the cord and the surrounding bones.

Three protective membranes invest the cord. From within outwards they are termed (1) the pia mater, (2) the arachnoid mater, and (3) the dura mater. The **pia mater** is a vascular membrane of trabecular tissue which forms the immediate investment. It is closely applied to the cord, and from its deep surface numerous fine septa penetrate into the substance of the cord. The **arachnoid mater** is an exceedingly delicate, transparent membrane which is loosely wrapped around the cord so as to leave a considerable interval between itself and the pia mater, termed the subarachnoid space, in which there is always a varying amount of cerebro-spinal fluid. Outside the arachnoid mater the **dura mater** forms a wide, dense, fibrous sheath which extends downwards for a considerable distance beyond the cord. The cord is suspended within its sheath of dura mater by a pair of wing-like ligaments, termed the **ligamenta denticulata**, which extend from the sides of the spinal cord, and each of them is attached by a series of pointed tooth-like processes to the inner surface of the dura mater (Fig. 880). Between the wall of the vertebral canal and the dura mater there is a narrow interval, called the *extradural space*, which is filled up by soft areolo-fatty tissue and numerous thin-walled veins arranged in a plexiform manner. The existence of this space allows for a considerable variation in the volume of cerebro-spinal fluid which surrounds the spinal cord. For further details, see p. 999.

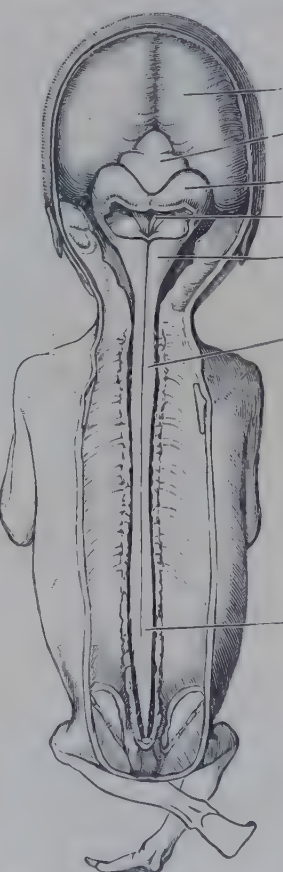

Fig. 741.—Human Fœtus in Third Month of Development, with Brain and Spinal Cord exposed from behind.

Thirty-one pairs of spinal nerves arise from the spinal cord. They are classified into eight cervical, twelve thoracic, five lumbar, five sacral, and one coccygeal; and, according to the attachments of these groups of nerves, the cord is divided into cervical, thoracic, lumbar, and sacral *regions*. It must be understood that these regions are determined by the nerve-attachments and not by any direct relationship between the parts of the spinal cord and the sections of the vertebral column which bear the same names. The differential growth between the spinal cord and the vertebral canal (to which reference has already been made) necessarily alters the primitive relations between the segmental levels of the spinal cord and the corresponding vertebral segments. Thus, in the adult, the first thoracic segment of the cord lies opposite the sixth cervical vertebra, and the first lumbar segment opposite the ninth thoracic vertebra.

Each spinal nerve is attached to the cord by an anterior and a posterior root, and as the roots are traced to their central attachments they are seen to break up into a number of separate bundles which spread out (in some cases very widely) as they approach the cord (Fig. 743). Each pair of nerves is therefore attached to a portion of cord of some length, and such a portion receives the name of a *segment* of the spinal cord. There is, however, no means of marking off one segment from another except by the attachments of the nerve-roots.

In the cervical and lumbar regions the nerve-roots are crowded together, so that little or no interval is left between the roots of neighbouring nerves. In the thoracic region, however, distinct intervals may be observed, and the root-bundles are more loosely arranged. From this it will be evident that the segments are not of equal length. In the cervical region they

measure about 12 mm. in length, in the thoracic region from 20 to 24 mm., and in the lumbar region about 10 mm.

Owing to the great difference between the lengths of spinal cord and vertebral column, the farther we pass down the greater is the distance between the attachment of the nerve-roots and the intervertebral foramina through which the corresponding nerves leave the vertebral canal. As the nerve-roots do not unite to form a spinal nerve-trunk till they reach the intervertebral foramen, it thus happens that the nerve-roots which spring from the lumbar and sacral regions attain a very great length and descend vertically in the lower part of the vertebral canal in a bunch or leash, in the midst of which lie the conus medullaris and the filum terminale. This great bundle of nerve-roots receives the appropriate name of the **cauda equina**.

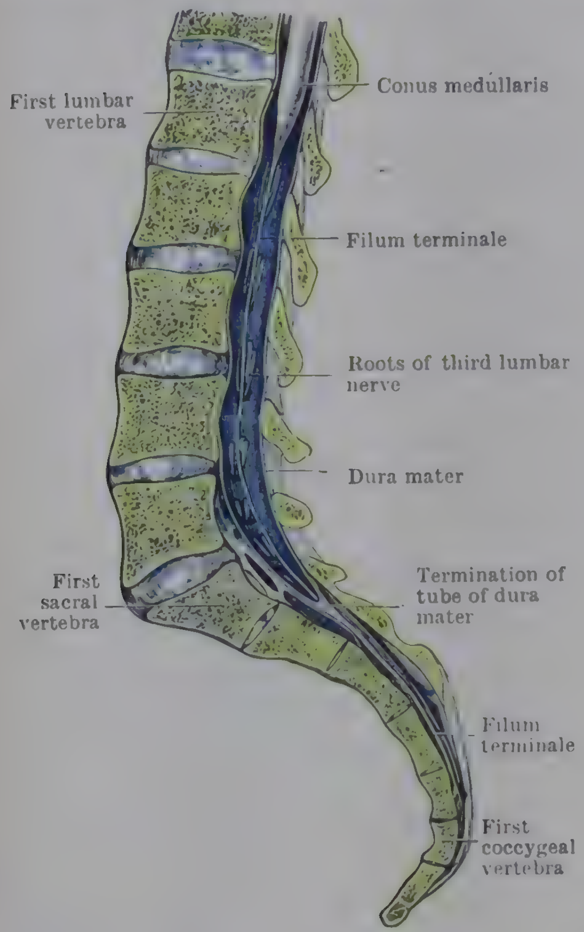

Fig. 742.—Conus Medullaris and the Filum Terminale.

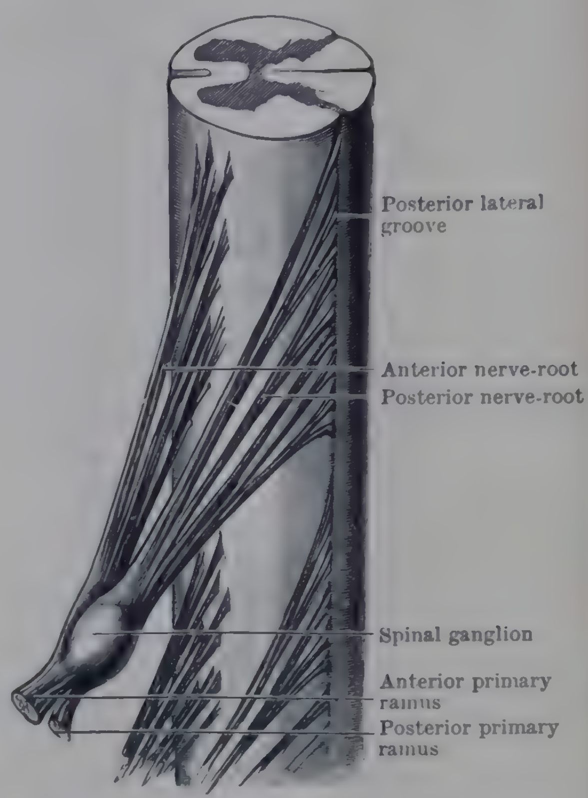

Fig. 743.—Roots of the Seventh Thoracic Nerve (semi-diagrammatic).

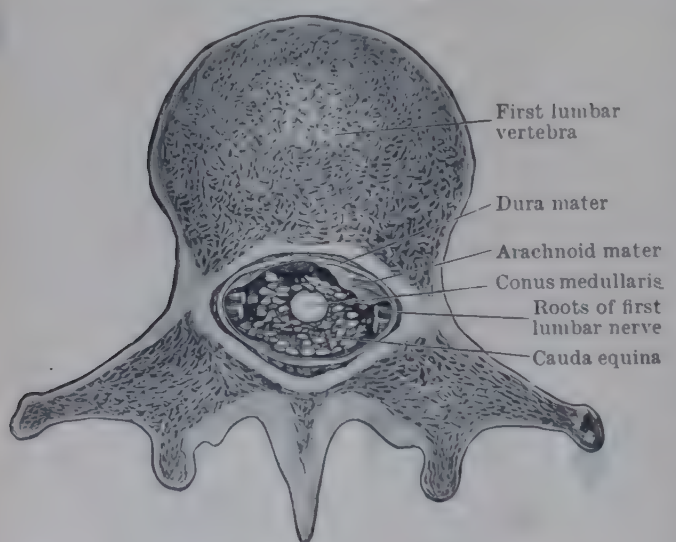

Fig. 744.—Section through Conus Medullaris and Cauda Equina as they lie in the Vertebral Canal.

Enlargements of Spinal Cord.—Throughout the greater part of the thoracic region, the cord presents a uniform girth, and a very nearly circular outline in transverse section. In the cervical and lumbar regions, however, it shows marked swellings. The **cervical enlargement** is the more evident of the two. It begins very gradually at the upper end of the cord, attains its greatest breadth (12 to 14 mm.) opposite the fifth or sixth cervical vertebra, and finally subsides opposite the second thoracic vertebra. This portion of the cord gives attachment to the great nerves which supply the upper limbs. The **lumbar enlargement** begins at the level of the tenth thoracic vertebra, and

acquires its maximum transverse diameter (11 to 13 mm.) opposite the last thoracic vertebra. Below, it rapidly tapers away into the conus medullaris. To the lumbar enlargement are attached the great nerves of the lower limbs.

The enlargements of the cord are associated with the outgrowth of the limbs. In the earlier developmental stages they are not present, and they take form only as the limbs become developed. In different animals their size corresponds to some extent with the size of the limbs. Thus, in the long-armed orang and gibbon the cervical swelling is very pronounced.

Development of Spinal Cord.—The early stages of the process by which the originally simple epithelial neural tube becomes converted into the central

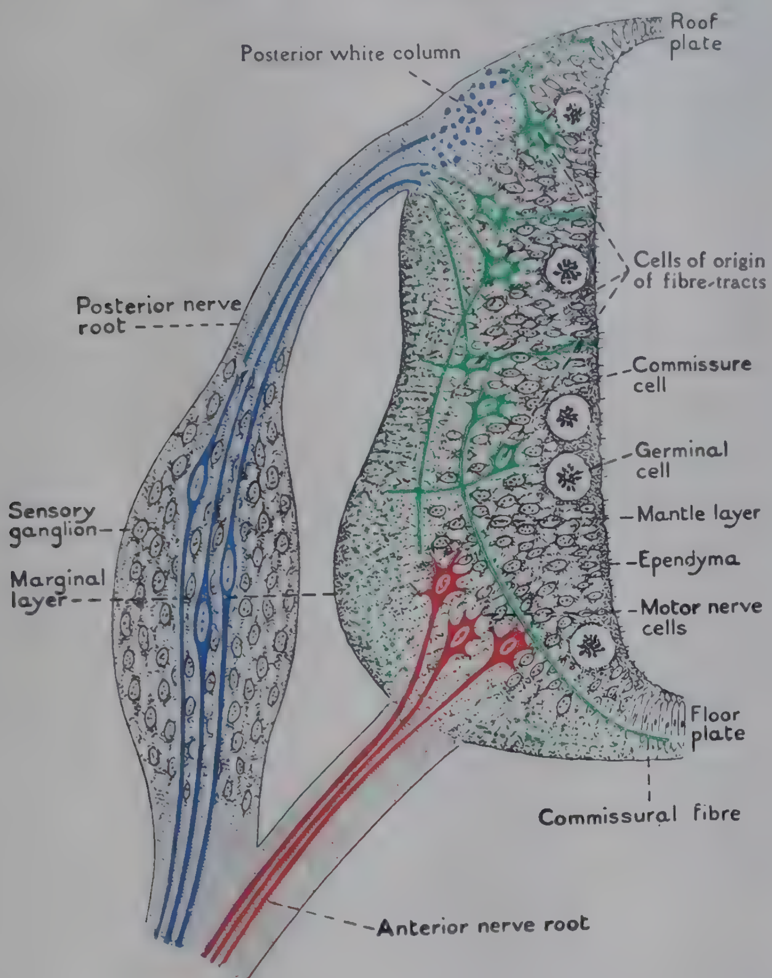

FIG. 745.—DIAGRAM OF TRANSVERSE SECTION OF EARLY NEURAL TUBE.

nervous system have already been considered. It remains to be explained how the features specially distinctive of the spinal cord are produced.

In the early stages (Fig. 745), the neuroblasts are scattered in the intermediate one of the three zones of which the thick side-wall of the neural tube is composed—the mantle layer. The motor nerve-cells soon congregate in large numbers in the ventral part of the basal lamina (Fig. 746), so that the mantle layer expands there into a broad excrescence, which is the rudiment of the **anterior grey column**. The anterior grey column contains the efferent or motor nerve-cells, the axons of which emerge as the **anterior root** of a spinal nerve. At this stage the rest of the mantle layer consists of a thin stratum of neuroblasts (Fig. 746)—mainly intercalated cells—which receive the sensory impressions that enter the cord through the **posterior root** and transmit impulses into axons passing (*a*) to the motor nuclei of the same side, (*b*) to the other side of the cord through the floor-plate (Fig. 745), or (*c*) into the superficial stratum (peripheral layer) of the cord, where they bend upwards or downwards as constituent elements of the **white columns**. As development proceeds (Fig. 745) the **grey substance** formed of these intercalated cells becomes much more abundant and forms a broad blunt boss (Fig. 746 B and C) which is the rudiment of the **posterior grey column**.

The surfaces of the grey columns become coated with a layer of white matter,

composed at first mainly of the medullated axons of cells in the root-ganglia and intercalated cells in the cord; and as the white columns increase in thickness they help to mould the form of the grey columns. This is displayed best in the case of the posterior grey column. The major portion of the white substance which accumulates behind (and afterwards lies on the medial side of) the posterior grey column—the **posterior white column**—does not consist of fibres springing from intercalated cells, either of the cord or any other part of the central nervous system, but of the direct continuations of the central processes of the cells in the spinal ganglia (Figs. 745 and 746). A large proportion of the fibres of the posterior root do not enter the grey columns immediately after their insertion into the alar lamina, but bifurcate to form two vertical nerve-fibres, one passing upwards and the other downwards, in the posterior white column before they end in the grey column some distance above or below the the place where they gained admission to the cord. As the cord grows, the originally blunt posterior grey column becomes drawn backwards into an increasingly attenuated edge and the posterior white column, which was placed originally upon its lateral surface (Fig. 746 A), and then upon its posterior surface (Fig. 746 B), gradually assumes a wedge-shaped form (Figs. 746 C and 748), on the medial side of the grey matter.

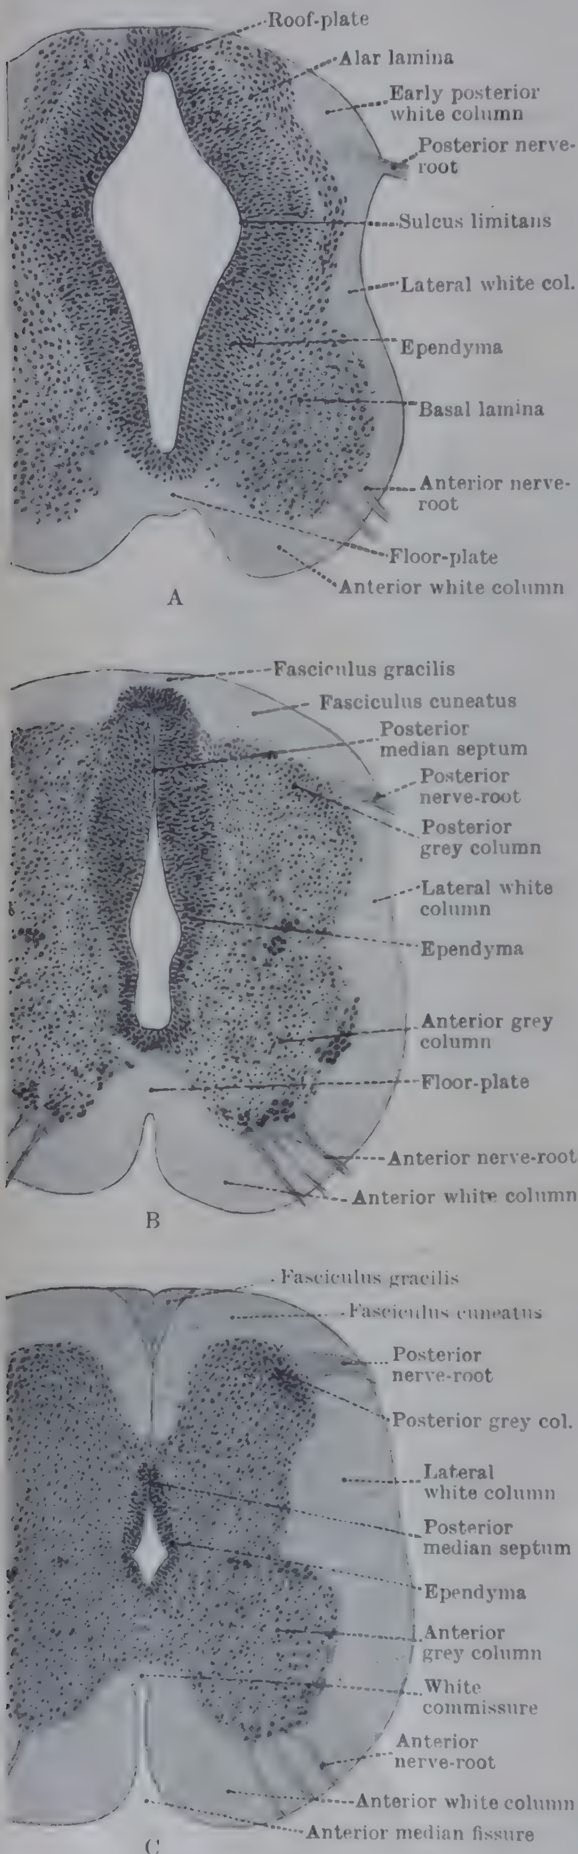

Fig. 746.—Three Stages in the Development of Spinal Cord. (After His.)

Development of Anterior Median Fissure, Posterior Median Septum, and Central Canal.—As the anterior columns of grey matter and white matter increase in size, the anterior surface of the cord, on each side of the median plane, bulges forwards, and the **anterior median fissure** (Fig. 746 A, B, and C) is produced as the natural result.

There has been considerable discussion as to the mode of formation of the **posterior median septum**; but there is no doubt as to the essential facts. Early in the third month the walls of the posterior three-fourths (of the sagittal extent) of the **central canal** become approximated (Fig. 746), and later they fuse to obliterate that part of the canal. But the part of the septum thus formed is only an insignificant portion of the whole. For most of the septum is produced by the gradual elongation of the epithelial cells that line the remnant of the central canal as the fibre-masses of the posterior white columns expand and separate the posterior surface of the cord farther and farther from the canal (see Fig. 735).

Furrows of Spinal Cord.—When cross-sections of the adult cord are made it is seen to be a bilateral structure partially divided into a right and a left half by the anterior median fissure in front and the posterior median septum behind. The anterior median fissure penetrates for rather less than a third of the antero-posterior diameter of the cord. The pia mater dips into it and forms a fold within it. The posterior median septum in the cervical and thoracic regions penetrates into the cord until it reaches a point slightly beyond its centre. It is extremely thin, and consists of ependymal and neuroglial elements, and is intimately connected with the adjacent sides of the two halves of the cord. The pia mater passes over the posterior median septum and sends no prolongation into it. In the lumbar region the septum becomes shallower, whilst the anterior median fissure deepens, and ultimately in the lower part of the cord the fissure and septum are very nearly equal in depth.

The two halves of the cord may show slight differences in the arrangement of parts; but they are virtually symmetrical. They are joined together by a fairly broad commissure which intervenes between the median fissure and the septum.

An inspection of the surface of each half of the cord brings into view a longitudinal groove or furrow at some little distance from the posterior median septum, along its whole length. Through the bottom of this groove the bundles of the posterior nerve-roots enter the spinal cord in accurate linear order. There is no corresponding furrow on the anterior part of each half of the cord in connexion with the emergence of the bundles of the anterior nerve-roots. They emerge irregularly over a broad strip of the anterior surface of the cord which corresponds in its width to that of the subjacent anterior grey column.

The grey columns and the nerve-roots divide the white matter into three white columns—anterior, lateral and posterior—the most lateral of the bundles of the anterior roots being taken as the line of demarcation between the anterior and lateral columns.

In the cervical region a distinct longitudinal groove (sulcus intermedius posterior) marks on the surface the position of a septum of pia mater which dips into the cord and divides the posterior white column into a lateral part termed the **fasciculus cuneatus** and a medial portion named the **fasciculus gracilis**.

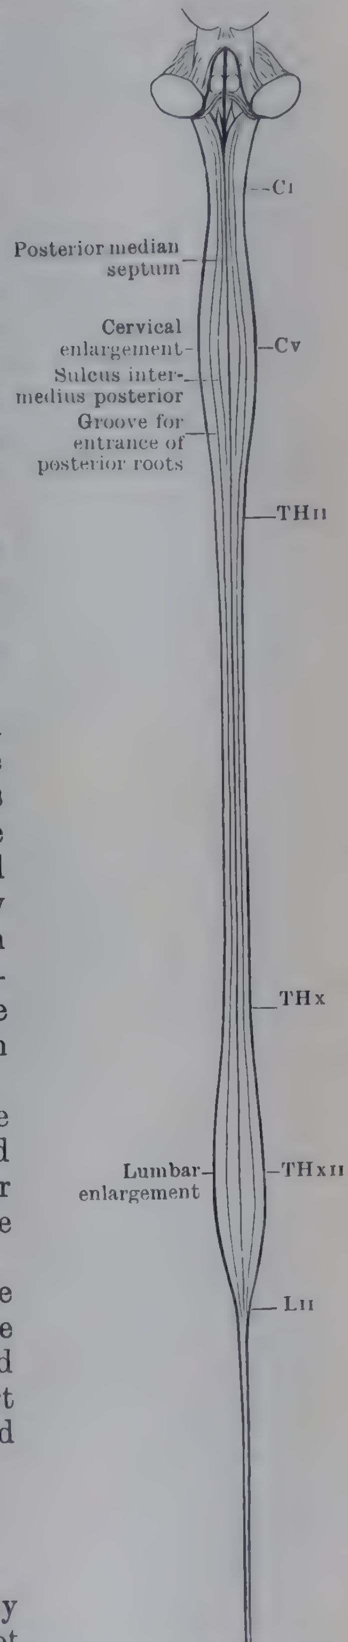

Fig. 747.—Diagram of the Spinal Cord as seen from behind.

Ci, Cv, etc., indicate levels in relation to the vertebræ.

Internal Structure of Spinal Cord

The spinal cord is composed of a central core of grey matter thickly coated with white matter. At only one spot does the grey matter come close to the surface, viz., at the entrance of the posterior nerve-roots.

Grey Matter of Spinal Cord.—The grey matter of the cord has the form of a fluted column, but it is customary to describe it as it appears in transverse sections. It then presents the appearance of the capital letter H. In each half of the cord there is a crescentic mass, the concavity of which is directed laterally. The crescents of opposite sides are connected across the median plane by a transverse band named the **grey commissure**. The posterior median septum extends forwards until it reaches the grey commissure. The bottom of the anterior median fissure, however,

is separated from it by a strip of white matter termed the **white commissure** (Fig. 749 A). In the grey commissure may be seen the **central canal**, which tunnels the entire length of the cord and is just visible to the naked eye as a minute speck.

Each crescentic mass of grey matter presents certain well-defined parts. The portions behind and in front of the grey commissure are termed respectively the **posterior** and the **anterior horns** and are the corresponding grey columns as seen in cross-section. They stand out in marked contrast to each other. The **anterior horn** is short, thick, and very blunt at its extremity. Further, its extremity is separated from the surface of the cord by a moderately thick layer of white matter. Through this layer the bundles of the anterior nerve-roots pass on their way to the surface. Throughout the greater part of the cord the **posterior horn** is elongated and narrow, and is drawn out to a fine point which almost reaches the surface (Fig. 748).

The apical part of the posterior horn differs a little in appearance from the general mass of the grey matter. It has a lighter and more translucent look and is called the **substantia gelatinosa**; it is V-shaped in outline and fits on the posterior horn like a cap.

In the thoracic region of the spinal cord, a pointed projection juts out from the lateral side of the grey matter nearly opposite the grey commissure. This is **the lateral horn** (Fig. 749 B). Traced upwards it becomes absorbed in the greatly expanded anterior grey column of the cervical enlargement. Followed in a downward direction it blends with the anterior column in the lumbar enlargement and contributes to the thickening of that column.

The grey matter is for the most part fairly sharply mapped off from the surrounding white matter; but in the cervical region, on the lateral side of the crescentic mass, fine bands of grey matter penetrate the white matter, and, joining with one another, form a network, the meshes of which enclose small islands of white matter. This constitutes what is called the **formatio reticularis** (Fig. 748). Although best marked in the cervical region, traces of the same reticular formation may be detected in the lower segments.

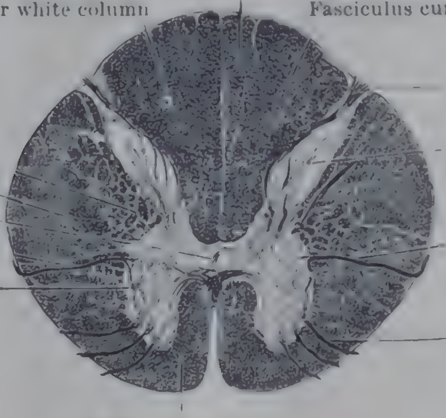

FIG. 748.—TRANSVERSE SECTION OF UPPER PART OF CERVICAL REGION OF SPINAL CORD. (From a specimen prepared by the Weigert-Pal method, by which the white matter is made dark and the grey matter bleached.)

Characters presented by Grey Matter in Different Regions of Spinal Cord.—The grey matter is not present in equal quantity nor does it exhibit the same form in all regions of the cord. Indeed, each segment presents its own special characters in both respects; but it will be sufficient if the broad distinctions which are evident in the different regions are pointed out.

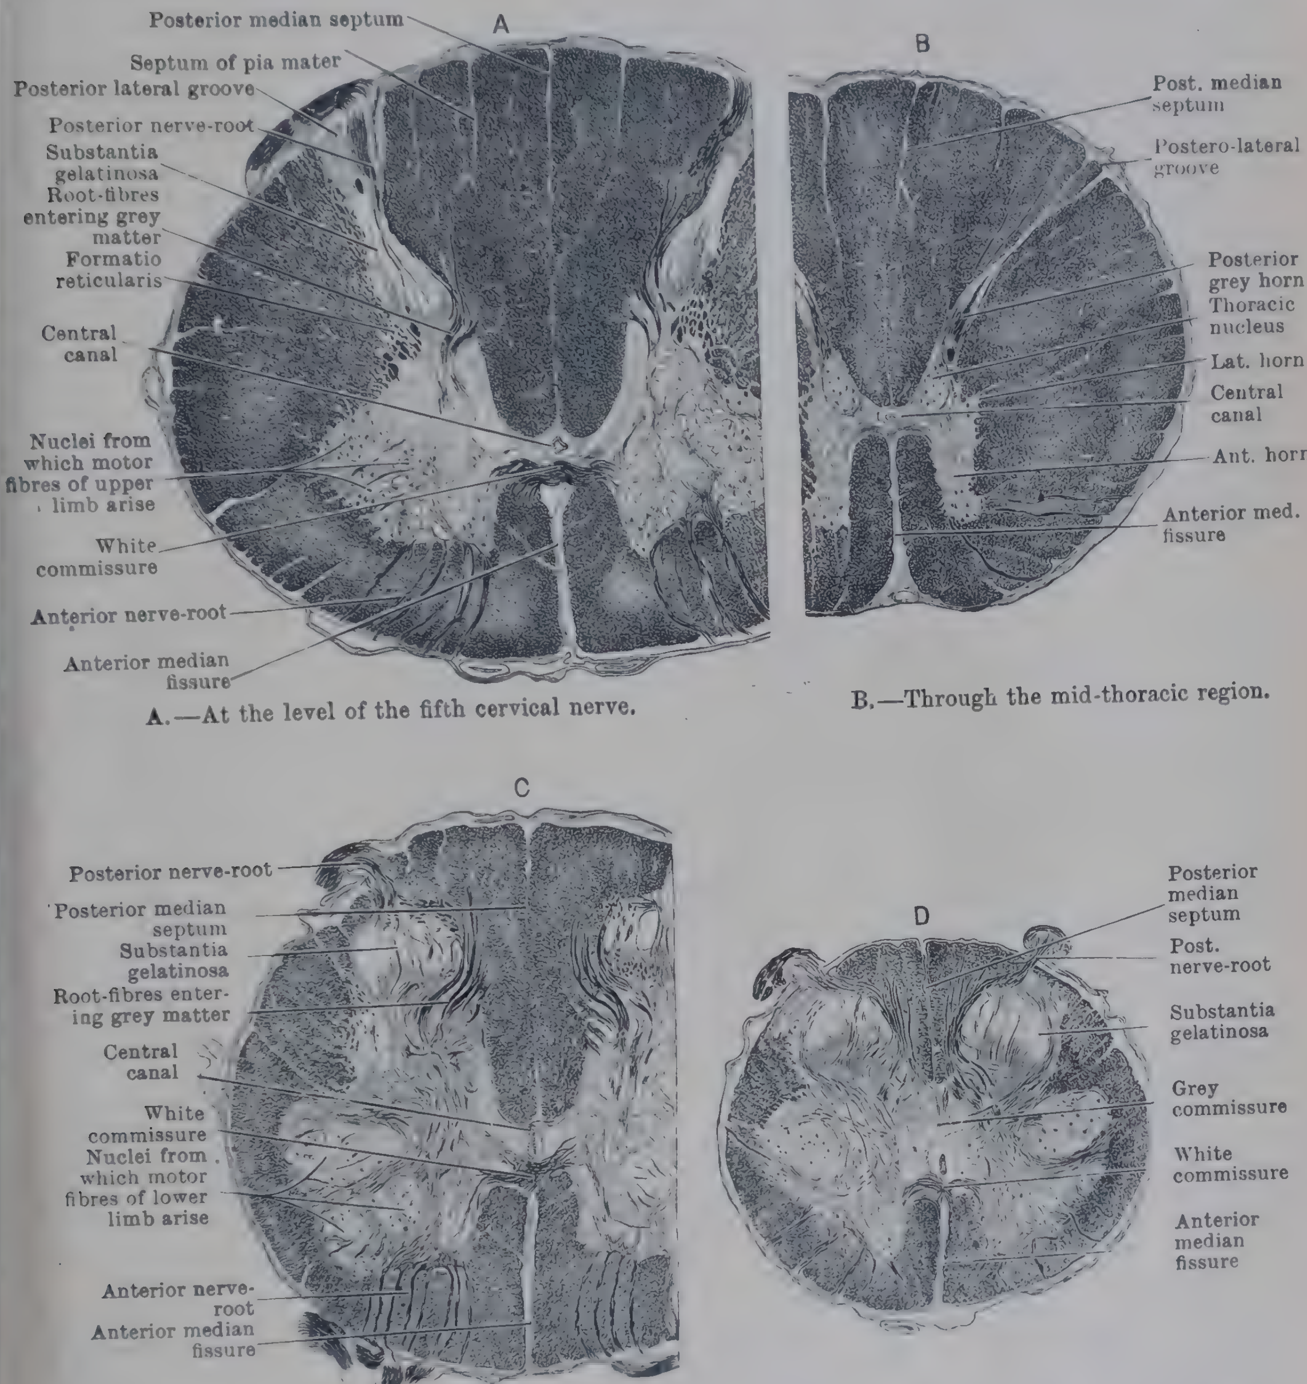
Wherever there is an increase in the size of the nerves attached to a particular part of the cord, a corresponding increase in the amount of grey matter will be observed. The regions where the grey matter bulks most largely are therefore the lumbar and cervical enlargements, for the great nerve-roots which go to form the nerves of the large limb-plexuses enter and pass out from these portions of the cord. In the thoracic region there is a reduction in the quantity of grey matter, in correspondence with the smaller size of the thoracic nerves.

In the *thoracic region* (Fig. 749 B) both horns of grey matter are narrow, but the posterior horn is the more attenuated. In this region the lateral horn also is characteristic, and the substantia gelatinosa in transverse section is pointed and attenuated.

In the upper three segments of the *cervical region* the anterior horns are not

large, and here they resemble the corresponding horns in the thoracic region. But in these segments (and more especially in the first and second) there is a marked attenuation of the neck of the posterior horn, and the grey commissure is very broad.

In the cervical enlargement the contrast between the two horns is most striking; the anterior horn is of great size and presents a very broad surface towards the front of the cord, whilst the posterior horn remains narrow. The great increase



A.—At the level of the fifth cervical nerve. B.—Through the mid-thoracic region.

C.—At the level of the fourth lumbar nerve. D.—At the level of the third sacral nerve.

FIG. 719.—SECTIONS THROUGH EACH OF THE FOUR REGIONS OF SPINAL CORD. (From specimens prepared by the Weigert-Pal method: the white matter is dark; the grey matter is bleached.)

in the bulk of the anterior horn is due to a marked addition of grey matter on its lateral side, and, seeing that this additional matter is traversed by a greater number of fibres, it stands out, in well-prepared specimens, more or less distinctly from the part of the horn that lies to the medial side and represents the entire anterior horn in the thoracic and upper cervical segments. This lateral addition contains the nuclei of origin of the motor nerves of the upper limb. The characteristic thickening of the anterior horn is evident, therefore, in those segments of the spinal cord which supply fibres to the brachial plexus, viz., the lower five cervical segments and the first thoracic segment.

In the *lumbar region* the anterior horns again broaden out for the lumbar enlargement, and for the same reason as in the cervical enlargement. The nuclear masses from which the motor fibres of the lower limbs take origin are added to the lateral part of the columns and give them a very characteristic appearance. In this region, however, the posterior horns also are broad and are capped by substantia gelatinosa which has a semilunar outline. There is consequently no difficulty in distinguishing, from an inspection of the grey matter alone, between transverse sections of the spinal cord taken from the cervical and lumbar enlargements.

In the lower part of the **conus medullaris** the grey matter in each half is an oval mass joined to its fellow of the opposite side by a thick grey commissure. Here, almost the entire bulk of the cord consists of grey matter, the white matter being reduced to a thin coating on the surface.

White Matter of Spinal Cord.—In transverse sections of the cord, the three columns into which the white matter is divided become very apparent. The **posterior white column** is wedge-shaped, and it lies between the posterior median septum and the posterior grey column. The **lateral white column** occupies the concavity of the grey crescent. Behind, it is bounded by the posterior grey column, whilst in front it extends as far as the most lateral fasciculi of the anterior nerve-roots. The **anterior white column** includes the white matter between the anterior median fissure and the anterior grey column, and also the white matter in front of the anterior grey column. The latter portion is traversed by the emerging fibres of the anterior nerve-roots.

In cross-sections the partition of pia mater which divides the posterior white column into the **fasciculus gracilis** and the **fasciculus cuneatus** is very strongly marked in the cervical region, but as it is traced downwards it becomes shorter and fainter, and finally disappears altogether at the level of the eighth thoracic segment.

The white matter is not present in equal quantity throughout the entire length of the spinal cord. It increases steadily from below upwards, and this increase is most noticeable in the lateral and posterior columns. The increase is simply related to the fact that the ascending sensory tracts of the cord become gradually more bulky as they receive accessions from succeeding posterior nerve-roots, while, in a reverse direction, the motor tracts become more attenuated as their component fibres end at successive levels in the anterior grey column. In the lower part of the conus medullaris the amount of grey matter is actually greater than that of the white matter; but in the lumbar region the proportion of grey to white matter is approximately 1 : 2, and in the thoracic and cervical regions 1 : 5.

Central Canal.—The central canal is a very minute tunnel situated in the grey commissure and is barely visible to the naked eye in transverse section. It traverses the entire length of the spinal cord; above, it passes into the medulla oblongata, where it opens into the fourth ventricle of the brain; below, it is continued for about 5 mm. into the filum terminale, and there it ends blindly. Only in the lumbar region does the central canal occupy the centre of the cord. In the thoracic and cervical regions, it lies much nearer the front than the back of the cord; but, as it is traced down into the conus medullaris, it inclines backwards. The width of the canal also varies in different parts of the cord. It is narrowest in the thoracic region; and in the lower part of the conus medullaris it expands into a fusiform dilatation very nearly 1 mm. in diameter.

The central canal is at first lined with a layer of ciliated columnar cells whose outer ends taper into slender processes which penetrate into the substance of the cord; but their cilia are very early lost, and it is not uncommon to find the canal blocked up by epithelial debris.

Filum Terminale.—The delicate thread to which this name is applied is continuous with the pia mater at the end of the conus medullaris. It is easily distinguished, by its silvery and glistening appearance, from the nerve-roots (**cauda equina**) amidst which it lies. It is about 18 cm. in length; and down to the level of the second sacral vertebra it is enclosed with the nerve-roots within the arachnoid and dura mater; as it pierces them at that point it derives a sheath from the dura mater. It then proceeds downwards in the sacral canal, and finally gains attachment to the periosteum on the back of the coccyx

(Fig. 742, p. 856). It encloses the lowest part of the central canal surrounded by a variable amount of grey matter. Clinging to the outer surface of the grey matter there are some bundles of nerve-fibres associated with some nerve-cells identical with those in the spinal ganglia. These nerve-fibres are believed to represent vestigial caudal nerves.

Component Parts of Grey Matter of Spinal Cord

As elsewhere in the central nervous system, **neuroglia** enters largely into the constitution of the grey matter of the cord. The **nervous elements** are (1) nerve-cells and (2) nerve-fibres—both medullated and non-medullated.

In two situations the grey matter presents peculiar features, viz., the apex of the posterior grey column and the tissue around the central canal. In both situations the grey matter stains more deeply with carmine and is more translucent; in other respects the central grey matter and the substantia gelatinosa are very different. The **central grey matter** forms a thick ring around the central canal. It is composed almost entirely of neuroglia, and is traversed by the fine processes from the outer ends of the ependymal cells which line the canal. In transverse sections, the **substantia gelatinosa**, in the cervical and thoracic regions, is V-shaped in outline, and embraces the tip of the posterior grey horn; in the lumbar region this cap has a semilunar outline. In the substantia gelatinosa the neuroglia is present in small quantity, and it is composed mainly of small nerve-cells in considerable numbers.

Nerve-Cells.—The nerve-cells are scattered plentifully throughout the grey matter, but perhaps not in such great numbers as might be expected when we note the enormous number of nerve-fibres with which they stand in relation. They are mostly multipolar, and send off several branching dendrites and one axon. In size they vary considerably, and as a rule (to which, however, there are many exceptions) the bulk of a nerve-cell has a relation to the length of the axon which proceeds from it.

When the nerve-cells are studied in a series of transverse sections of the spinal cord, it will be noticed that a large proportion of them are grouped in clusters in certain districts of the grey matter; and as these groups are seen in very much the same position in successive sections, it is clear that the cells are arranged in longitudinal columns of greater or less length. Thus, we recognize: (1) a ventral column of cells in the anterior grey column; (2) an intermedio-lateral column in the lateral grey column, where that exists; and (3) a postero-medial column of cells (thoracic nucleus), forming a most conspicuous group in the medial part of the neck of the posterior grey column in the thoracic region.

Other cells, besides those forming these columns, are scattered irregularly throughout the posterior grey column and the part of the grey crescent which lies between the two columns.

Ventral Cell-Columns and the Origin of Fibres of Anterior Nerve-Roots.—The ventral cell-groups occupy the anterior grey column, and in them are found the largest and most conspicuous cells in the spinal cord. They extend from one end of the cord to the other. These ventral nerve-cells have numerous wide-spreading dendritic processes, and it is to be noticed that certain of the dendrites do not confine their ramifications to the grey matter. Thus, some of the cells along the medial border of the anterior grey column send dendrites across the median plane in the commissure to end in the anterior grey column of the opposite side; whilst others, lying along the lateral margin of the anterior grey column, send dendrites in amongst the nerve-fibres of the adjoining white matter.

The axons of a large proportion of the ventral cells converge together, and, becoming medullated, they form bundles which pass out from the grey matter and through the white matter in front of the anterior grey column to emerge finally as the fibres of the anterior nerve-roots. These cells, then, are the sources from which the nerve-fibres of the anterior nerve-roots proceed, and in consequence they are frequently spoken of as the "motor cells" of the spinal cord. Whilst this is the arrangement of the axons of the great majority of the motor cells, it should be

noted that a few cross the median plane in the white commissure and emerge among the fibres of origin of the opposite anterior nerve-root.

The ventral cells are not scattered uniformly throughout the anterior grey column. They are aggregated more closely together in certain parts, and thus form sub-columns more or less perfectly marked off from each other.

Thus, one sub-column of ventral cells occupies the medial part of the anterior grey column throughout almost its whole length. In only two segments of the cord is it

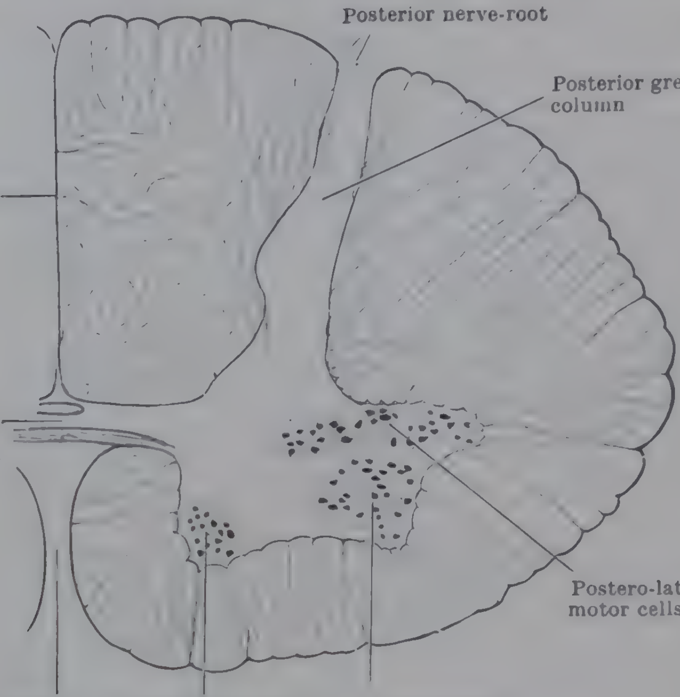


FIG. 750.—SECTION THROUGH FIFTH CERVICAL SEGMENT OF SPINAL CORD.
This and the following three figures are founded on Plates in Bruce's *Atlas of the Spinal Cord.*

absent, viz., the fifth lumbar and the first sacral; at that level alone is its continuity broken. It is termed the *antero-medial column* or group of ventral cells. Behind that cell-column there is another classed with it to which the name of *postero-medial column* is given, but this column of cells is not continuous throughout the entire length of the spinal cord. It is present in the thoracic region, where the motor nuclei for the muscles of the limbs are absent; and it is seen also in two or three of the segments of the cervical region and in the first lumbar segment; elsewhere it is not represented.

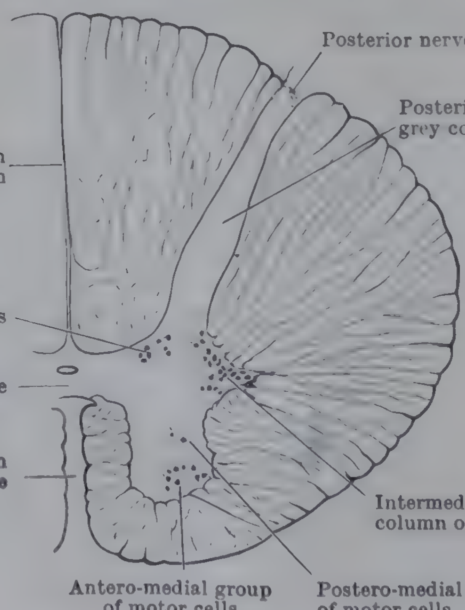

FIG. 751.—SECTION THROUGH EIGHTH THORACIC SEGMENT.

In the cervical and lumbar enlargements, where the marked lateral out-growth is added to the lateral side of the anterior grey column, certain groups of large multipolar cells are visible. They are the nuclei of origin of the motor fibres of the limbs, and consequently they are not represented in the upper three cervical segments, nor in any of the thoracic segments (with the exception of the first) nor in the lowest two sacral segments.

These *lateral cells* are arranged in several columns which extend for varying distances in the superadded lateral parts of the anterior grey column.

The two main columns are an *antero-lateral* and a *postero-lateral column*; in certain segments there is also a *retro-postero-lateral column*, and in a number of segments in the lumbar and sacral regions a *central column* of cells (Bruce, 1901; Romanes, 1941).

There can be no doubt that the grouping of the motor cells in the anterior grey column stands in relation to the muscle-groups to which their axons are distributed; but from what has been said it will be apparent that sharply defined cell-clusters associated with particular muscles do not exist. Still, much can be learned regarding the localization of the motor nuclei in the anterior grey column from the study of the changes which occur in the cell-columns after atrophy of isolated muscles or groups of muscles, and after complete or partial amputation of limbs. It has been pointed out that the long muscles of the trunk (as, for example, the different parts of the sacro-spinalis muscle) receive nerve-fibres from all the segments of the cord. Now, it has been noted that there is only one cell-column—the antero-medial column—which pursues an almost uninterrupted course throughout the entire length of the cord. It may be assumed, therefore, that the nerve-fibres which go to the long trunk-muscles take origin in those medial cells.

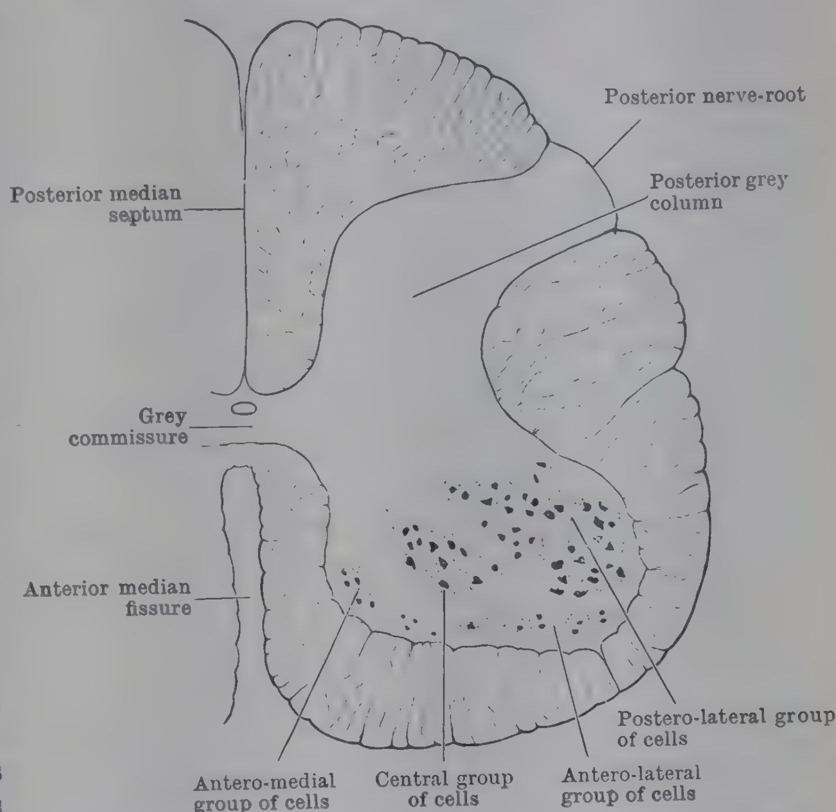

Fig. 752.—Section through Third Lumbar Segment of Cord.

Intermedio-Lateral Cell-Column.—The intermedio-lateral cells form a long slender column which extends throughout the entire thoracic region in the lateral grey column and is prolonged into the first and second lumbar segments. In transverse sections through the cord, this column presents a very characteristic appearance, because its cells are small and are closely packed together. Although these cells, as a continuous column, are restricted to the region indicated, it should be noted that part of the same group reappears in the third and fourth sacral segments. From these cells very fine fibres arise and leave the spinal cord, intermingled with the motor fibres of the anterior nerve-roots; they pass into the sympathetic ganglia, of which they constitute the white rami communicantes. They are the splanchnic efferent fibres of the cord.

Thoracic Nucleus.—This occupies the posterior grey column and is the most conspicuous of all the cell-groups in the cord. It does not, however, extend along its whole length; indeed, it is almost entirely confined to the thoracic segments of the cord, which is the reason for the designation "thoracic nucleus". It begins opposite the seventh or eighth cervical nerve, and it ends at the level of the second lumbar nerve. In transverse section it presents an oval outline and is seen in the medial part of the neck of the posterior grey column immediately behind the grey commissure (Fig. 751). On the lateral side it is circumscribed by numerous curved fibres from the entering posterior nerve-root, and in the lower thoracic region (opposite the eleventh and twelfth thoracic nerves) it becomes so marked that it forms a bulging on the medial side of the posterior grey column.

The cells of the thoracic nucleus are large, and have several dendrites. The axons enter the lateral white column to form a strand of fibres described later as the posterior spino-cerebellar tract.

Nerve-Fibres in Grey Matter of Spinal Cord.—Nerve-fibres, both medullated and non-medullated, pervade every part of the grey matter. They are of three kinds, viz., (1) main axons of the cells, (2) collaterals, (3) terminations of nerve-fibres. Many of the nerve-fibres which compose the white columns give off numerous fine collateral branches which pass into the grey matter from all sides and finally end in relation with the nerve-cells. The majority of the nerve-fibres themselves, which thus give off collaterals, finally enter the grey matter and end similarly. The axons of the majority of the cells in the grey matter leave it and enter either a peripheral nerve or a tract in the white matter.

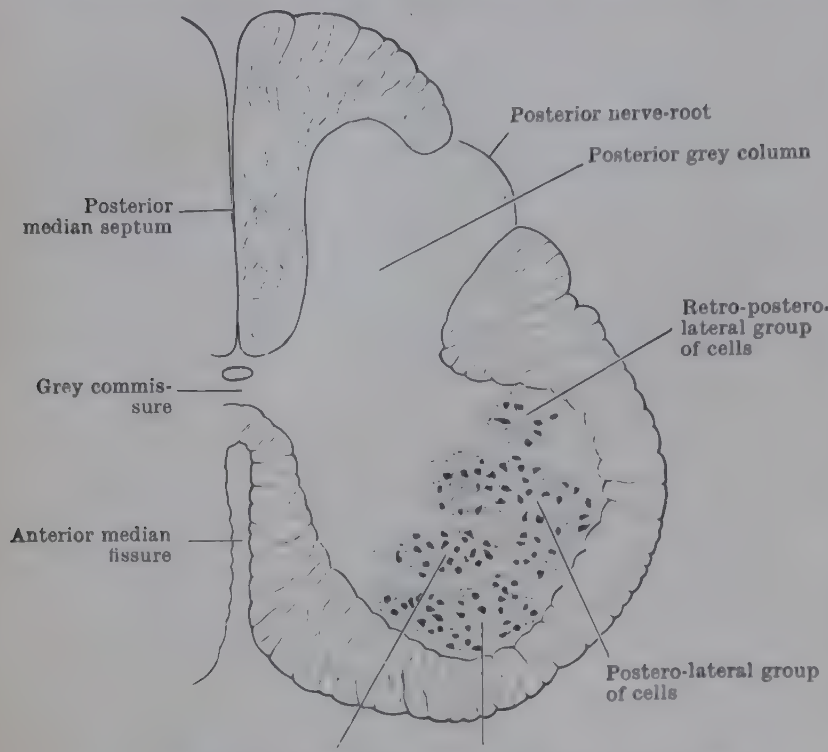

FIG. 753.—SECTION THROUGH FIRST SACRAL SEGMENT.

The nerve-fibres thus derived are interwoven together in the grey matter in a dense and seemingly inextricable interlacement.

COMPONENT PARTS OF WHITE MATTER OF SPINAL CORD

The white matter is composed of nerve-fibres embedded in neuroglia. The fibres, for the most part, pursue a longitudinal course; and, from the deep surface of the pia mater, fibrous septa are carried in along vertical planes between the fibres so as to form an irregular and very imperfect fibrous framework of support. The neuroglia is disposed in a layer of varying thickness subjacent to the pia mater, and it is carried into the cord so as to give a coating to both sides of the various pial septa. The neuroglia is disposed also around the various nerve-fibres, so that each of them may be said to lie in a sheath of that substance. The nerve-fibres are mostly medullated, but have no investment of Schwann cells. It is the medullary substance of the nerve-fibres which gives to the white matter its opaque, milky-white appearance. When a thin transverse section is stained in carmine and examined under the microscope the white matter presents the appearance of a series of closely applied circles, each with a dot in the centre (Fig. 754). The dot is the cut axon, and the dark ring which forms the circumference of the circle is the wall of the neuroglial canal occupied by the fibre. The medullary substance is very faintly seen. It presents a filmy or cloudy appearance between the axon and the neuroglial ring.

Arrangement of Nerve-Fibres of White Matter in Tracts.—When the white matter of a healthy adult spinal cord is examined, the fibres are seen to vary considerably in size; and although there are special places where larger or smaller nerve-fibres are present in greater numbers than elsewhere, yet, as a rule, both large and small fibres are mixed together. From normal preparations no definite indication can be obtained of the fact that the longitudinally arranged fibres are grouped together in more or less discrete tracts, the fibres of which run a definite course and present definite connexions. Yet this is known to be the case, and the existence of the separate tracts has been proved both by embryological

investigation and by the examination of the effects of injuries produced in the nervous system experimentally in living animals or accidentally in Man.

By the **experimental method** it has been shown that when a nerve-fibre is severed the part which is detached from the nerve-cell degenerates, whilst the part which remains connected with the nerve-cell undergoes little or no change. This is called "Wallerian" degeneration. Thus, if in a living animal one-half of the spinal cord is cut across, and after a few weeks the animal is killed and the cord examined, it will be seen that there are degenerated tracts of fibres in the white matter both above and below the plane of division; but, still further, it will be manifest also that the tracts which are degenerated above the plane of division are not the same as those which are degenerated below that level. The interpretation is obvious. The nerve-tracts which have degenerated above the plane of section are the offshoots of nerve-cells which lie in lower segments of the cord or in spinal ganglia below the plane of section. Severed from their nerve-cells, they undergo what is called *ascending degeneration.* On the other hand, the nerve-tracts which have degenerated in the portion below the plane of division are the axons of cells which lie at a higher level than the plane of section—either in higher segments of the spinal cord or in the brain itself. Cut off from the nerve-cells from which they proceed, they provide an example of *descending degeneration.*

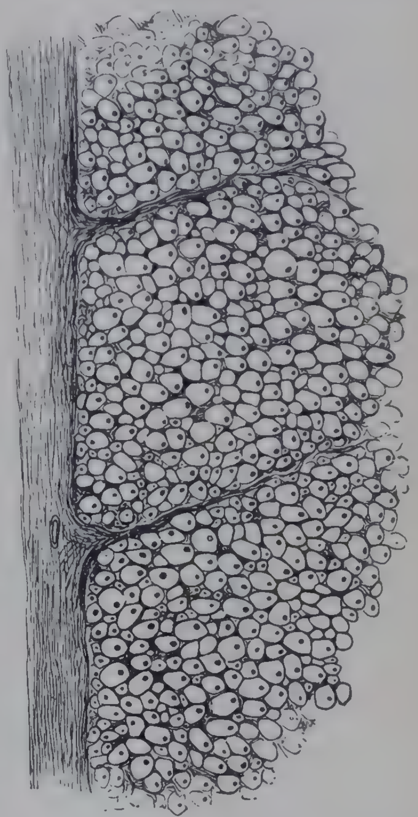

Fig. 754.—Transverse Section through White Matter of Spinal Cord. (Highly magnified.)

The **embryological method** was first employed by Flechsig, and it is often referred to as Flechsig's method. It is based upon the fact that nerve-fibres in the earliest stages of their development are naked axons, unprovided with medullary sheaths. Further, the nerve-fibres of different strands assume their medullary sheaths at different periods. If the fœtal central nervous system is examined at different stages of its development, it is in some cases possible to locate the different tracts of fibres by evidence of this kind. Speaking broadly, the fibres which myelinate first are those which bring the central nervous system into relation with the peripheral parts (skin, muscles, etc.); then, those fibres which bind the various segments of the central nervous system together; next, those which connect the spinal cord with the cerebellum; and, lastly, the tracts which connect the cerebral hemispheres with the spinal cord. The fibre-tracts concerned in the performance of automatic movements therefore become mature before those which provide for the controlling influence of the higher centres. It by no means follows that in all the higher animals corresponding strands myelinate at relatively corresponding periods. Take a young animal which from the time of its birth is able to move about and perform voluntary movements of various kinds in a more or less perfect manner, and compare it with the helpless new-born infant, which is capable of automatic movements only. In the lower animal, the motor tracts which descend from the cerebrum into the spinal cord myelinate at an early period; in the infant, the corresponding fibres do not obtain their medullary sheaths until after birth. The study of the dates at which the various strands of nerve-fibres myelinate therefore not only gives the anatomist a means of locating their position in the white matter of the central nervous system, but also provides some indication of their functions and the periods at which these functions become fully operative (Langworthy, 1923; Lucas Keene & Hewer, 1931; Romanes, 1947).

It is a matter of interest to note that influences which either accelerate or retard the periods at which nerve-fibres are brought into functional activity have also an effect in determining the dates at which the fibres assume their sheaths of myelin. Thus, when a child is prematurely born the whole process of myelination is, as it were, hurried up; and further, when in new-born animals light is freely admitted to one eye and carefully excluded from the other, the fibres of the optic nerve of the former myelinate more rapidly than those of the other.

Study of the minute structure of the central nervous system in normal or experimental material, especially of tissues that have been stained by the methods of Golgi and Ramón y Cajal or by the use of methylene blue, completes the results attained by the other methods, by demonstrating the precise mode of origin and termination of the various tracts.

Posterior White Column and Posterior Roots of Spinal Nerves.—In the cervical and upper thoracic regions of the spinal cord the posterior white column is divided by a septum of pia mater into the **fasciculus cuneatus**, which lies laterally and next to the posterior grey column, and the **fasciculus gracilis**, which lies medially and next to the posterior median septum. The nerve-fibres of the fasciculus cuneatus are for the most part larger than those of the

fasciculus gracilis; and both tracts have a very intimate relation to the posterior nerve-roots; indeed, they are both composed almost entirely of fibres which enter the cord by those roots and then pursue a longitudinal course.

The nerve-fibres of the posterior nerve-roots enter opposite the apex of the posterior horn and divide within the fasciculus cuneatus into ascending and descending branches which diverge abruptly as they pass upwards and downwards.

The **descending fibres** are, as a rule, short, and soon end in the grey matter. They form a bundle, called the **semilunar tract**, which lies between the fasciculus gracilis and fasciculus cuneatus, and undergoes descending degeneration when the cord is divided (Fig. 755).

The **ascending fibres** vary greatly in length, and, at differing distances from the point where the parent fibres enter the cord, they end in the grey matter. A small contribution, however, of ascending fibres, from each posterior nerve-root, extends upwards to end in the medulla oblongata (Figs. 736 and 757).

As each posterior nerve-root enters, its fibres range themselves in the lateral part of the posterior white column close up against the posterior grey column. The nerve-

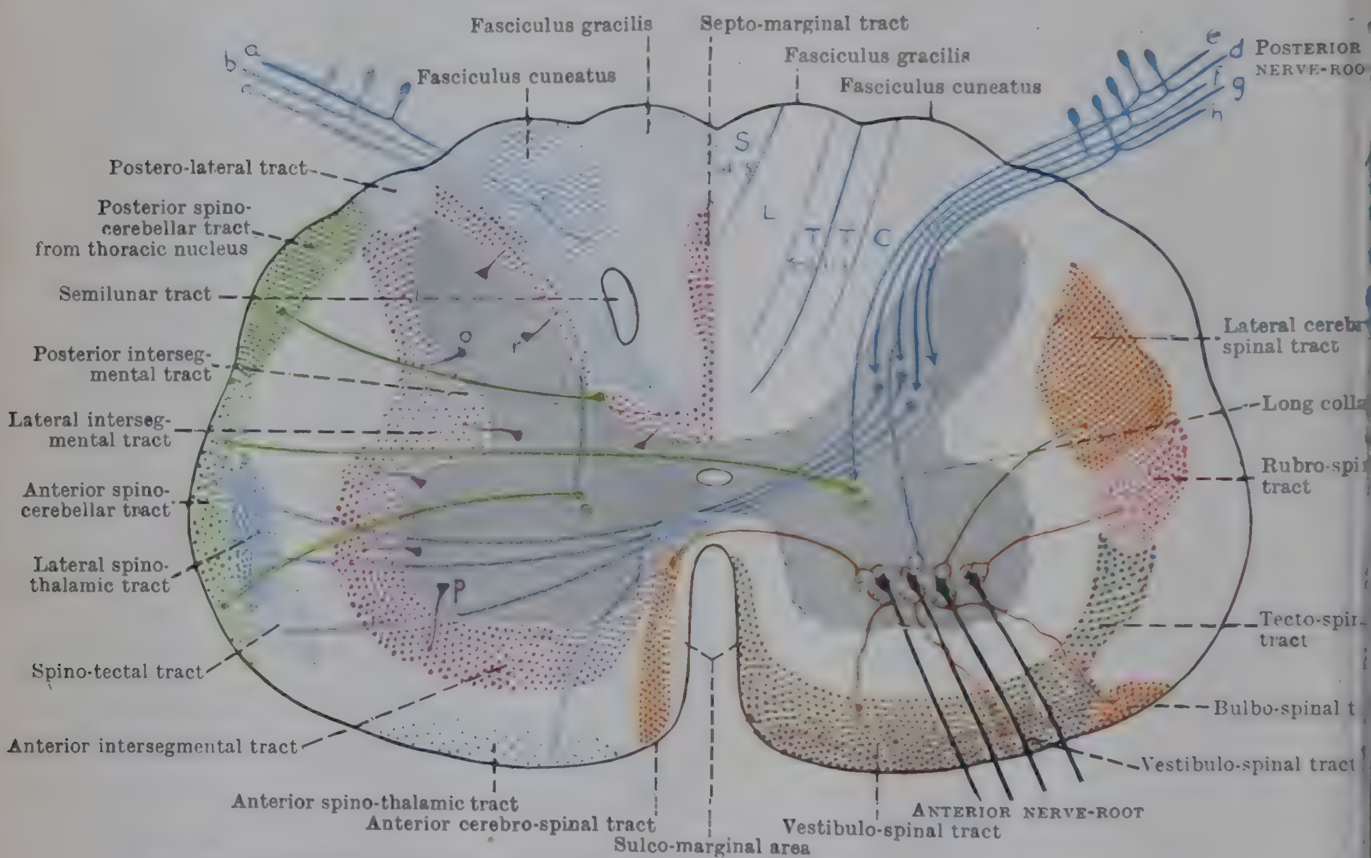

FIG. 755.—DIAGRAM TO ILLUSTRATE THE POSITION OF THE VARIOUS TRACTS IN THE SPINAL CORD.

fibres of the nerve-root next above take the same position, and consequently those which entered from the nerve immediately below are displaced medially, and come to lie in the posterior white column nearer to the median plane. This process goes on as each nerve-root enters, and the result is that the fibres of the lower nerves are gradually pushed nearer and nearer to the posterior median septum in a successive series of lamellar bundles. The greater number of the fibres which are thus carried upwards from the posterior nerve-roots sooner or later leave the posterior white column and enter the grey matter, to end there in relation to some of its cells; but every posterior nerve-root sends a few fibres up the whole length of that portion of the spinal cord which lies above, and thus the posterior white column gradually increases in bulk as it is traced upwards, and, in all except the lowest part of the cord, the posterior white column is separable into a fasciculus gracilis and a fasciculus cuneatus. The fasciculus gracilis is composed of the long ascending fibres of the posterior nerve-roots which have entered the lower segments. To put the matter differently: the fibres of the sacral roots are displaced medially by the entering lumbar fibres, these are, in their turn, pushed medially by the entering thoracic fibres, and, lastly, the fibres of the cervical roots displace the thoracic fibres.

The difference between the fasciculi simply is this, that the fasciculus gracilis is composed of the fibres of posterior nerve-roots which have entered the cord at a lower level than those that form the fasciculus cuneatus. The fibres of the fasciculus gracilis, taking them as a whole, run therefore a very much longer course.

Our knowledge of the constitution of the posterior white columns is derived largely from the study of the course of degeneration in monkeys after the cord has been cut across—either partially or completely. But we have also a direct knowledge of the lamination of the posterior columns of the human spinal cord (Fig. 756) acquired from the examination of cases in which the cord or its nerve-roots had been injured during life. We have some information of the lamination of crossed ascending fibres also in the anterior and lateral white columns of the human cord. That information is given diagrammatically in Fig. 756. It will be noted that of the fibres which cross before they ascend in this column, those from the lower segments are superficial, and the latest arrivals from the opposite side (*i.e.*, those from the upper segments) travel deep in the white matter.

Experimental and clinical evidence has established that the long fibres of the tracts of the posterior column convey impulses which have their origin in sensory nerve-endings in the skin, and also in muscles, joints, and related structures (proprioceptive impulses). Hence, an interruption of these fibres leads to a defect of motor co-ordination and to an inability to recognize passive movements. It also interferes with finer tactile sensibility and with those aspects of tactile sensation into which a spatial element enters, *e.g.*, the localization of a tactile stimulus and the discrimination of compass-points. It is useful to anticipate at this point by noting that the fibres of the ascending tracts of the posterior column finally end in two collections of nerve-cells in the medulla—the nucleus gracilis and nucleus cuneatus. From here the proprioceptive impulses are relayed by a great sensory tract—the medial lemniscus—which after decussation ascends to the thalamus of the opposite side. Lastly, a third relay of neurons projects the impulses from the thalamus to the sensory areas of the cerebral cortex.

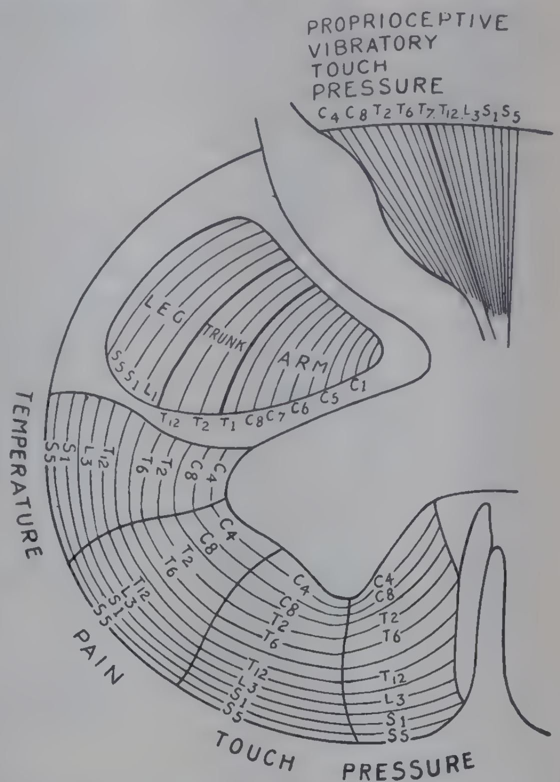

FIG. 756.—DIAGRAM (after Foerster, 1936) to show: (i) the peripheral position in the antero-lateral white column of ascending fibres from the lowest segments of the cord and the position progressively nearer the grey matter of those from higher segments ; (ii) the medial position in the posterior white column of fibres ascending from the lowest segments and the progressively lateral position of those from higher segments ; (iii) lamination of fibres within the lateral cerebro-spinal tract.

Numerous collateral fibres stream into the posterior grey column both from the ascending and descending branches of the entering fibres of the posterior nerve-roots. They are classified into long and short collaterals. The **long collaterals** extend forwards into the anterior grey column and end in relation to the anterior nerve-cells. The **short collaterals** end in relation to the nerve-cells in the substantia gelatinosa and other nerve-cells of the posterior grey column.

The majority of the fibres of each posterior nerve-root enter the cord on the medial side of the apex of the posterior horn. The manner in which they are related to the fasciculus cuneatus and the fasciculus gracilis has been noticed ; but a certain number of those fibres which lie most laterally take a curved course forwards on the medial side of the posterior horn and then pass into it. In the thoracic region these curved fibres end in connexion with the cells of the thoracic nucleus (Fig. 749 B, p. 861, and Fig. 751).

Postero-Lateral Tract.—This is a small tract of nerve-fibres of minute calibre which assume their medullary sheaths at a comparatively late period and, indeed, many of them are non-medullated. It is placed at the surface of the cord close in front of the entering posterior nerve-roots. It is formed by some of the lateral fibres of the posterior nerve-roots which do not enter the fasciculus cuneatus, but pass upwards close to the substantia gelatinosa, in which most of them ultimately end. There is evidence to show

that these fibres are largely concerned with the transmission of impulses that underlie the sensation of pain.

It is evident that the fibres which enter the cord through each posterior nerve-root have three main modes of distribution: (1) the majority take part in the formation of the posterior white column, and pass upwards or downwards to end in the grey matter at some other level in the central nervous system; (2) some fibres, and many collaterals of fibres in the fasciculus cuneatus, lie close to the posterior grey column and describe a series of graceful curves as they pass forwards, before turning laterally into all regions of the grey matter to end at the same level as they enter the cord; (3) a third series form the postero-lateral tract and end in connexion with the cells of the substantia gelatinosa and other cells in the posterior and anterior grey columns.

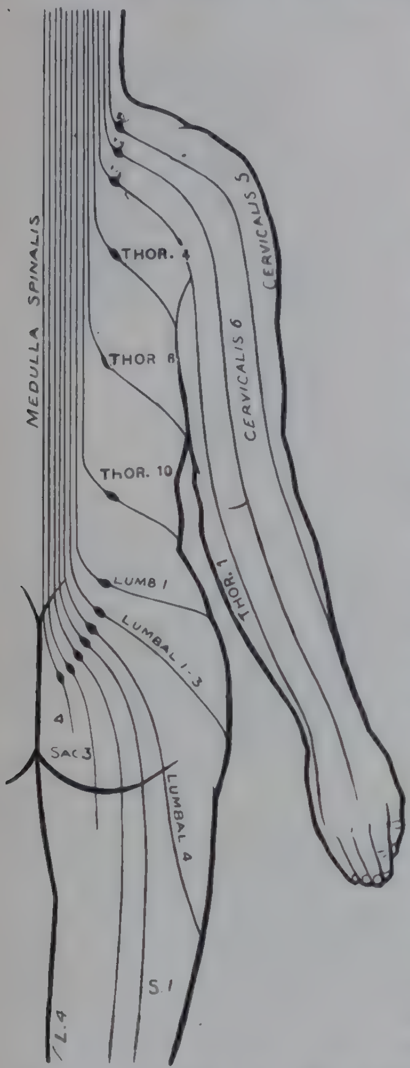

Fig. 757.—Diagram to show the Manner in which Fibres of Posterior Nerve-Roots enter and ascend in the Posterior White Column.

The fibres derived from the posterior nerve-roots which ascend in the posterior white columns to the medulla oblongata of the brain constitute a direct sensory tract; there are other fibres which form crossed sensory tracts termed the **spino-thalamic tracts.** The latter fibres arise as the axons of certain of the cells in the posterior grey column in relation to which fibres from the posterior nerve-roots have ended, and, after crossing to the opposite side of the cord through the white commissure, they ascend in the cord to the brain, where they ultimately reach the thalamus. As the spino-thalamic fibres ascend in the cord they are gathered into two loose and not very sharply defined strands, called the **anterior** and **lateral spino-thalamic tracts**, which pass upwards in the corresponding white columns.

The lateral spino-thalamic tracts are mainly concerned with the transmission of impulses related to the sensations of temperature and pain, while crude tactile and pressure impulses are carried up the cord by the fibres of the anterior spino-thalamic tract. It is of some importance to recognize that the fibres which form these tracts cross over from the opposite side of the spinal cord close in front of the central canal. Hence pathological conditions affecting this part of the spinal cord (*e.g.*, syringomyelia) are liable to involve these decussating fibres and to lead to defects of cutaneous sensations at lower levels of the body.

Association Fibres in the Posterior White Column.—The whole of the fibres of the posterior white column are not derived from the posterior nerve-roots. A few fibres have a different origin. They are derived from certain of the cells of the grey matter, and, having entered the posterior white column, they divide into branches which pass upwards and downwards in the column for a varying distance before they finally turn in to end in the grey matter at higher and lower levels. These fibres, therefore, are links of connexion between different segments of the cord, and they constitute the **posterior intersegmental tract**. Our information regarding these fibres is at present defective; but it is believed that the deepest part of the column, *i.e.*, the part next the grey commissure, and the **septo-marginal tract**, placed in apposition with the posterior median septum and in the adjoining part of the surface, belong mainly to this category.

Lateral and Anterior White Columns.—It is convenient to consider the anterior along with the lateral column and to call the whole mass of white substance left after elimination of the posterior white column the **antero-lateral white column.** In contact with the surface of the grey columns there is a broad band of white matter, the parts of which are known respectively as **anterior** and **lateral intersegmental tracts.** They are composed mainly of fibres which spring

from nerve-cells in the grey columns, and, after passing for varying distances upwards or downwards, end in the grey matter of the cord. They constitute an intrinsic system of fibres linking together different levels of the spinal cord. They become medullated before any other fibres, except the root-fibres and their continuations in the posterior white column. When cut across, some of the fibres degenerate above the injury and others below it.

The best-known long or extrinsic systems of fibres in the antero-lateral white column are the **cerebro-spinal** and **spino-cerebellar tracts**.

There are, however, many other tracts at least as important as these, but there is as yet no close agreement as to their precise limits or connexions. One reason for this is that some of the elements of one tract may become intermingled with those of another; moreover, the position and relations of certain of them vary considerably at different levels of the cord. In Fig. 755 an attempt has been made to indicate the present state of our knowledge of these great strands of white fibres. The diagram is not intended to represent any definite level of the cord, though certain features are shown which occur only in the cervical region; and in respect of other features, the arrangement found in lower regions of the cord has been introduced to make the diagram more serviceable.

Much of the apparent complexity of this chart will disappear if the reader recalls some general statements (p. 849) made with regard to the main features of the brain. It was then explained that when afferent nerves which come from the skin and muscles enter the cord, they not only establish relations with the motor nuclei and other spinal structures in the neighbourhood of their insertion, but also give rise, directly or indirectly (see Fig. 736), to many tracts which pass upwards to reach the medulla oblongata, the cerebellum, the mid-brain, the thalamus, and the cerebral hemisphere. In the neighbourhood of each level where these ascending sensory tracts end, such as, for example, the region of the vestibular nucleus and cerebellum, the tectum of the mid-brain, the corpus striatum, and the cerebral hemisphere, great descending tracts originate and pass downwards in the spinal cord (Fig. 736—the red lines). Thus we have cerebro-spinal, rubro-spinal, tecto-spinal, vestibulo-spinal, and bulbo-spinal tracts passing down the spinal cord; and each system eventually ends in relation to the series of motor nuclei—many of them in the spinal cord.

In the antero-lateral white column the various fasciculi will be found to be grouped roughly into three bands: next to the grey matter there are the intersegmental tracts; then comes a band of descending (motor) fasciculi; and then, on the surface, a series of ascending (sensory) fasciculi. This arrangement, however, is not maintained with any degree of exactitude in the anterior column, where the sharp demarcation between ascending and descending fasciculi is in great part destroyed by the intermingling of fibres passing in opposite directions.

It has already been explained that of the fibres which enter the spinal cord in the posterior root the great majority enter the posterior white column, where they bifurcate (Fig. 755 *a*); one branch of each fibre passes upwards either in the fasciculus gracilis or in the fasciculus cuneatus, or it may pass from the latter into the former; the other descends in the semilunar tract. Other fibres enter the postero-lateral tract. But all the remaining fibres of the posterior root, together with the majority of the fibres of the fasciculus cuneatus, sooner or later enter the grey matter (Fig. 755 *b* to *h*) of the cord.

Some of them (*b*) pass directly to end in the **thoracic nucleus** of their own side; and from its cells fresh fibres arise which pass laterally through the posterior grey column and lateral white column to reach the surface, where they bend upwards as constituent fibres of the **posterior spino-cerebellar tract**. These fibres pass upwards through the whole length of the cord (above their place of origin), into the medulla oblongata, and thence into the cerebellum through its inferior peduncle. Other fibres on the same side (*c*), and perhaps also on the other side (*d*), end amidst cells scattered in the base of the posterior grey column, the axons of which pass into the **anterior spino-cerebellar tract**. In this tract they ascend through the spinal cord, medulla oblongata, and pons, to enter the cerebellum by the superior peduncle. The two spino-cerebellar tracts convey to the cerebellum the afferent

impulses from the muscles and associated structures that underlie the unconscious control of muscular co-ordination and the regulation of muscular tonus.

Among the descending tracts that connect various parts of the brain (see Fig. 736) with the motor nerve-cells in the anterior grey column may be mentioned the **cerebro-spinal**, the **rubro-spinal** (from the red nucleus), the **tecto-spinal** (from the superior corpus quadrigeminum), the **vestibulo-spinal** (from the terminal nucleus of the vestibular nerve), and the **bulbo-spinal tracts**.

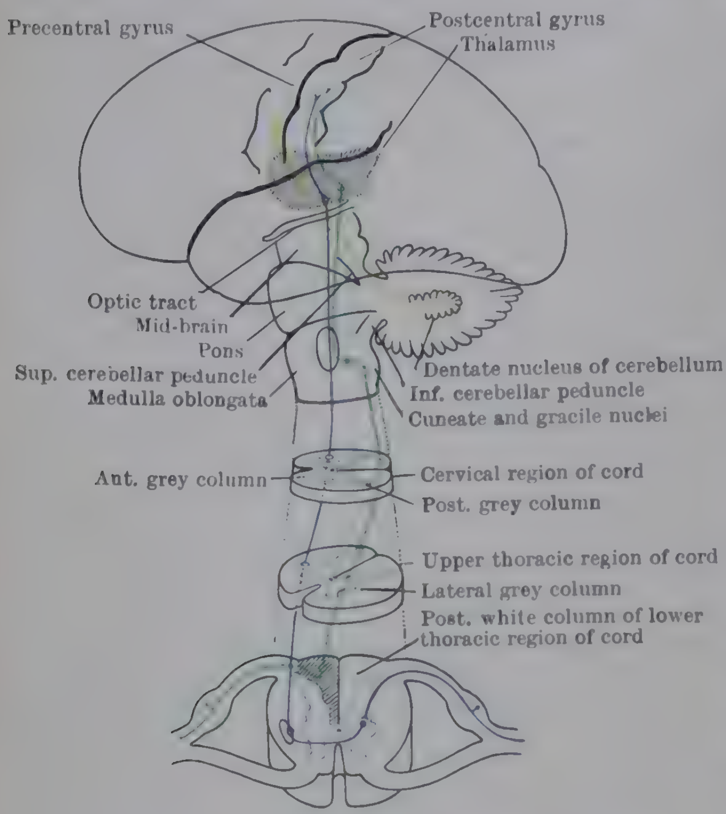

FIG. 758.—DIAGRAM OF TRACTS ASCENDING IN SPINAL CORD AND BRAIN TO THALAMUS AND CEREBRAL CORTEX.

Blue: Spino-thalamic fibres cross in the cord and ascend to the thalamus in the anterior (not shown) and lateral spino-thalamic tracts.
Green: Fibres which run up in the posterior white column and convey proprioceptive impulses to the cuneate and gracile nuclei, whence the medial lemniscus carries them across the median plane and then upwards to the ventral nucleus of the thalamus. From the thalamus, the sensory impulses (blue and green) are relayed to the postcentral gyrus of the cerebral cortex.
Yellow: Dentato-thalamic fibres carry impulses from the dentate nucleus of the cerebellum to the anterior part of the ventral nucleus of the opposite thalamus, whence the impulses are relayed to the precentral gyrus.

There are two cerebro-spinal tracts, crossed and uncrossed. They are composed of fibres of diverse origin in the cerebral hemisphere but, from the functional point of view, the most important are those which arise from conspicuous large pyramidal cells in the motor area of the cerebral cortex and pass downwards through the brain-stem to gain the spinal cord. On the front of the medulla (as we shall see later) they form a prominent column on each side of the median plane, and these columns are termed the *pyramids*. Hence the cerebro-spinal tracts are often referred to as the "pyramidal tracts". As they enter the cord, most of the fibres cross the median plane to the opposite side to form the crossed cerebro-spinal tract. This tract, therefore, conveys impulses to the motor cells of the spinal cord from the opposite cerebral hemisphere. The few fibres which continue down into the anterior white column of the spinal cord without undergoing a decussation constitute the uncrossed or direct cerebro-spinal tract. Not only is the crossed cerebro-spinal tract much larger than the uncrossed, it is also by far the more important clinically.

The crossed cerebro-spinal tract is situated in the lateral white column of the cord and is commonly termed the **lateral cerebro-spinal tract**. It occupies a position immediately antero-lateral to the posterior grey column, and subjacent to the posterior spino-cerebellar tract, which separates it from the surface of the cord. Below the point where the posterior spino-cerebellar tract begins, the lateral cerebro-spinal tract becomes superficial, and in this position it can be traced as low as the fourth sacral segment. As it descends in the cord it gradually diminishes in size, because as it traverses each spinal segment numerous fibres leave it to enter the anterior column of grey matter and end in connexion with the motor cells from which the fibres of the anterior nerve-roots arise. The entire strand is ultimately exhausted in this way. Numerous collateral fibres spring from the fibres of the cerebro-spinal tracts; they enter the grey matter and end in a similar manner. Thus, a single fibre may be connected with several segments of the spinal cord before it finally ends. The lateral cerebro-spinal tract must be regarded as a great motor pathway which brings the spinal motor apparatus under voluntary control, for it is known that the initiation and control of voluntary move-

ments depend on its integrity. The fibres of the cerebro-spinal tracts are sometimes referred to as *upper motor neurons*, in contradistinction to the motor cells of the spinal cord and the efferent fibres of the peripheral nerves to which they give rise, which are the *lower motor neurons*.

In many marsupials, rodents, and ungulates the crossed cerebro-spinal tract lies in the posterior white column of the spinal cord.

The uncrossed cerebro-spinal tract, as already mentioned, lies in the anterior white column of the cord and is named the **anterior cerebro-spinal tract.** It is usually of small size and lies near the anterior median fissure. As a rule it

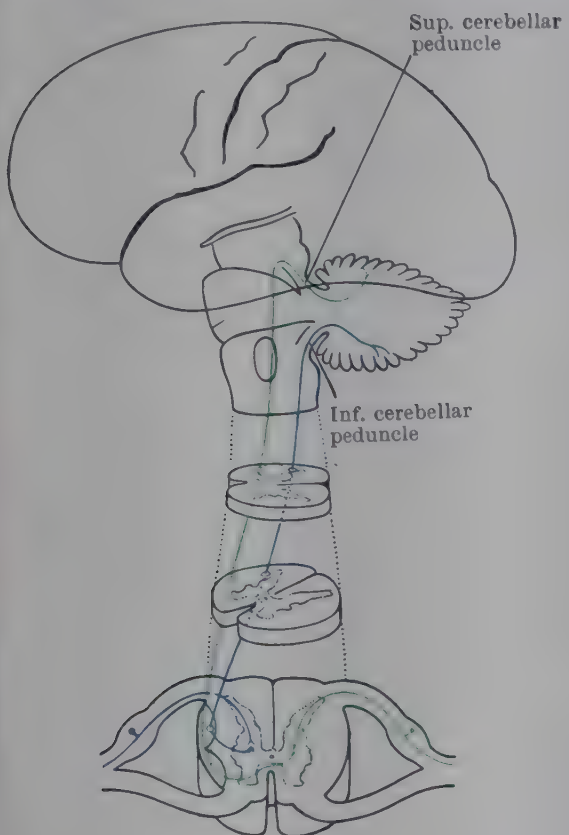

Fig. 759.—Diagram of Spino-Cerebellar Tracts.

Blue: Path of proprioceptive impulses conveyed by posterior spino-cerebellar tract (arising in thoracic nucleus of same side) through inferior cerebellar peduncle to vermis of cerebellum.
Green: Path of proprioceptive impulses conveyed by anterior spino-cerebellar tract (arising in the base of the posterior grey column of both sides, but chiefly opposite side) to vermis of cerebellum through superior peduncle.

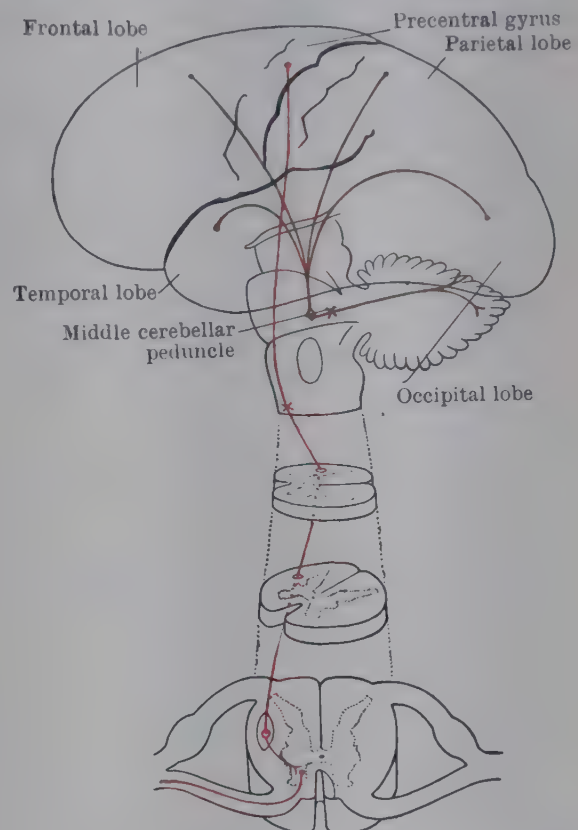

Fig. 760.—Diagram of Cortico-Spinal and Cortico-Ponto-Cerebellar Fibres.

Red: Path of efferent impulses conveyed by pyramidal fibres from motor area of cerebral cortex through lateral (crossed) cerebro-spinal tract to motor cells in anterior grey column of spinal cord, and thence by fibres of anterior nerve-root.
Brown: Cortico-ponto-cerebellar system, conveying impulses from cerebral cortex to nuclei pontis and thence to opposite half of cerebellum.

cannot be traced lower than the middle of the thoracic region, and its relative size varies greatly in different individuals. Although the fibres of this tract do not to any significant extent cross the median plane as they enter the cord, they do not actually end on the same side of the cord; at successive levels along the path of the tract they make use of the white commissure and cross to the opposite side to terminate in relation to motor cells in the same manner as the fibres of the lateral cerebro-spinal tract.

From the decussation of the cerebro-spinal tracts it follows that their destruction in any part of their course through one side of the brain must result in paralysis of the muscles supplied by the efferent fibres of the opposite side of the spinal cord. This paralysis, it should be noted, affects only the *voluntary* movement of these muscles.

In cases of old brain-lesions it is sometimes possible to detect some degenerated fibres in the lateral cerebro-spinal tract of the sound side, and from that it is supposed that the tract contains a few uncrossed fibres. If this is the case, each side of the spinal cord actually stands in connexion with the motor area of both cerebral hemispheres. Experimental evidence has shown that, strictly speaking, this is true, but the homolateral connexions are too few to have any practical significance from the clinical point of view.

It may be noted that the fibres of the cerebro-spinal tracts are not medullated until the time of birth. Indeed, they are the latest of all the tracts of the spinal cord to undergo myelination (p. 867).

The rubro-spinal tract is situated in the lateral white column immediately anterior to the lateral cerebro-spinal tract. It is composed of fibres which have their origin in the red nucleus of the opposite side of the mid-brain and undergo decussation immediately after leaving the red nucleus. The rubro-spinal fibres

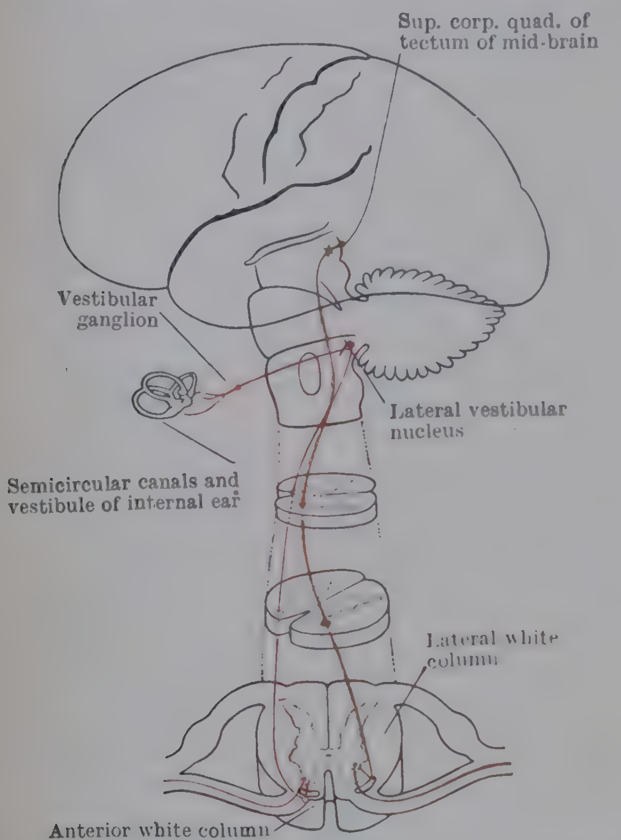

FIG. 761.—DIAGRAM OF VESTIBULO-SPINAL AND TECTO-SPINAL TRACTS.

Red : Fibres of the vestibular nerve send their peripheral branches to the semicircular canals and their central branches to vestibular nuclei in medulla oblongata and pons. The vestibulo-spinal tract arises from the lateral vestibular nucleus and descends in the anterior white column of the cord (mainly on the same side). At successive levels, fibres leave the tract and make synaptic contact with motor cells in the anterior grey column.

Brown : The tecto-spinal tract arises in the mid-brain from the superior corpus quadrigeminum and descends through the brain-stem into the antero-lateral white column of the cord on a deeper plane than the vestibulo-spinal tract. At successive levels, fibres make synaptic connexion with the motor cells.

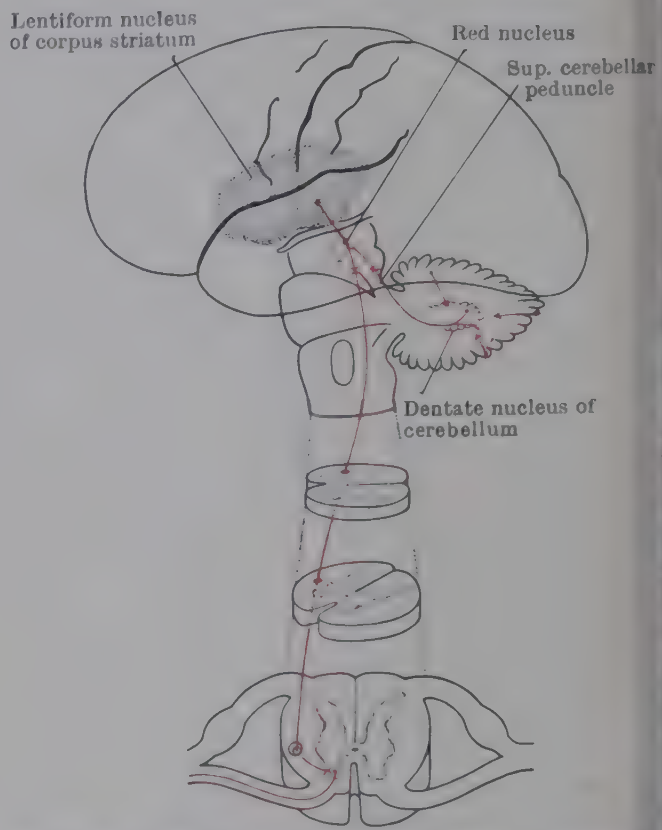

FIG. 762.—DIAGRAM OF THE RUBRO-SPINAL SYSTEM OF FIBRES.

Red : The rubro-spinal tract arises in the mid-brain from the red nucleus, crosses the median plane at once and descends through the brain-stem into the lateral white column of the spinal cord. At successive levels, its fibres leave the tract to make synaptic connexion with motor cells. The tract is relatively much bigger in lower mammals than in Man.

The red nucleus receives afferent fibres from the corpus striatum of the cerebrum and from the cerebellum. Fibres from all parts of the cerebellar cortex run to the dentate nucleus in the centre of the same cerebellar hemisphere. Fibres from the dentate nucleus are carried by the superior cerebellar peduncle into the mid-brain, where they cross the median plane and end in the red nucleus.

terminate in connexion with the motor cells of the spinal cord in the same manner as the fibres of the cerebro-spinal tracts. Since the red nucleus itself receives efferent fibres from the opposite side of the cerebellum, it follows that the rubro-spinal tract provides a pathway through which one-half of the cerebellum can exert an influence over the lower motor neurons of the *same* side of the spinal cord. It has already been mentioned, and it is well to emphasize again, that in the human brain the rubro-spinal tract is poorly developed; it probably extends into only the upper part of the spinal cord.

The **tecto-spinal tract** is a rather diffuse collection of fibres spread out through the superficial part of the anterior white column and extending laterally into the lateral column. They arise from the superior corpus quadrigeminum of the mid-brain and decussate before descending into the spinal cord. Like the rubro-spinal tract, the tecto-spinal tract is an important motor system in many lower mammals in which the mid-brain is a relatively larger and more important element of the central nervous system. In the human brain, however, in which

functional centres of control are relegated to the more elaborate organization of the cerebral hemispheres, the tecto-spinal tract becomes correspondingly reduced. The fibres of the tecto-spinal tract convey impulses by which the reflex centres of the tectum of the mid-brain (particularly the visual centres) influence the activity of the lower motor neurons of the spinal cord.

The **vestibulo-spinal tract** occupies the surface layer of white matter in the anterior white column. Its fibres are derived from the lateral vestibular nucleus (Deiters' nucleus), and, while most of them remain uncrossed, an appreciable number cross to reach the opposite side of the spinal cord. They terminate at successive levels in connexion with the motor cells of the anterior horn, and they provide a pathway by which impulses from the semicircular canals (concerned with equilibratory reflexes) can modify the activity of the lower motor neurons.

The **bulbo-spinal tract** forms a small triangular area at the surface immediately to the lateral side of the anterior nerve-roots, but there is great uncertainty as to its mode of origin; it has been called the *fasciculus olivo-spinalis*, because its discoverer, Helweg, believed it to originate from the olivary nucleus in the medulla. However, there are good reasons for supposing that this cannot be the case, and that it must arise elsewhere in the hind-brain.

Besides the descending tracts and the spino-cerebellar tracts, the anterior and lateral white columns of the spinal cord also contain the anterior and lateral spino-thalamic tracts, which have already been mentioned. The relative positions occupied by these tracts are shown in the diagram in Fig. 755. Closely intermingled with the lateral spino-thalamic tract are ascending fibres which also take their origin from cells in the posterior grey column of the opposite side but end in the superior corpus quadrigeminum of the mid-brain. These fibres comprise the **spino-tectal tract**. They contribute to the reflex activities of the mid-brain by transmitting somatic sensory impressions to the superior corpus quadrigeminum.

The student will find it convenient at this stage to gain a general idea of the course of the main ascending and descending tracts of the spinal cord, and their connexions, even though he may be as yet unacquainted with the regions of the brain where they terminate or have their origin. The five schematic diagrams in Figs. 758 to 762 have been contrived with this end in view. They should be studied at this juncture, and reference made to them later when the various tracts come under further consideration.

White Commissure.—The white commissure is composed of medullated nerve-fibres that pass from one side of the spinal cord to the other and enter the anterior grey column and the anterior white column. It is to be regarded more as a decussation than as a commissure, and its width, which varies slightly in different regions, fluctuates in correspondence with the diameter of the spinal cord.

Amongst the fibres which cross in the white commissure may be mentioned: (1) the fibres of the anterior cerebro-spinal tract; (2) the fibres of the spino-thalamic and spino-tectal tracts; (3) collaterals from both the anterior and lateral white columns; (4) axons of many of the cells of the grey matter; (5) the dendrites of some of the medial anterior cells.

Grey Commissure.—Although this is composed of grey matter with a large admixture of neuroglia, numerous nerve-fibres pass transversely through it to establish relations between the cells of the two sides of the spinal cord.

ENCEPHALON OR BRAIN

The **brain** is the enlarged and greatly elaborated upper part of the cerebro-spinal nervous axis. A brief reference has already been made (p. 836) to the embryological and evolutionary factors which have contributed to its development. In this section we are concerned with its adult structure and connexions.

The brain is surrounded by the same membranes that envelop the cord (the

dura mater, arachnoid mater, and pia mater), and it almost completely fills the cavity of the cranium. So closely, indeed, is the skull moulded on the brain that the impress of the brain is in many places evident upon the inner surface of the cranial wall. The relations of cranium to brain are therefore very different from those presented by the vertebral canal to the spinal cord, for the cord, as we have noted, occupies only a small part of the cavity of its bony case.

General Appearance and Connexions of Brain.—On first inspection, the human brain, deprived of its membranous coverings, appears to consist mainly of a pair of large, symmetrical, ovate masses of richly convoluted nervous tissue, closely pressed together but separated in the median plane by a deep longitudinal fissure. These are the **cerebral hemispheres**, the surface layer of which is composed of grey matter—the *cerebral cortex*. In its intrinsic structure the cerebral cortex is the most highly organized part of the whole brain and it reaches its acme of development in Man. Its great surface expansion in the human brain is reflected in its elaborate convolutions as well as in the relatively large size of the cerebral hemispheres. The hemispheres, indeed, cover the whole of the rest of the brain so that, when viewed from above, they are the only parts of the brain which are visible. If the longitudinal fissure is opened up, the cerebral hemispheres can be seen to be connected across the median plane by a massive bridge of white matter. This is the **corpus callosum**, and it is composed of commissural fibres through which the cortex of one hemisphere is linked up with that of the opposite hemisphere.

If the corpus callosum is split along the median plane, it will be seen to be some distance above the roof of the *third ventricle* (Fig. 764). This is the cavity of that part of the fore-brain which is called the diencephalon, and its lateral wall is formed on each side by an ovate mass of grey matter—the thalamus.

The **thalamus** (which is not visible in the intact brain) is to be regarded primarily as a sensory relay-station through which a variety of sensory impulses are projected on to the cerebral cortex. For this purpose it receives a number of ascending tracts from the spinal cord and hind-brain, as well as a considerable proportion of retinal fibres by way of the optic tract, while abundant fibre-connexions (the thalamic radiations) run from it to extensive areas of the cerebral cortex.

The third ventricle communicates with the *fourth ventricle* (in the hind-brain) by a narrow channel which tunnels the mid-brain and is called the *aqueduct of the mid-brain*. Anteriorly the third ventricle communicates by the interventricular foramina with the *lateral ventricles*, which lie within the cerebral hemispheres.

If the brain is viewed from its basal aspect, many parts of the mid-brain and hind-brain come to view (Fig. 763). The base of the brain presents a very uneven surface which is more or less accurately adapted to the inequalities of the floor of the cranial cavity. Posteriorly is seen the **medulla oblongata**—a short cylindrical structure which is the upward continuation of the spinal cord through the foramen magnum. The medulla lies in front of the cerebellum, fitting into a depression—the vallecula cerebelli—which intervenes between the ventral surfaces of the two cerebellar hemispheres. On each side of the medulla, the rounded surface of each cerebellar hemisphere is apparent.

The **cerebellum** as a whole is a relatively large structure whose surface layer of grey matter—the *cerebellar cortex*—is crossed from side to side by closely set, parallel fissures. Above, the cerebellum is covered over by the posterior or occipital lobes of the cerebral hemispheres. It is connected with the mid-brain, pons, and medulla (which, together, are referred to as the brain-stem) by three pairs of peduncles. These can be seen in some part of their extent in the intact brain without further dissection. If the medulla is gently displaced downwards from the under surface of the cerebellum, a large bundle of nervous tissue is seen to extend on each side from its posterior part into the substance of the cerebellum. These bundles are the **inferior cerebellar peduncles**. As they pass up they diverge from each other, leaving a triangular space which marks the position of the lower part of the fourth ventricle.

Turning again to the base of the brain, the medulla is found to terminate abruptly at the lower margin of a prominent white elevation called the **pons**. This is formed superficially of closely-packed transverse fibres which on each side are compressed into a rope-like strand that plunges into the corresponding cerebellar hemisphere. This is the **middle cerebellar peduncle**, and its fibres have their origin in grey matter which lies within the substance of the pons—*nuclei pontis*.

Immediately in front of the pons there is an irregular recess. It is bounded behind by the pons, on each side by the temporal lobe of the cerebral hemisphere, and in front by the orbital portions of the frontal lobes. Passing laterally from each side of the anterior part of the recess is the deep cleft—the *lateral sulcus* of

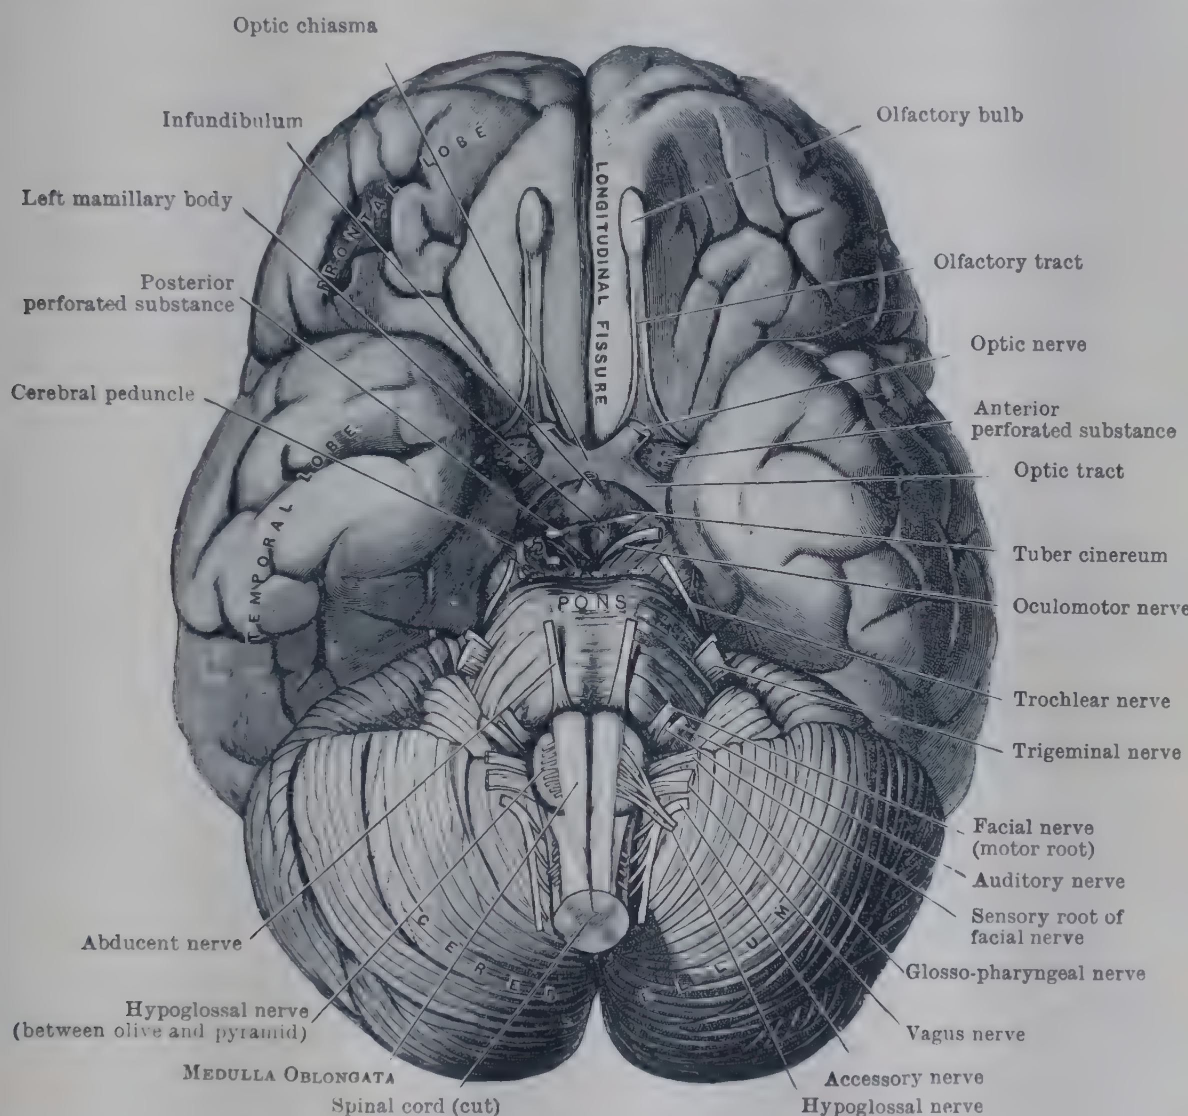

FIG. 763.—BASE OF THE BRAIN WITH THE CRANIAL NERVES ATTACHED.

the cerebrum—which intervenes between the projecting extremity of the temporal lobe and the frontal lobe of the cerebrum.

Within the deep hollow on the base of the brain two large rope-like strands—the **cerebral peduncles**—may be seen issuing from the inferior surface of the cerebral hemispheres. The importance of these peduncles is emphasized by the fact that, among other fibre-systems, they contain the fibres of the cerebro-spinal tracts which are passing from their origin in the cerebrum to the spinal cord. As they extend downwards the peduncles converge so that when they disappear into the substance of the pons they are in close apposition to each other. The cerebral peduncles form the front of the mid-brain, and if the cerebellum and cerebral hemispheres are carefully separated it is possible to catch a glimpse of the back or "roof" of the mid-brain (tectum) which is marked by four hemispherical eminences —the **corpora quadrigemina**.

It is convenient at this stage to note that the inferior corpora quadrigemina are auditory centres in which ascending auditory tracts terminate, while the superior corpora quadrigemina are predominantly visual centres, and are connected to the spinal cord also by spino-tectal and tecto-spinal tracts.

Extending to the posterior surface of the mid-brain just below the inferior corpora quadrigemina, the **superior cerebellar peduncles** can be detected passing upwards from the cerebellum.

Referring again to the base of the brain, we see a deep triangular depression between the cerebral peduncles—the *interpeduncular fossa.* In the floor of the fossa the following structures are visible from behind forwards: (1) the posterior perforated substance; (2) the mamillary bodies; and (3) the tuber cinereum. All these structures are incorporated in the floor of the third ventricle and form component parts of the **hypothalamus.**

The **posterior perforated substance** is a layer of grey matter in which there are numerous small apertures. These transmit a series of small arteries—the central branches of the posterior cerebral arteries.

The **mamillary bodies** are two small, white, hemispherical eminences placed side by side immediately in front of the posterior perforated substance.

The **tuber cinereum** is a slightly raised area of grey matter occupying a position between the mamillary bodies behind and the optic chiasma in front. Attached to the anterior part of the tuber cinereum can usually be seen a process called the **infundibulum**—the stalk which connects the *hypophysis cerebri* (pituitary body) with the base of the brain. The hypophysis itself is usually torn away in the removal of the brain from the cranial cavity.

In front of the tuber cinereum the **optic chiasma** is evident as a broad white transverse band, formed by the union of the two optic nerves. In the substance of the optic chiasma the fibres from the retina undergo a partial decussation. They then continue backwards as the optic tracts, and, if the temporal lobe is slightly displaced, each of these can be traced round the lateral aspect of the cerebral peduncle.

On the under surface of the frontal lobe of each cerebral hemisphere is the **olfactory bulb** which, in the skull, lies in contact with the cribriform plate of the ethmoid and here receives the olfactory nerve-fibres which come up from the nasal cavity. From the olfactory bulb a slender *olfactory tract* runs backwards. Immediately behind its attachment to the brain is an area of grey matter—the **anterior perforated substance**—marked by a cluster of small foramina. These transmit important blood-vessels into the substance of the brain—the central branches of the anterior and middle cerebral arteries.

In the preceding paragraph we have enumerated the main features of the brain which are to be seen on its basal aspect. All the cranial nerves also are evident on the base of the brain, but these will be treated in detail in later sections. Their position and appearance are shown in Fig. 763.

Weight of the Brain.—The average weight of a man's brain is about 1350 grammes. A woman's brain weighs rather less, but this difference is simply related to the smaller bulk of the body. If the body-weight is discounted, it appears that the difference in the relative weights of the brain in the two sexes is insignificant. The variations met with in brain-weight are very considerable, but only in rare cases has a brain weighing less than 1000 grams been found to be associated with apparently normal intellectual functions. In microcephalic idiocy the brain, owing to arrested development, is sometimes very small.

MEDULLA OBLONGATA

The **medulla oblongata** is the continuation upwards of the spinal cord. It is a little more than 1 inch (25 mm.) in length, and it may be regarded as beginning about the level of the foramen magnum. From there it proceeds upwards in a very nearly vertical direction, and ends at the lower border of the pons. At first its girth is similar to that of the spinal cord, but it rapidly expands

as it approaches the pons, and consequently it presents a more or less conical form. Its anterior surface lies behind the grooved surface of the basilar portion of the occipital bone, and its posterior surface is related to the vallecula of the cerebellum. The medulla oblongata is divided into bilaterally symmetrical halves by the **anterior and posterior median fissures.**

The **anterior median fissure**, as it passes from the spinal cord on to the medulla oblongata, is interrupted at the level of the foramen magnum by several strands of fibres which cross the median plane from one side to the other. This intercrossing is termed the *decussation of the pyramids*. Above the decussation it is continued upwards to the lower border of the pons, but is often made very

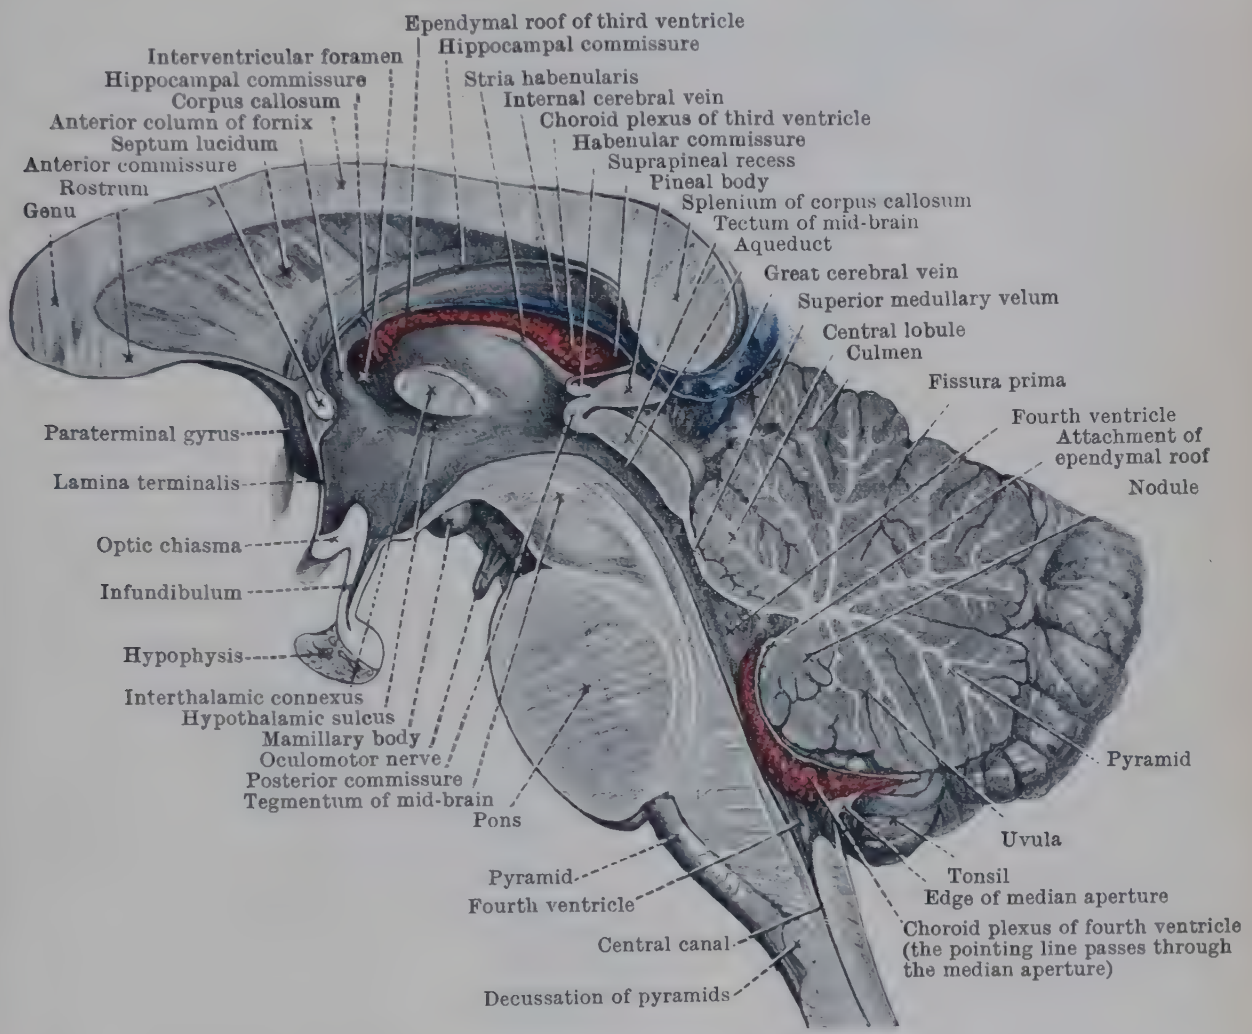

FIG. 764.—THE PARTS OF THE BRAIN CUT THROUGH IN A MEDIAN SECTION.
The side-walls of the ventricular cavities also are shown.

shallow by numerous external arcuate fibres which emerge between its lips and then curve laterally to reach the posterior part of the medulla oblongata. At the lower margin of the pons the fissure expands slightly and ends in a blind pit named the **foramen cæcum.**

The **posterior median fissure** is present only on the lower half of the medulla oblongata. As it ascends it rapidly becomes shallower. Half-way up, where the central canal opens into the fourth ventricle, the lips of the posterior median fissure are thrust apart and constitute the boundaries of a triangular field which is seen when the ependymal roof of the lower part of the fourth ventricle is removed. This triangular field is the lower part of the floor of the fourth ventricle. The lower half of the medulla oblongata, containing as it does the continuation of the central canal of the spinal cord, is frequently termed the closed part of the medulla oblongata; the upper half, above the opening of the canal, which contains the lower part of the fourth ventricle, is called the open part of the medulla oblongata.

The examination of the floor of the fourth ventricle will be deferred for the present, and the appearance presented by the surface of the medulla oblongata may now engage our attention. In the spinal cord the corresponding surface area is divided into three districts by the motor and sensory roots of the spinal nerves. Of those the sensory enter along the bottom of a narrow groove, whilst the motor are spread over a relatively broad surface area and have no groove in relation to their emergence. In the medulla oblongata, corresponding rows of rootlets enter and emerge from the surface of each side. The rootlets of the hypoglossal nerve carry up the line of the anterior nerve-roots of the spinal cord. In one

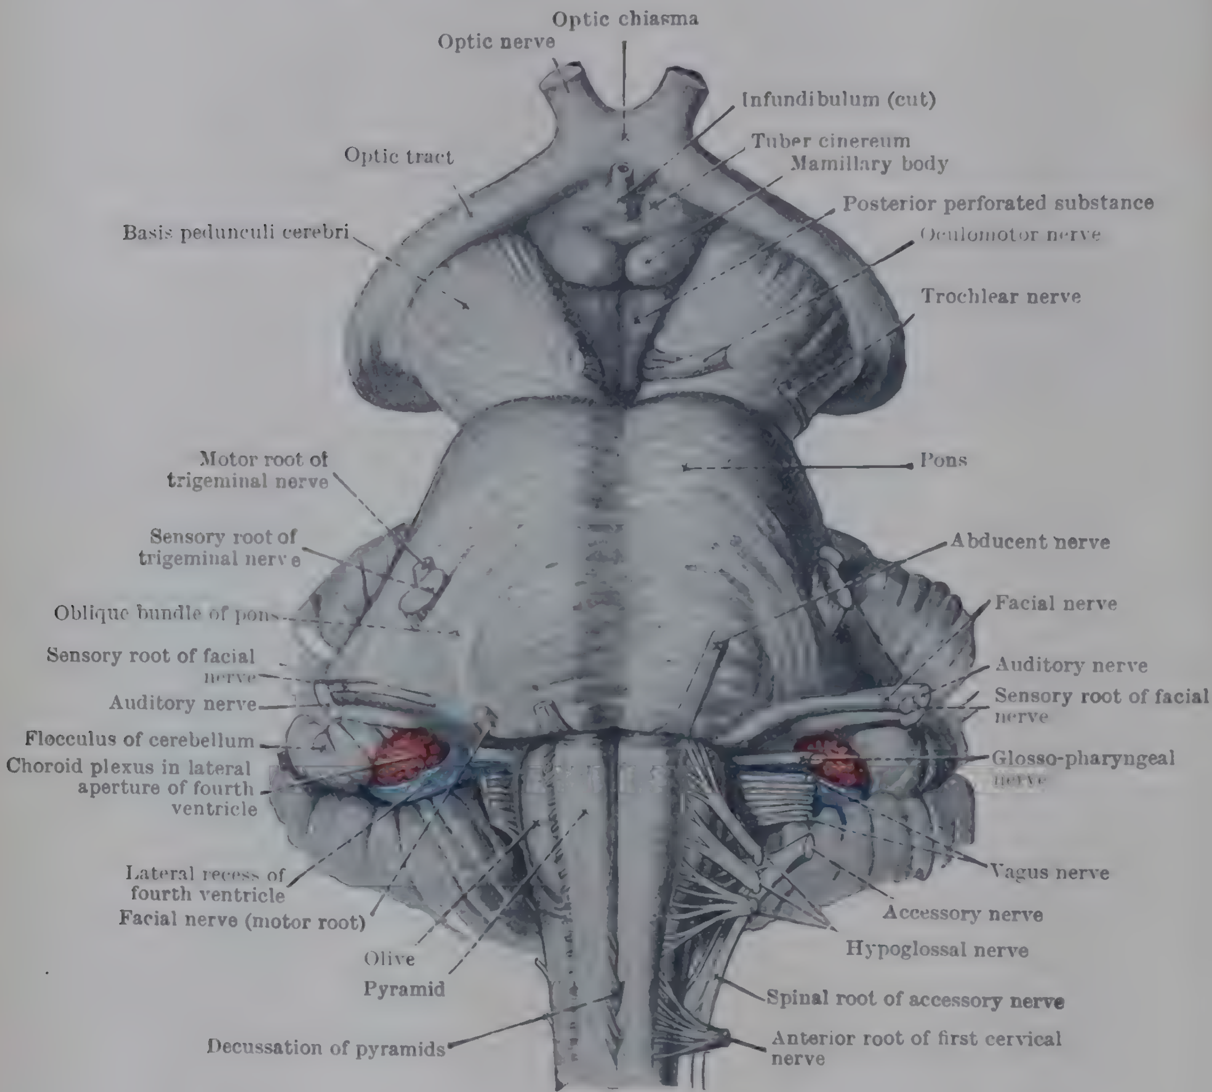

FIG. 765.—FRONT VIEW OF MEDULLA OBLONGATA, PONS, AND MID-BRAIN.

respect, however, they differ: they emerge in linear order and along the bottom of a distinct furrow termed the antero-lateral sulcus. The rootlets which carry up the line of the posterior nerve-roots are those of the accessory, the vagus, and the glosso-pharyngeal nerves. They are attached along the bottom of a furrow named the postero-lateral sulcus. The root-bundles of these nerves differ, however, in that they are not all composed of afferent fibres. Certain of them are purely efferent (roots of accessory), whilst others contain a considerable number of efferent as well as afferent fibres and are therefore to be regarded as mixed roots.

The sulci and the two rows of nerve-roots divide the surface of each half of the medulla oblongata into three districts, viz., an anterior, a lateral, and a posterior, similar to the surface areas of the three white columns of the spinal cord. Indeed, at first sight, they appear to be direct continuations upwards of those three columns; that, however, is not the case, because the fibres of the columns undergo a rearrangement as they proceed upwards into the medulla oblongata.

Anterior Area of Medulla Oblongata—Pyramid.—The district between the anterior median fissure and the groove through which the rootlets of the hypoglossal nerve issue from the medulla oblongata receives the name of the **pyramid**. An inspection of the surface is sufficient to show that the pyramid is a compact strand of longitudinally directed nerve-fibres. It represents, in fact, the portion of the great cerebro-spinal tract which carries fibres from the cerebral hemisphere to all the motor nuclei on the opposite side of the medulla oblongata and spinal cord. Slightly constricted at the place where it emerges from the pons (Fig. 765), it swells immediately to form a prominent rounded column which passes vertically downwards, separated from the pyramid of the other side by the anterior median fissure. Towards the lower part of the medulla oblongata it gradually tapers.

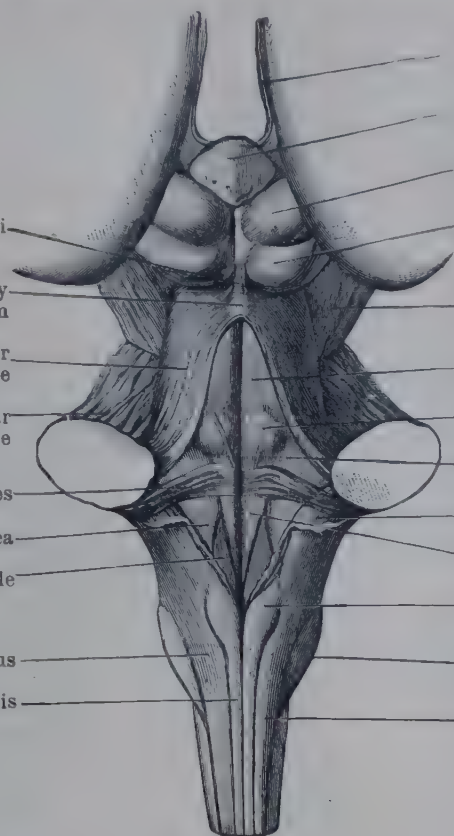

FIG. 766.—POSTERIOR VIEW OF MEDULLA, PONS, AND MID-BRAIN OF FULL-TIME HUMAN FŒTUS.

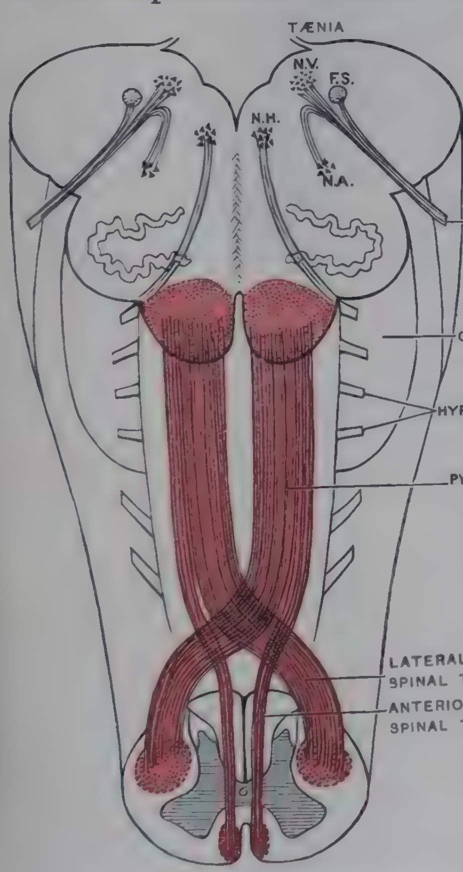

FIG. 767.—DIAGRAM OF THE DECUSSATION OF THE PYRAMIDS. (Modified from van Gehuchten.)
N.H., Hypoglossal nucleus; N.V., Vago-glosso-pharyngeal nucleus; F.S., Tractus solitarius; N.A., Nucleus ambiguus.

Although the pyramid at first sight appears to be continuous with the anterior white column of the cord, only a very small proportion of the fibres contained in that column are derived from the pyramid. At the level of the lower end of the medulla oblongata, the pyramid divides into two parts, viz., a small portion composed of a variable number of the most lateral fibres of the pyramid, which forms the anterior cerebro-spinal tract, and a much larger portion, situated next the median fissure, called the lateral cerebro-spinal tract. As we have seen, the anterior cerebro-spinal tract is continued down into the anterior white column, where it takes up a position next the median fissure. The lateral cerebro-spinal tract is broken up into three or more coarse bundles which sink backwards and at the same time cross the median plane to take up a position in the posterior part of the opposite lateral white column of the cord. The term **decussation of the pyramids** is applied to the intercrossing of the bundles of the lateral cerebro-spinal tracts of opposite sides.

The anterior cerebro-spinal tract is therefore the only part of the pyramid which has a place in the anterior white column of the cord. The largest part of this

column is the anterior intersegmental tract, and as it is traced up into the medulla oblongata, it is thrust aside by the decussating bundles of the lateral cerebro-spinal tract and thus comes to occupy a deep position in the substance of the medulla oblongata, behind and to the lateral side of the pyramid.

Lateral Area of Medulla Oblongata.—This is the district between the hypoglossal roots in front and the root-bundles of the accessory, vagus, and glosso-pharyngeal nerves behind. It presents a very different appearance in its upper

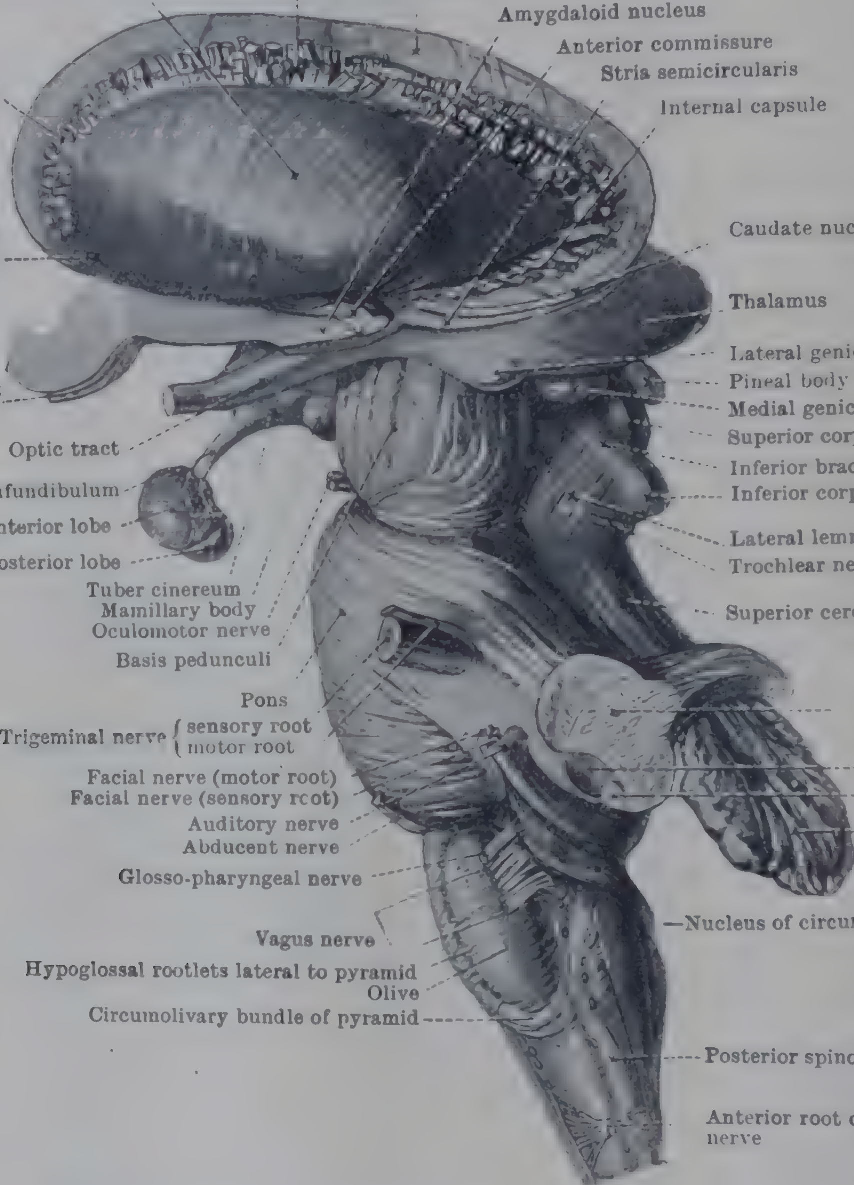

FIG. 768.—LEFT LATERAL ASPECT OF BRAIN AFTER REMOVAL OF THE CEREBRAL HEMISPHERE (EXCEPT CORPUS STRIATUM) AND THE CEREBELLUM (EXCEPT DENTATE NUCLEUS).

and lower parts. In its lower portion it simply appears to be a continuation upwards of the lateral area of the cord; in its upper part a striking oval prominence bulges out on the surface and receives the name of the **olive**.

The lower part of this district, however, is very far from being an exact counterpart of the lateral white column of the cord. The lateral cerebro-spinal tract is no longer present, seeing that, in the medulla oblongata, it forms the greater part of the pyramid of the opposite side. Another strand of fibres, viz., the posterior spino-cerebellar tract, prolonged upwards in the lateral white column, gradually leaves this portion of the medulla oblongata. This tract lies on the surface, and is frequently visible to the naked eye as a white band (Fig. 768) which inclines obliquely backwards into the posterior district of the medulla oblongata to join the inferior cerebellar peduncle. The remainder of the fibres

of the lateral white column are continued upwards in the lateral area of the medulla oblongata.

The **olive** is a smooth oval prominence on the upper part of the lateral area of the medulla oblongata. Its long axis is vertical and is about half an inch long. It is the bulging produced by the subjacent **olivary nucleus**—a crumpled thin-walled sac of grey matter which is separated from the surface by a thin layer of white matter.

External Arcuate Fibres.—The external arcuate fibres are seen as a number of fine curved bundles crossing transversely over the surface of the olive or skirting its lower pole. They vary greatly in number and distinctness, and not infrequently it is difficult to detect them on surface inspection. They take their origin in the arcuate nuclei, which form a thin stratum of grey matter covering the pyramids, and, after crossing the median plane, curve laterally and backwards to enter the inferior cerebellar peduncle. Since the arcuate nuclei are to be regarded as caudal extensions of the pontine nuclei (see p. 899), the external arcuate fibres are evidently aberrant fibres of the pons which do not enter the cerebellum by way of the middle peduncle, but make use of the inferior peduncle instead.

There is frequently present, especially on the left side, a bundle of fibres that is often mistaken for a group of arcuate fibres. It is the **circumolivary bundle of the pyramid** (Figs. 768, 782). It is a bundle of varying size which emerges from the pyramid, bends backwards, curving round the lower border of the olive, and then passes obliquely upward and backwards to end in a fusiform ridge of grey matter—the **nucleus of the circumolivary bundle**—which crosses the inferior peduncle very obliquely (Fig. 768, the ridge immediately behind the roots of the vagus nerve).

Posterior Area of Medulla Oblongata.—In its lower half, this area is bounded behind by the posterior median fissure, and in its upper half by the lateral margin of the medullary part of the floor of the fourth ventricle. In front it is separated from the lateral area by the row of rootlets that belong to the accessory, vagus, and glosso-pharyngeal nerves. The upper and lower parts appear to be continuous but in reality are almost quite distinct from each other—as in the lateral area.

The lower part of the posterior area corresponds more or less closely with the posterior white column of the cord. In the cervical region the posterior white column is divided by a septum of pia mater into the **fasciculus gracilis** medially and the **fasciculus cuneatus** laterally. They are prolonged upwards into the medulla oblongata, and in the lower part of the posterior area they stand out distinctly and are separated one from the other by a groove. When they reach the level of the lower part of the fourth ventricle, they end in slight prominences called respectively the **gracile tubercle** and the **cuneate tubercle**. The right and left gracile tubercles are thrust apart by the opening up of the medulla oblongata to form the floor of the fourth ventricle, and the central canal opens into the fourth ventricle in the angle between the two.

The elongated prominences formed by the enlarged extremities of the fasciculi gracilis and cuneatus are due to two elongated nuclei which lie subjacent to the strands and represent the termini of the uppermost extensions of the spinal posterior root fibres. They are termed respectively the **nucleus gracilis** and **nucleus cuneatus**.

A third longitudinal elevation is present on the lower part of the posterior area of the medulla, though it is frequently too ill-defined to be readily apparent on surface inspection. This is placed on the lateral side of the fasciculus cuneatus—between it and the posterior row of nerve-roots—and it has no counterpart in the posterior white column of the cord. It is called the **tubercle of the trigeminal nerve.** It is produced by a mass of substantia gelatinosa coming close to the surface and forming a bulging in that situation. Extremely narrow below, it widens as it is traced upwards, and finally ends in an expanded extremity. A thin layer of white matter, composed of longitudinally arranged fibres, is spread over this district, and separates the substantia gelatinosa from the surface. These fibres constitute the **spinal tract of the trigeminal nerve**, which here assumes a

the medulla the spinal tract lies immediately in front of the inferior cerebellar peduncle—so closely applied that, on surface view, the tract seems to form part of the peduncle. In this part of its course, the tract is shut off from the surface by the posterior spino-cerebellar tract, the external arcuate fibres, and the circum-olivary bundle as they incline backwards towards the peduncle, and, further, the root-fibres of the glosso-pharyngeal and vagus nerves emerge through it.

Inferior Cerebellar Peduncle.—The inferior cerebellar peduncle forms almost the whole of the upper part of the posterior area of the medulla oblongata. It lies between the floor of the fourth ventricle and the roots of the vagus and glosso-pharyngeal nerves. It is a thick, round bundle which inclines upwards and laterally, and then takes a sudden bend backwards to enter the cerebellum. It is one of the links that connect the cerebellum with the medulla oblongata and spinal cord. A study of the surface of the medulla oblongata yields some important information regarding the constitution of the inferior cerebellar peduncle. Thus, the posterior spino-cerebellar tract (Fig. 768), from the lateral column of the cord, can be traced into it: large numbers of fibres which take a curved course on the surface of the medulla oblongata may likewise be followed into it; these are the external arcuate fibres. Numerous other fibres enter this peduncle on its deep aspect, but they will be studied at a later stage.

PONS

The **pons** is the conspicuous white prominence seen on the base of the brain between the medulla oblongata and the cerebral peduncles in front of the cerebellum. It is convex from side to side and from above downwards, and transverse streaks on its surface show that, superficially at least, it is composed of bundles of nerve-fibres, most of which course transversely. On each side these transverse fibres form a large compact strand which sinks in a backward and lateral direction into the hemisphere of the cerebellum. This strand is termed the **middle cerebellar peduncle.** It forms the second stage in the connexion between the cerebral cortex of one side and the cerebellum of the opposite side (Fig. 769). This connexion is effected by cortico-pontine fibres which run from most areas of the cerebral cortex to reach the pons, terminating there in relation to the pontine nuclei; from these nuclei ponto-cerebellar fibres take origin and cross the median plane to the opposite cerebellar hemisphere. It is these fibres which constitute the middle cerebellar peduncles.

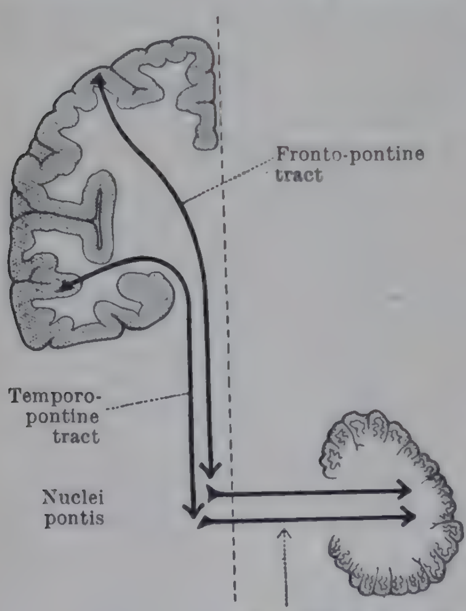

Fig. 769.—Diagram of Cortico-Cerebellar connexion.

The *anterior surface* of the pons is in relation to the dorsum sellæ and the upper part of the clivus of the skull. It presents a median groove (**basilar sulcus**) which gradually widens as it is traced upwards; this lodges the basilar artery. The median depression is produced by the prominence caused on each side by the passage of the cerebro-spinal bundles downwards through the pons. The **trigeminal nerve**, with its large, entering sensory root and its small, emerging motor root, is attached to the side of the pons, nearer its upper than its lower border (Fig. 768). The term *pons* is conventionally restricted to that portion which lies between the two trigeminal nerves, and the designation *middle cerebellar peduncle* is applied to the part which extends beyond the nerve into the hemisphere of the cerebellum. The **abducent nerve**, the **facial nerve**, and the **auditory nerve** are attached to the brain at the lower border of the pons—the abducent nerve opposite the lateral border of the pyramid and the facial and auditory farther from the

median plane. The auditory nerve is in contact with a little pedunculated lobule of the cerebellum called the **flocculus**; the motor root of the facial is on its medial side, and the sensory root, which is very much thinner, is more or less hidden between them (Figs. 765, 768). The sensory root, it should be noted, also contains visceral efferent fibres (see p. 930). A large bundle of fibres on the front of the pons departs from the transverse course pursued by most of the pontine fibres, and, starting at the medial side of the trigeminal nerve, passes almost vertically downwards between the motor and sensory roots of the facial nerve (Fig. 765) and reaches the side of the medulla oblongata, where it passes into the nucleus of the circumolivary bundle (Fig. 768). This bundle is known as the **oblique bundle of the pons.**

Immediately below the insertion of the auditory nerve at the lower margin of the pons a small pouch of the ependymal roof of the fourth ventricle (**lateral recess**) projects laterally, partly behind the glosso-pharyngeal nerve. Through an elliptical aperture in this ependymal process (**lateral aperture of the fourth ventricle**) a little cauliflower-like mass of choroid plexus is extruded between the auditory and the glosso-pharyngeal nerves (Fig. 765).

The *posterior surface* of the pons looks towards the cerebellum, and presents a triangular area covered with grey matter which forms the upper part of the floor of the fourth ventricle. This area is directly continuous inferiorly with the medullary part of the floor of the ventricle, and is bounded on each side by a band of white matter termed the **superior cerebellar peduncle** (Fig. 770).

Superior Cerebellar Peduncles.—The superior peduncles are hidden from view by the upper part of the cerebellum. They emerge from the hemispheres of the cerebellum, and, as they proceed upwards on the back of the pons, they converge towards each other until, at the lower margin of the inferior corpora quadrigemina, the medial margins of the two peduncles become almost contiguous (Fig. 770). At first they form the lateral boundaries of the upper part of the fourth ventricle; but as they ascend and approach closer to each other, they gradually come to overhang that cavity, and thus enter into the formation of its roof. They disappear from the surface by dipping under cover of the quadrigeminal bodies and entering the substance of the mid-brain.

Superior Medullary Velum.—Filling up the triangular interval between the medial margins of the two superior peduncles there is a thin layer of white matter which completes the roof of the upper part of the fourth ventricle; it receives the name of the **superior medullary velum.** When traced downwards, the velum is seen to be carried, with the superior cerebellar peduncles, into the white matter of the cerebellum. Spread out on its posterior surface there is a small, thin, tongue-shaped prolongation of the cortex of the cerebellum termed the **lingula**; and the fourth pair of cranial nerves (**trochlear**) issues from its substance close to the inferior quadrigeminal bodies.

FOURTH VENTRICLE

The **fourth ventricle of the brain** is rhomboidal in outline. Below, it tapers to a point and becomes continuous with the central canal of the lower half of the medulla oblongata; above, it narrows in a similar manner and is continued into the **aqueduct of the mid-brain.** The **floor** of the fourth ventricle is formed below by the medulla and above by the dorsal surface of the pons. On each side a long, curved, and narrow prolongation of the ventricular cavity is carried laterally from its widest part and curves round the upper part of the corresponding inferior cerebellar peduncle. It is termed the **lateral recess.** The **roof** of the cavity is very thin and is intimately connected with the cerebellum, which conceals it from view.

Roof of Fourth Ventricle.—The roof of the fourth ventricle is tent-shaped (as seen in sagittal section). Above, it is formed by a thin lamina of white matter—the **superior medullary velum**—which stretches across between the superior cerebellar peduncles. Below, it is similarly formed by the **inferior medullary velum** which stretches across between the inferior cerebellar peduncles. Except at its lateral margins the inferior medullary velum consists of little more

than a layer of ependymal epithelium. It is therefore an extremely attenuated structure. Moreover, it is largely deficient in its lower part, so that an opening is formed through which the cavity of the fourth ventricle communicates directly with the subarachnoid space on the surface of the brain. This opening is termed the **median aperture of the fourth ventricle**. Similar openings are present at the extremities of the lateral recesses—the **lateral apertures of the fourth ventricle.** These three openings are of extreme importance, for they provide the only routes whereby the cerebro-spinal fluid (which is secreted inside the ventricular cavities) can escape on to the surface of the brain. It occasionally happens that they become occluded by inflammatory adhesions: in such a case the circulation of the

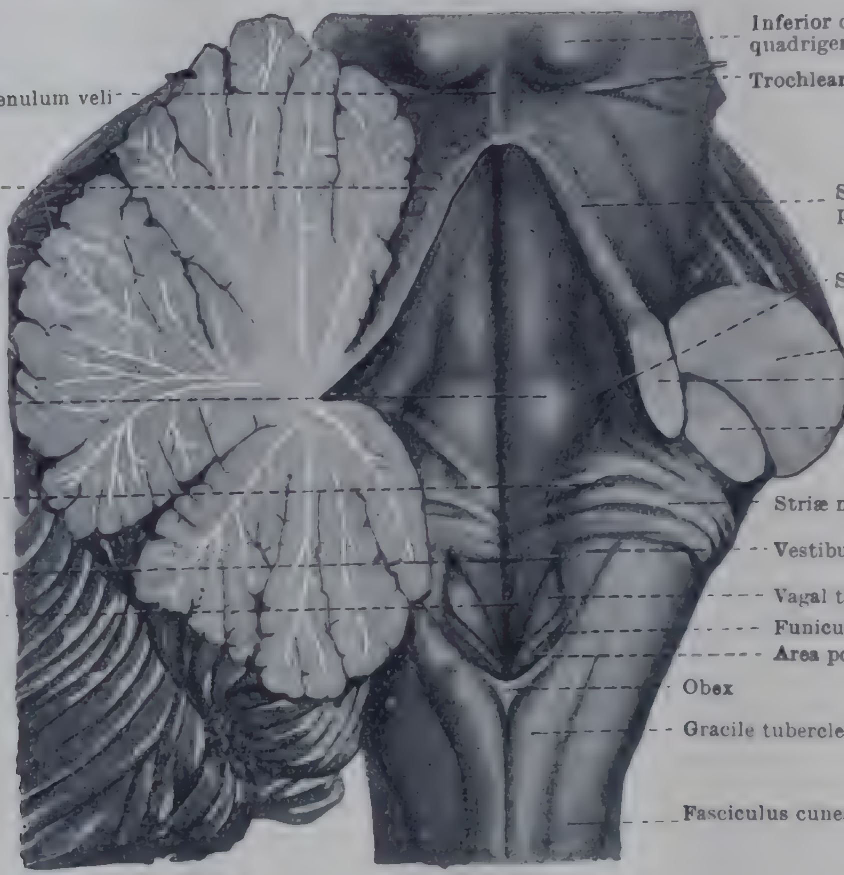

FIG. 770.—FLOOR OF THE FOURTH VENTRICLE. The right half of the cerebellum has been removed. The left half is drawn over to the left so as to expose the floor of the ventricle fully.

cerebro-spinal fluid is obstructed and the ventricles become progressively distended by its accumulation, leading to a condition of hydrocephalus.

The ependymal epithelium of the inferior medullary velum is invaginated into the cavity, on each side of the median plane, by vascular tufts of pia mater. These form the **choroid plexuses** of the fourth ventricle and, like similar plexuses found in the other ventricular cavities of the brain, they are concerned with the secretion of cerebro-spinal fluid. On each side, an extension of the choroid plexus becomes extruded through the lateral aperture of the fourth ventricle, and (as already noted) reaches the subarachnoid space on the base of the brain close to the root of the auditory nerve.

Floor of Fourth Ventricle.—The widest part of the floor is opposite the inferior cerebellar peduncles as they turn backwards to enter the cerebellum (Fig. 770). Above this level the floor is formed by the pons, and below it by the ventral part of the upper half of the medulla oblongata. Beneath the ependyma of the floor there is a thick layer of grey matter continuous below with that which surrounds the central canal and above with that around the aqueduct. The floor is circumscribed by definite lateral boundaries. From below upwards these are: (1) the gracile tubercle, (2) the cuneate tubercle, (3) the inferior peduncle, and (4) the superior peduncle of the cerebellum.

The floor of the fourth ventricle is divided into two symmetrical portions by

a median groove. Crossing each half of the floor, at its widest part, there are several more or less conspicuous bundles of fibres termed the **striæ medullares.** They appear on the side and the back of the inferior peduncle, pass transversely medially, and disappear from view in the median furrow. The striæ vary in different specimens, both in direction and prominence. It is not uncommon to find that no trace of them is visible on the surface. The connexions and functional significance of the striæ medullares are obscure. They were at one time believed to arise from the dorsal cochlear nucleus and to constitute some of the pathways for auditory impulses; hence they were called "auditory striæ". Recent studies, however, have thrown some doubt on this supposition (Rasmussen & Peyton, 1946).

In each half of the lower part of the floor there is a small, triangular, and rather sharply circumscribed depression immediately below the striæ medullares. It is termed the **inferior fovea.** The apex points upwards towards the striæ, and the basal angles are prolonged downwards as diverging grooves (Fig. 770). In this manner the lower half of the floor is mapped out into three triangular areas. The medial division is slightly elevated and is termed the **hypoglossal triangle,** because subjacent to the medial part of this area is the nucleus of the hypoglossal nerve. The intermediate area, between the two diverging grooves, is the **vagal triangle**—so called because the dorsal nucleus of the vagus nerve is subjacent to it. Near the lateral angle is the **vestibular area.** The base of this area is directed upwards and runs directly into an eminence over which the striæ medullares pass. Subjacent to that district of the floor of the ventricle lies the chief nucleus of the vestibular division of the auditory nerve.

When the floor of the ventricle is examined under water with a magnifying glass, the hypoglossal triangle is seen to consist of a narrow medial strip which corresponds to the hypoglossal nucleus, and a wider lateral part which has been shown to be the surface representation of another nucleus termed the **nucleus intercalatus.**

In the upper half of the floor also there is a slight depression which is termed the **superior fovea.** The longitudinal prominence between the superior fovea and the median fissure is called the **eminentia medialis**; it swells out inferiorly to form a rounded hillock called the **colliculus facialis,** and, below that, it is continuous with the floor of the hypoglossal triangle. As already stated, the **vestibular area** extends upwards into the pontine part of the ventricular floor and forms an elevated region in the most lateral part of its widest portion, below and to the lateral side of the superior fovea. Proceeding upwards from the superior fovea to the opening of the aqueduct there is a shallow depression termed the **locus cœruleus,** because it usually presents a faint slate-blue colour. When the ependyma is scraped away from the surface of the locus cœruleus, the colour is seen to be due to the **substantia ferruginea**—a name applied to a linear group of strongly pigmented cells. In transverse sections through the upper part of the pons, the substantia ferruginea appears on the cut surface as a small, brown spot.

General Plan and Development of Hind-Brain

The structure of the hind-brain differs in a marked degree from that of the spinal cord: indeed, in its upper part, it presents very little in common with the cord. Some of the largest fasciculi which come up from the spinal cord (such as the posterior white columns) end in the lower part of the medulla oblongata; others leave the medulla oblongata and pass into the cerebellum; and most of the bundles of fibres which pass upwards or downwards, from or to the spinal cord, come to occupy very different positions in the medulla oblongata and pons.

The grey matter, instead of being moulded into compact columns, becomes broken up into a series of discrete nuclei. Thus, there are developed from the basal lamina of the rhombencephalon, not one compact mass like the spinal anterior grey column, but three distinct broken columns of efferent nuclei (Figs. 767 and 774): (1) a **medial somatic column**, which in turn is broken up into two parts, a medullary nucleus (*hypoglossal*) which supplies the motor fibres to the

tongue muscles, and a pontine nucleus (*abducent*) which supplies the lateral rectus muscle of the eye; (2) a **branchial column**, broken up into separate nuclei, viz., *ambiguus, facial*, and *trigeminal*, which supply the striated muscles of the larynx, pharynx, and face and those concerned with mastication; and (3) a **splanchnic column** of nuclei, giving efferent fibres which pass out in the vagus, glossopharyngeal, and facial nerves, to be widely distributed to plain muscle, glands, and other tissues in the head, neck, thorax, and abdomen.

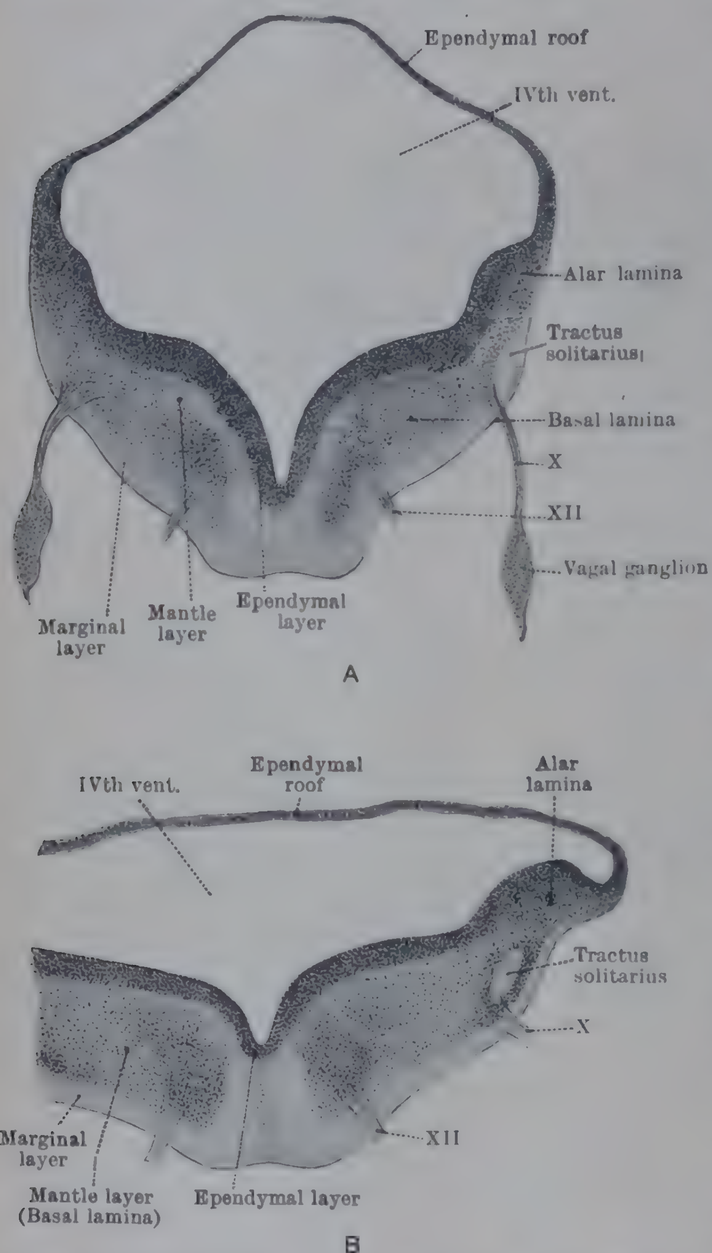

Fig. 771.—Transverse Sections across the Medulla Oblongata in two Human Embryos, representing Different Stages in the Expansion of the Roof and the falling laterally of the Side-Walls. (From His, slightly modified.)

Further, the terminal nuclei of the sensory nerves which are developed in the alar lamina of the rhombencephalon do not unite to form a definite posterior grey column, as happens in the spinal cord, but form discrete masses; and as these act as receptive centres for a much greater variety of sensory nerves than are represented in the spinal nerves there is a much greater number of nuclei than would be formed if the various components of the posterior grey column in the spinal cord were dissociated. Thus, there are terminal nuclei in the medulla oblongata not only for the ordinary cutaneous nerves, but also for nerves coming from the mucous membranes of the alimentary and respiratory organs as well as from other visceral structures; and there are also special nerves of taste (glossopharyngeal and the sensory root of the facial), of hearing (cochlear part of the auditory), and of equilibration (vestibular part of the auditory). But that does not exhaust the peculiar features of the terminal sensory nuclei of the rhombencephalon. In the description of the spinal cord attention was called to the fact that certain of the fibres of the posterior nerve-roots do not end in the grey matter of the cord but pass upwards to the medulla oblongata. Special terminal nuclei are developed from the alar lamina to receive these fibres. They are the nucleus gracilis and nucleus cuneatus.

The development of the cerebellum (as an elaboration and extension of the terminal nucleus of the vestibular nerve) is another disturbing factor, for it receives and gives off large numbers of fibres which add considerably to the complexity of the hind-brain. Moreover, there is developed from the alar lamina a whole series of other masses of grey matter—the **olivary nucleus, arcuate nuclei, nucleus of the circumolivary bundle**, and **nuclei pontis**—as links in the complex chains that bind many parts of the central nervous system to the great co-ordinating mechanism of the cerebellum.

Thus it comes about that, instead of having, as in the spinal cord, a definite column of grey matter ensheathed in a thick mass of white substance, the rhomb-

encephalon is composed of many scattered masses of grey matter; and its white substance is represented partly by great longitudinal strands, and also by many great systems of fibres that pass transversely through its substance or on its surface, *e.g.*, the superficial fibres of the pons and many of the arcuate fibres.

From what has already been said concerning the external form of the medulla oblongata and pons it will be apparent that the distortion of the neural tube which occurred as the result of the pontine flexure has also been largely responsible for the distinctive features of this region of the brain.

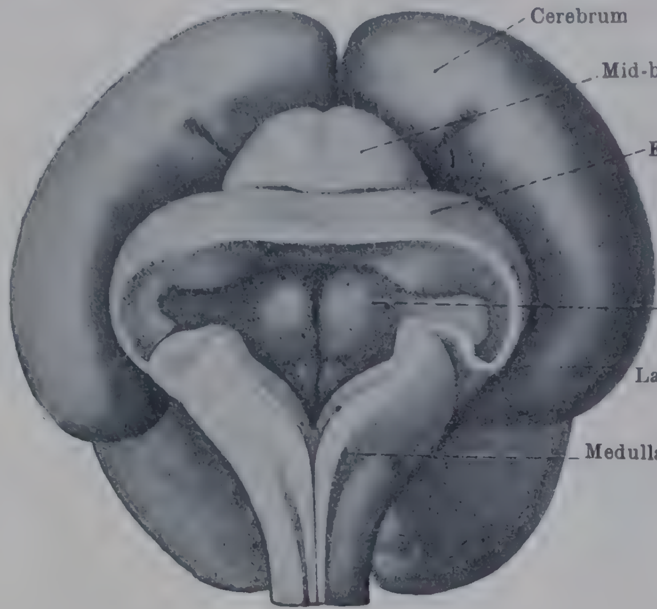

Fig. 772.—Brain of Fœtus of Eleven Weeks, viewed from behind. The ependymal roof of the fourth ventricle has been removed. At this stage the cerebellum is in the form of a simple band or plate which arches over the back of the anterior part of the cavity of the hind-brain. (His, 1904.)

As the pontine flexure develops, a strain is thrown upon the thin roof-plate, which yields and becomes stretched so as to permit the thick lateral walls of the neural tube to fall laterally (Figs. 771 and 772). One result of this process is the great lateral expansion of the cavity of the hind-brain, which assumes the characteristic rhomboid form. If the thin and greatly attenuated ependymal roof is torn away from the rhombencephalon of an embryo of the third month the fourth ventricle will present the appearance (viewed from behind) shown in Fig. 772. The ventricle is seen to be prolonged laterally, on each side, to form a little recess on the lateral side of the rhombencephalon. This is the **lateral recess.**

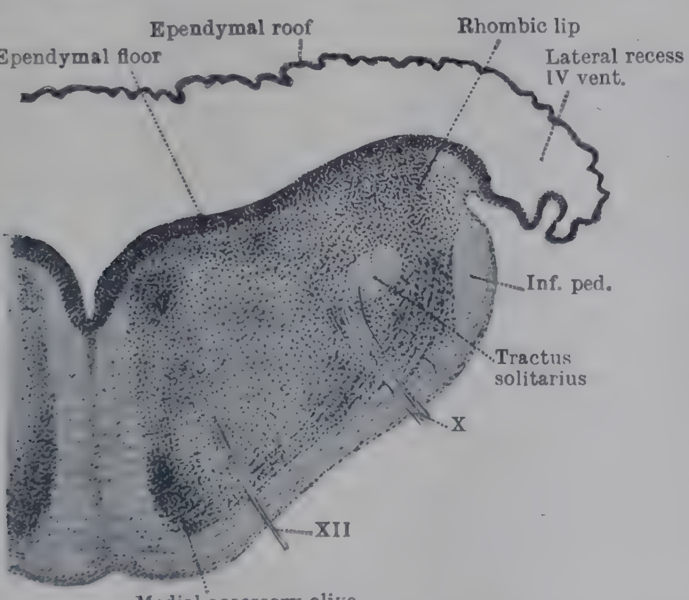

Fig. 773.—Transverse Section of Medulla Oblongata at a Later Stage than those shown in Fig. 771. (After His.)

As a result of the pontine flexure, also, the side-walls of the neural tube in the neighbourhood of the bend fall away from each other and eventually come to be placed in the same transverse plane, one with the other and also with the floor-plate. At the time this process is in operation (see Fig. 771) the alar and basal laminæ are particularly well defined, and the limiting sulci are accentuated by the bending of the side-wall; but that sharp distinction is soon lost as the result of the great expansion of the basal lamina (Fig. 773). This is due not only to growth of its intrinsic elements, but even more to the displacement into it of large numbers of neuroblasts which give the appearance of migrating from the alar into the basal lamina. Later still, the development of the great sensory and motor tracts contributes largely to the increase of the dimensions of the basal lamina.

As the two basal laminæ (one on each side of the median plane) increase in

thickness the epithelial cells in the intervening floor-plate become stretched and lengthened (Fig. 771), so that a definite septum or **raphe** is formed between the two halves of the rhombencephalon.

The fate of the extreme dorsal edge of the alar lamina is very interesting. The auditory nerve is inserted into it in the region of the lateral recess, and from it masses of neuroblasts develop to form receptive nuclei for the two parts (cochlear and vestibular) of the nerve—the **cochlear nuclei** and **vestibular nuclei**. Afferent fibres, bringing impulses from muscles, joints, and related structures in all parts of the body, make their way into a portion of the terminal vestibular nuclei, and these grow to form a large thickening of the edge of the alar lamina above the lateral recess. Eventually, as the thickening extends medially (Fig. 772), it reaches and invades the roof-plate and fuses with the corresponding rudiment of the other side. Thus, a semilunar band—the primitive cerebellum—is formed as an arch across the roof of the metencephalon. The part of the dorsal edge of the alar lamina which lies below the vestibular nuclei becomes everted to form what is known as the **rhombic lip** (Fig. 773). It is destined to be transformed into a series of masses of grey matter, some of which emit fibres to carry impulses into the cerebellum. But most of these fibres pass not so much to the part of the cerebellum derived from their own side as to that of the opposite side. Thus, from above downwards, the thickened margin of the fourth ventricle on each side develops into the following structures: cerebellum, the vestibular nuclei, the cochlear nuclei, the nuclei pontis (and arcuate nuclei), the olivary nucleus, the nucleus gracilis and the nucleus cuneatus. At an early stage of development the neuroblasts which form the rudiments of the nuclei pontis, arcuate nuclei, and the olivary nucleus appear to undergo a migration whereby they become displaced from their site of origin in the alar lamina to a more ventral position in the basal lamina.

It has been suggested that this apparent migration is an expression of a principle of neural differentiation which has been termed **neurobiotaxis**. This principle, enunciated by Kappers in 1907, refers to the tendency of nerve-cells during embryological development (and also in the course of evolution) to shift their position towards the source of the impulses which predominantly influence their activity. Thus, if we imagine a group of nerve cells which are mainly activated by stimuli reaching them from a direction x, the cells will tend gradually to change their relative position and move towards x. In the present instance, it seems that the cells of the nuclei pontis (for example) " migrate " into the basal lamina for the reason that they come under the influence of impulses conveyed by efferent paths from the cortex which are situated in this region of the neural tube. It may be noted that the " neurobiotactic " migration of nerve-cells is probably due to a relative rather than an actual displacement. As the result of differential growth of the embyro, neurons tend to become greatly elongated in order to reach the tissues which they supply. This elongation involves almost entirely the axonal (or efferent) processes, and as a result the cell-bodies become apparently approximated, *relatively* to the termination of their axons, more and more to the fibres from which they receive their afferent impulses (Kappers, 1921).

Internal Structure of Medulla Oblongata

Olivary Nuclei.—The most conspicuous of the isolated clumps of grey matter in the medulla are the olivary nucleus and the two accessory olivary nuclei. The **olivary nucleus** is the grey substance which produces the swelling known as the olive, and is a very striking object in transverse sections through this region. It is seen as a thick wavy line of grey matter folded on itself to enclose a space filled with white matter. It is in reality a crinkled lamina arranged in a purse-like manner, with an open mouth or **hilum** directed towards the median plane. The hilum does not reach the upper and lower ends, and in transverse sections through either end of the nucleus the grey lamina is seen in the form of a completely closed capsule. Out of the hilum streams a dense mass of fibres. These are efferent fibres destined for the cerebellar hemisphere of the opposite side, and they have their origin in the nerve-cells which compose the grey matter of the olivary nucleus.

The **accessory olivary nuclei** are two short bands of grey matter which are

placed the one dorsal to the main nucleus and the other medial to it. In transverse section each of these nuclei is rod-like (Fig. 774).

The **medial accessory olivary nucleus** extends lower down than the main nucleus, and its lower part is much larger than its upper. It begins immediately above the decussation of the pyramids, where it is seen on the lateral side of the cerebro-spinal tract and the medial lemniscus (Fig. 776). Higher up, it lies across the hilum of the main nucleus and on the lateral side of the medial lemniscus. The **dorsal accessory olivary nucleus** is immediately dorsal to the main nucleus. The two accessory nuclei fuse together at their upper ends.

The nerve-cells of the olivary nucleus are small and round, and emit a large series

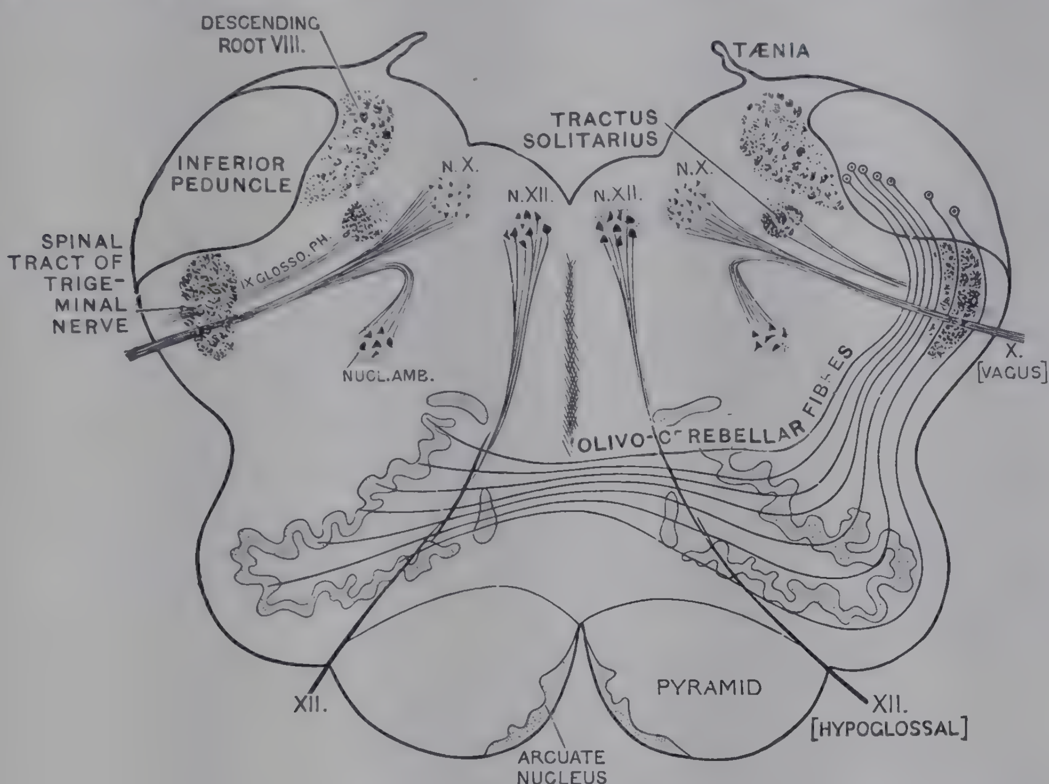

Fig. 774.—Diagram of Section of Medulla Oblongata to show the Course of the Olivo-Cerebellar Fibres.

N.X., Vago-glossopharyngeal nucleus. N.XII., Hypoglossal nucleus.

of short, radiating, complexly branched dendrites, so that the cell-body seems to lie in the centre of a spherical mass formed by its own dendrites and an almost equally complex mass of intertwined end-branches of the axons which carry impulses to these cells. A large descending tract which arises in the globus pallidus of the corpus striatum descends in the mesencephalon and rhombencephalon to end amidst the cells of the lateral part of the olivary nucleus. It is the **pallido-olivary tract** (Fig. 779).

The axons emitted by the cells of the olivary nucleus cross the median plane to the opposite inferior peduncle and pass into the cerebellum. These fibres are seen only in the upper part of the medulla oblongata. They form the deep part of the inferior cerebellar peduncle and constitute its chief bulk. Streaming out from the hilum of the olivary nucleus, they cross the median plane, and in the opposite side of the medulla oblongata they pass through and around the olivary nucleus of that side. Ultimately they are gathered together behind the olivary nucleus to take up a position in the deep part of the inferior peduncle. In passing back, they traverse the spinal tract of the trigeminal nerve and break it up into several separate bundles. The olivo-cerebellar fibres thus connect the olivary nucleus of one side with the opposite side of the cerebellum, and each part of it is connected with a definite part of the cerebellum.

The connexion of the cerebral cortex with the cerebellum by means of cortico-pontine and ponto-cerebellar fibres (Fig. 769) is found only in mammals. In all other vertebrates the olivary nucleus is the link between the higher, subcortical motor centres (the globus pallidus of the corpus striatum) and the cerebellum. Fibres from this motor controlling centre descend (in the brain of birds, reptiles, amphibians, and fishes) to terminate in

a structure homologous with the medial accessory olivary nucleus in the human brain, which is connected with the vermis of the cerebellum. In the mammalian brain, when motor functions are assumed by the cerebral cortex, the cortex becomes connected (Fig. 769) with the opposite cerebellar hemisphere by means of a new system of fibres—the middle peduncle. The assumption of motor control by the cerebral cortex, however, does not minimize the importance of the olive. On the contrary, a new olivary structure develops on the lateral side of the archaic olive, and in monkeys and Man this lateral nucleus attains a large size and complexity so as to become much the largest element in the olivary complex. The newly developed lateral olive receives fibres (pallido-olivary tract) from the globus pallidus, and each part of the rapidly expanding olivary lamina becomes connected with a definite part of the hemisphere of the cerebellum (Fig. 796, p. 910). As the cerebellum develops, the olivary nucleus increases in size. The function of the cerebellum is now believed to be concerned with the control of muscular tone. Hence, as more highly skilled movements are made possible by the development of the cerebral cortex, the connexions of the globus pallidus with the parts of the cerebellum which regulate the tone that is essential for the development of skill keep pace with the cerebral connexion of the corresponding cerebellar areas.

Decussation of Pyramids and Resulting Changes.—As a series of successive transverse sections through the lower part of the medulla oblongata and the upper part of the spinal cord are examined under the microscope, the most striking change which meets the eye is the decussation of the lateral cerebro-spinal tracts. We have already seen that, from their position alongside the anterior median fissure of the medulla oblongata, most of the fibres of the pyramid cross the median plane and, after passing through the anterior grey column, turn downwards in the lateral white column of the opposite side of the cord. Strands from the right lateral cerebro-spinal tract alternate with corresponding strands from the left side, and the interval between the bottom of the anterior median fissure and the grey matter surrounding the central canal becomes filled up with a great mass of intercrossing bundles of fibres.

As we have noted, the decussating pyramidal bundles pass through the anterior grey column, and cut it into two portions (Fig. 775). The basal part remains in position on the front and lateral side of the central canal, and forms part of the thick layer of grey matter which surrounds it. The detached head of the anterior column is set free; and from the large multipolar cells which lie in its midst some of the fibres of the anterior root of the first cervical nerve, and also some of the fibres of the accessory nerve, take origin.

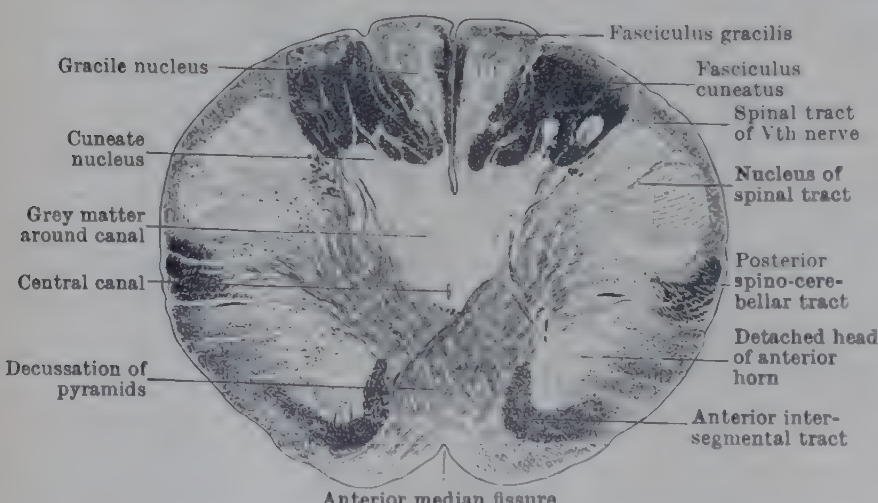

Fig. 775.—Transverse Section of Lower End of Medulla Oblongata of Full-time Fœtus.

Treated by the Weigert-Pal method. The grey matter is bleached white, and the tracts of medullated fibres are black.

In the medulla oblongata another effect of the decussation of the pyramids is seen in the submergence from the surface of the anterior intersegmental tract. At the site of the decussation, the intersegmental tract is thrust aside, and in the medulla oblongata it takes up its position as a flattened band on the lateral side of the pyramid (Fig. 775). Above the decussation, this strand lies close to the median plane behind the pyramid, where it is separated from its fellow of the opposite side by the median raphe alone (Fig. 776). In the upper part of the medulla oblongata it approaches still nearer to the dorsal surface and appears to form the greater part of a strand termed the medial longitudinal

bundle (Figs. 778 and 779). The detached head of the anterior grey column of the cord, as it is traced upwards, clings closely to its original relationship with the anterior intersegmental tract. It is applied to the lateral side of that strand, and, gradually becoming smaller, finally disappears at the level of the lower part of the olivary nucleus.

Cuneate and Gracile Fasciculi, with their Nuclei.—As the fasciculus gracilis and the fasciculus cuneatus of the spinal cord are traced up into the medulla oblongata they seem to increase in bulk, and in transverse sections appear as wedge-shaped strands quite distinct from each other. They increase in width and lose considerably in depth, and consequently the transverse diameter of the area which they occupy becomes greater. As a result of this, and also owing to the removal of the lateral cerebro-spinal tract from the lateral white column of the cord immediately in front, the posterior horn of grey matter is gradually

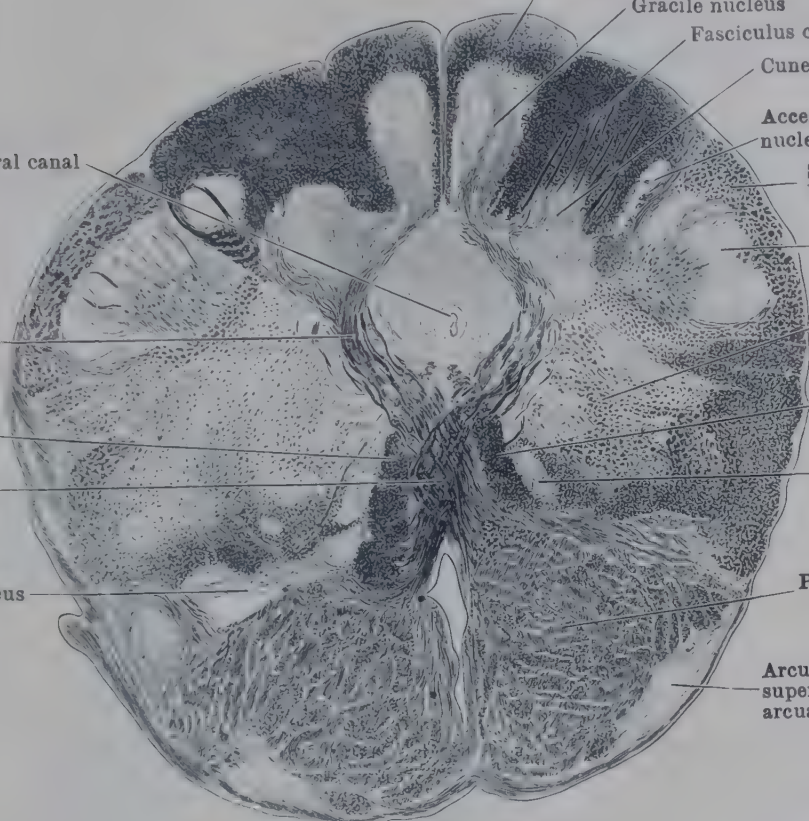

FIG. 776.—SECTION THROUGH ADULT MEDULLA OBLONGATA IMMEDIATELY ABOVE THE DECUSSATION OF THE PYRAMIDS (Weigert-Pal specimen).

rotated forwards and comes to lie transversely and in the same straight line with its fellow of the opposite side (Figs. 775 and 776). The substantia gelatinosa, simultaneously, becomes increased in quantity and presents a horseshoe-shaped outline in transverse section. It clasps within its concavity the slightly reduced head of the posterior horn, and forms with it a conspicuous circular mass of grey matter which lies close to the surface, producing a slight bulging called the **tubercle of the trigeminal nerve** (see p. 883). The basal portion of the posterior horn remains posterior and lateral to the central canal, and forms a portion of the central grey mass of the closed part of the medulla oblongata; but very soon the neck of the posterior horn, which at that level is greatly reduced owing to the absence of entering posterior nerve-roots, is invaded by bundles of fibres which traverse it in different directions and convert it into a diffuse mass of nerve-cells and interlacing fibres—the *formatio reticularis.* By this means the rounded head of the posterior horn is cut off from the central grey matter, and from that point upwards it remains as an isolated grey column intimately associated with the spinal tract of the trigeminal nerve. It has, in fact, become the **nucleus of the spinal tract of the trigeminal nerve.**

The gracile and cuneate nuclei are seen in their most typical form in sections

immediately above the level of the decussation of the pyramids (Figs. 776 and 777).

The **gracile nucleus** appears as a relatively slender mass of grey matter in the interior of the fasciculus gracilis.

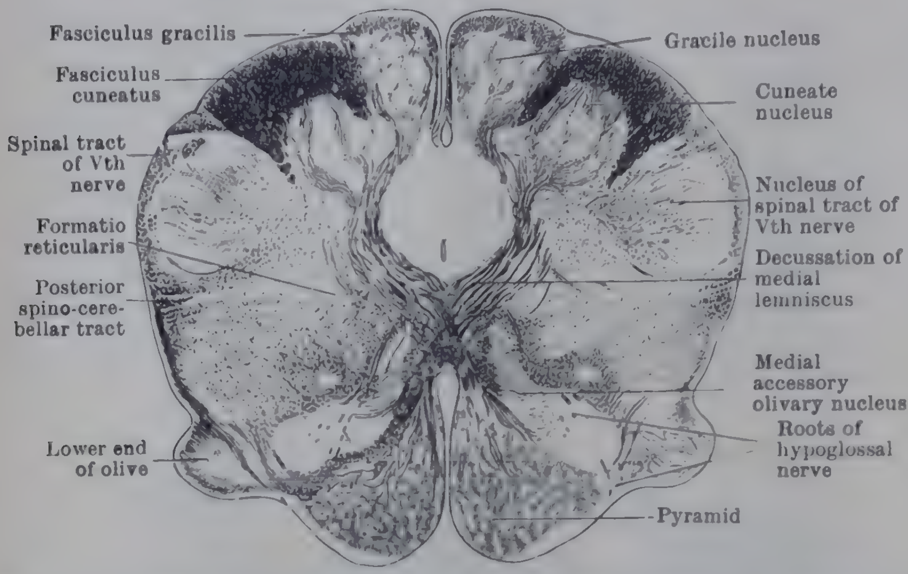

Fig. 777.—Transverse Section through Fœtal Medulla Oblongata immediately above the Decussation of the Pyramids. (Weigert-Pal specimen.)

The **cuneate nucleus** is a direct offshoot from that part of the base of the posterior grey column which is preserved as a portion of the central grey mass. In transverse section it is seen to invade the deep part of the fasciculus cuneatus, and it gradually grows dorsally into its substance. It differs in appearance from the gracile nucleus, because throughout its whole length the grey nucleus and the fibres of the strand are separated from each other by a sharp line of demarcation. A little higher up, a second and much smaller mass of grey matter termed the **accessory** or **lateral cuneate nucleus** appears in the fasciculus cuneatus superficial to the main nucleus (Fig. 776). This accessory nucleus receives fibres of the fasciculus cuneatus which are derived from the posterior roots of the cervical nerves and convey proprioceptive impulses from the neck and upper limb. Experimental evidence indicates that the accessory cuneate nucleus sends fibres to the same side of the cerebellum.

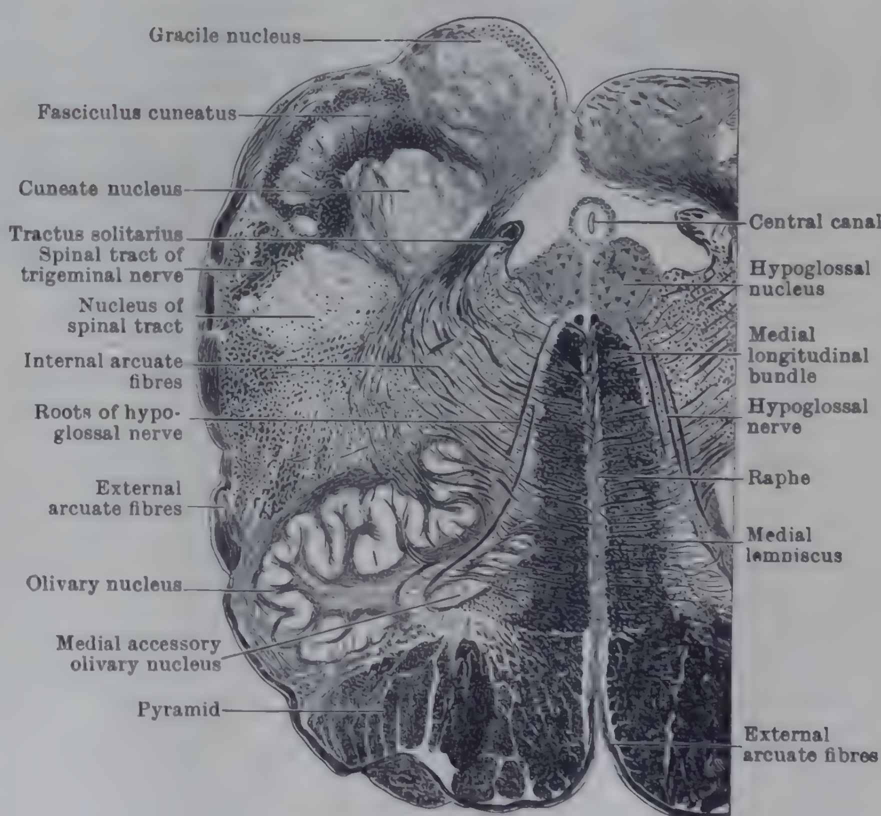

Fig. 778.—Transverse Section of Medulla Oblongata at the Level of the Olive.

As a series of sections is studied from below upwards, it will be noticed that the number of fibres in the gracile and cuneate fasciculi rapidly decreases, until, at the level of the gracile and cuneate tubercles, these eminences are composed almost entirely of the grey nuclei, covered by a thin layer of the few remaining fibres of the two fasciculi.

When the central canal of the medulla oblongata opens up into the fourth ventricle the gracile and cuneate nuclei are pushed laterally, and the gracile nucleus soon comes to an end; but the cuneate nucleus extends upwards for a

short distance farther and terminates only when the inferior cerebellar peduncle begins to take definite shape.

Sensory Decussation.—Immediately above the level of the decussation of the pyramids another decussation of fibres takes place in the substance of the medulla oblongata in the median plane behind the pyramids. This is the **decussation of the lemniscus medialis**, or the **sensory decussation**, so called in contradistinction to the term "motor decussation" which is sometimes applied to the decussation of the pyramids. The fibres which take part in this decussation are called **internal arcuate fibres**, and they are derived from the cells of the gracile and cuneate nuclei (but not the accessory cuneate nucleus). From the deep aspects of these nuclei fibres stream forwards and medially towards the median raphe, forming a series of concentric curves in the substance of the medulla oblongata.

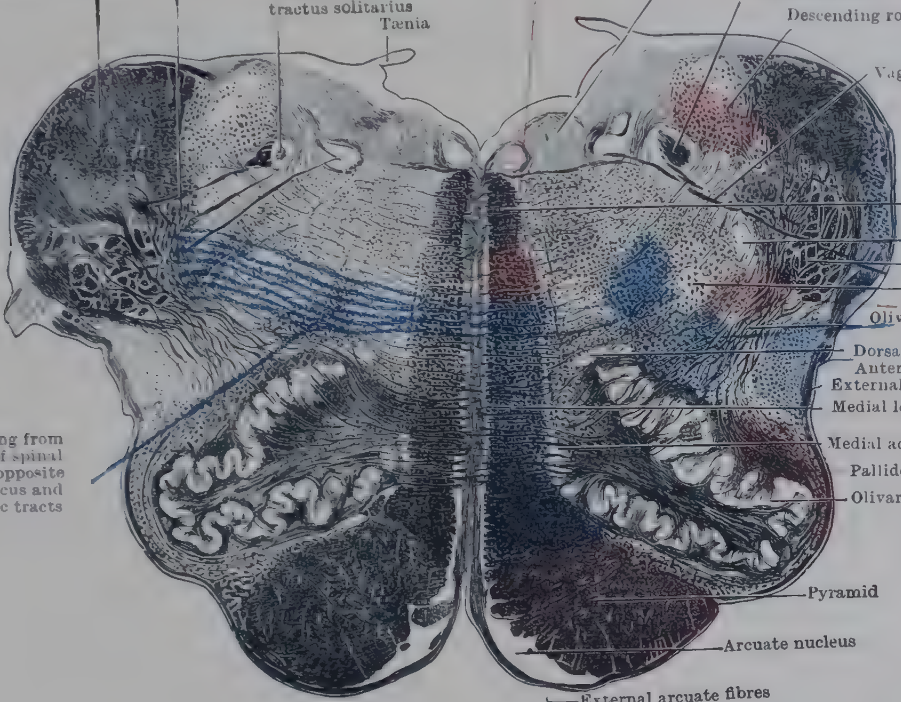

FIG. 779.—TRANSVERSE SECTION AT THE LEVEL OF THE MIDDLE OF THE OLIVE.

The floor of the fourth ventricle is seen, and it will be noticed that the inferior cerebellar peduncles have now taken definite shape. Some of the descending tracts in red ; ascending tracts in blue.

They cross the median plane and decussate with the corresponding fibres of the opposite side behind the pyramids. Having gained the opposite side they immediately turn upwards and form a conspicuous strand of longitudinal fibres which ascends close to the median plane and is separated from its fellow of the opposite side by the median raphe alone. This strand is termed the **medial lemniscus.**

As we proceed up the medulla oblongata, the first internal arcuate fibres seen are coarse bundles which curve forwards in a narrow group round the central grey matter (Figs. 776 and 777). Soon, finer bundles are seen describing wider curves on the lateral side of the coarser group, until a very large part of each half of the medulla is seen to be traversed by these arcuate fasciculi (Fig. 778). The internal arcuate fibres decussate in the median plane with their fellows of the opposite side. They then change their direction and turn upwards, and the lemniscus, as already stated, takes form and gradually increases in volume as it ascends. This great and important tract is thus laid down between the pyramid and the medial longitudinal bundle, and, as a result, this bundle is pushed still farther backwards; therefore, when the lemniscus is fully established, the longitudinal bundle comes to lie immediately beneath the grey matter of the floor of the fourth ventricle (Fig. 779). But the lemniscus is not in direct contact with the longitudinal bundle, for a strand of fibres—the **tecto-spinal tract**—separates them, as well as fibres from the sensory nucleus of the fifth cranial nerve which are crossing the raphe to join the medial lemniscus (Fig. 779).

It is important to realize at this stage the full significance of the decussation of the lemniscus and to have a clear conception of the connexions of the fibres which take part in it. The posterior white column, which ends in the cuneate and gracile nuclei, is derived from the posterior roots of the spinal nerves. The lemniscus fibres therefore carry on the impulses which are conveyed up the spinal cord in the posterior white column of the opposite side. These impulses are relayed through the gracile and cuneate nuclei. At its origin, the lemniscus is transferred to the opposite side of the medulla oblongata. But it will be remembered that a large proportion of the fibres of the entering posterior nerve-roots of the spinal nerves end in connexion with the cells of the posterior grey column of the cord. It must not be supposed that the path represented by the latter fibres comes to a termination thereby; for, from the cells of the posterior column, other fibres arise which cross in the white commissure to the opposite side and proceed up the spinal cord to the lateral part of the medulla oblongata. These fibres constitute the **spino-thalamic tracts** already referred to. The practical bearing of this is that, owing to the crossing of the medial lemniscus and lower down of the spino-thalamic fibres, unilateral lesions of the medulla oblongata are apt to produce complete hemi-anæsthesia; whilst unilateral lesions of the spinal cord produce only partial hemi-anæsthesia.

The pyramid forms a massive tract in front of and quite distinct from the medial lemniscus. The medial lemniscus, the tecto-spinal tract, and the medial longitudinal bundle are, in the first instance, not marked off from each other. They appear as a broad flattened band applied to the raphe with its posterior edge in contact with the grey matter on the floor of the fourth ventricle, and the anterior edge with the pyramid, but in the upper part of the medulla the lemniscus and medial longitudinal bundle begin to draw asunder, and to grow denser, making the intervening tecto-spinal tract more distinct (Fig. 779).

The **medial longitudinal bundle** occupies a position corresponding to that occupied in the spinal cord by the anterior intersegmental tract, with which it appears to be continuous. As they are followed upwards, these fibres are thrust back by the two decussations: the lower decussation pushing them behind the pyramids, and the upper decussation displacing them still farther backwards to a position behind the medial lemniscus. The bundle consists of a heterogeneous collection of fibres, ascending and descending, which link together the nuclei of the cranial nerves at different levels in the brain-stem. Its most important element consists of fibres from the lateral vestibular nucleus proceeding to motor nuclei, in particular those of the third, fourth, sixth, and eleventh cranial nerves of both sides.

Inferior Cerebellar Peduncle.—The gracile and cuneate nuclei gradually give place to the **inferior peduncle** in the upper part of the medulla oblongata. Fibres from various quarters converge to form this great strand. It first takes shape as a thin superficial layer of longitudinal fibres which are gathered together immediately lateral to the cuneate nucleus; but after that nucleus has come to an end, and as the upper part of the medulla oblongata is reached, the inferior peduncle is seen to have grown into a massive strand which presents a kidney-shaped or an oval outline on transverse section (Fig. 779); and it ultimately enters the white central core of the cerebellum. The principal fibres which build up this peduncle are the following: (1) the posterior spino-cerebellar tract (conveying proprioceptive impulses mainly from the same side of the body), (2) external arcuate fibres from the arcuate nuclei;

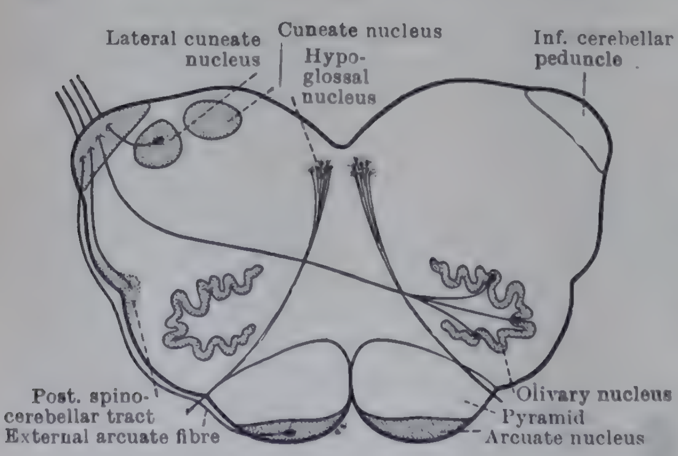

Fig. 780.—Diagram showing the Origin of some of the Fibres which enter into the Composition of the Inferior Cerebellar Peduncle.

(3) fibres from the accessory (lateral) cuneate nucleus (conveying impulses from the neck and upper limb of the same side); and (4) olivo-cerebellar fibres (Fig. 780).

Thus, the inferior peduncle conveys to the cerebellum: (1) fibres that conduct impulses from the posterior spinal roots, mainly of the same side; and (2) fibres from the olivary and arcuate nuclei which convey impulses from the higher regions of the brain.

It is commonly stated that the inferior cerebellar peduncle contains also numerous fibres from the gracile and cuneate nuclei (in addition to the accessory cuneate nucleus). However, there is no certain evidence that this is so; on the contrary, the results of recent experimental work indicate that the efferent fibres of the gracile and cuneate nuclei all enter into the composition of the medial lemniscus along which they are conveyed to the thalamus.

Formatio Reticularis.—Behind the olive and the pyramid is the **formatio reticularis.** In the medulla oblongata it occupies a position which, to a large extent, corresponds with that of the deeper part of the lateral white column in the spinal cord. In transverse section it appears as an extensive area divided into a lateral and a medial field by the roots of the hypoglossal nerve as they traverse the substance of the medulla oblongata to reach the surface. In the lateral portion, which lies behind the olive, a considerable quantity of grey matter, continuous with that in the spinal cord, is present in the reticular formation; it is therefore called the **formatio reticularis grisea**. In the medial part, which lies behind the pyramid, the grey matter is extremely scanty, and the reticular matter here is termed the **formatio reticularis alba.**

The nerve-fibres which traverse the formatio reticularis run both in a transverse and in a longitudinal direction. The **transverse fibres** are the internal arcuate and olivo-cerebellar fibres. The **longitudinal fibres** are derived from different sources in the two fields. In the formatio grisea they represent to a large extent the fibres of the lateral white column of the cord, after the removal of the posterior spino-cerebellar and the lateral cerebro-spinal tracts. They consist, therefore, of the fibres of the rubro-spinal, pallido-olivary, spino-thalamic, and anterior spino-cerebellar tracts of the spinal cord. In the formatio alba the longitudinal fibres are the medial lemniscus, the tecto-spinal tract, and the medial longitudinal bundle, all of which have been described already.

Central Canal and the Grey Matter which surrounds it.—The central canal, as it proceeds upwards through the lower half of the medulla, is gradually forced backwards, owing to the accumulation of fibres in front of it. First the decussation of the pyramids and then the sensory decussation tend to push it backwards; and the formation of the longitudinal strands in which those intercrossings result (viz., the pyramid and the medial lemniscus), together with the continuation upwards of the anterior intersegmental tract, leads to a great increase in the amount of tissue which separates it from the anterior surface of the medulla oblongata. The canal is surrounded by a thick layer of grey matter which is continuous with the basal portions of the anterior and posterior grey columns of the cord. This central grey matter is sharply defined on each side by the internal arcuate fibres as they curve forwards and medially around it. Finally, the central canal opens, in the upper part of the medulla oblongata, into the cavity of the fourth ventricle. The central mass of grey matter which surrounds the canal is now spread out in a thick layer on the floor of the fourth ventricle, and in such a manner that the portion which corresponds to the basal part of the anterior grey column is close to the median plane, whilst the part which represents the base of the posterior grey column occupies a more lateral position. It is important to note this, because it explains why the nucleus of origin of the hypoglossal nerve is placed in the medial part of the floor, whilst the nuclei of termination of the afferent fibres of the vagus, glosso-pharyngeal, and auditory nerves lie in the lateral part of the floor.

Three Areas of Flechsig.—In transverse sections through the upper part of the medulla oblongata, the root-fibres of the hypoglossal and vagus nerves are seen traversing its substance. The nucleus of origin of the hypoglossal is placed in the grey matter of the floor of the fourth ventricle close to the median plane; the nucleus of the vagus is situated immediately to the lateral side of the hypoglossal nucleus. From these nuclei the root-bundles of the two nerves, passing forwards, diverge from each other and divide the substance of the medulla, as seen in transverse section, into the three areas of Flechsig, viz., an anterior, a lateral, and a posterior.

The **anterior area**, which is bounded medially by the median raphe and laterally by the hypoglossal roots, contains: (*a*) the pyramid; (*b*) the medial lemniscus; (*c*) the tecto-spinal tract; (*d*) the medial longitudinal bundle; (*e*) the medial accessory olivary nucleus; (*f*) the arcuate nucleus.

The **lateral area** lies between the root-fibres of the hypoglossal and those of the vagus. It contains: (*a*) the olivary nucleus; (*b*) the dorsal accessory olivary nucleus; (*c*) the nucleus ambiguus; (*d*) the splanchnic efferent nucleus of the vagus and glosso-pharyngeal nerves; (*e*) the formatio reticularis grisea.

The **posterior area** is situated behind the vagus roots, and within its limits are seen: (1) the inferior cerebellar peduncle; (2) the upper part of the cuneate nucleus; (3) to the medial side of that a crowd of transversely cut bundles of fibres, loosely arranged and forming the descending root of the vestibular nerve; (4) close to them, but placed more deeply, a round, compact, and very conspicuous bundle of transversely cut fibres, viz., the tractus solitarius; (5) a large bundle—the spinal tract of the trigeminal nerve—close to the lateral side of its nucleus, which is composed of substantia gelatinosa.

Internal Structure of Pons

When transverse sections are made through the pons, it is seen to be composed of a basilar part and a dorsal part. The dorsal part is the upward prolongation

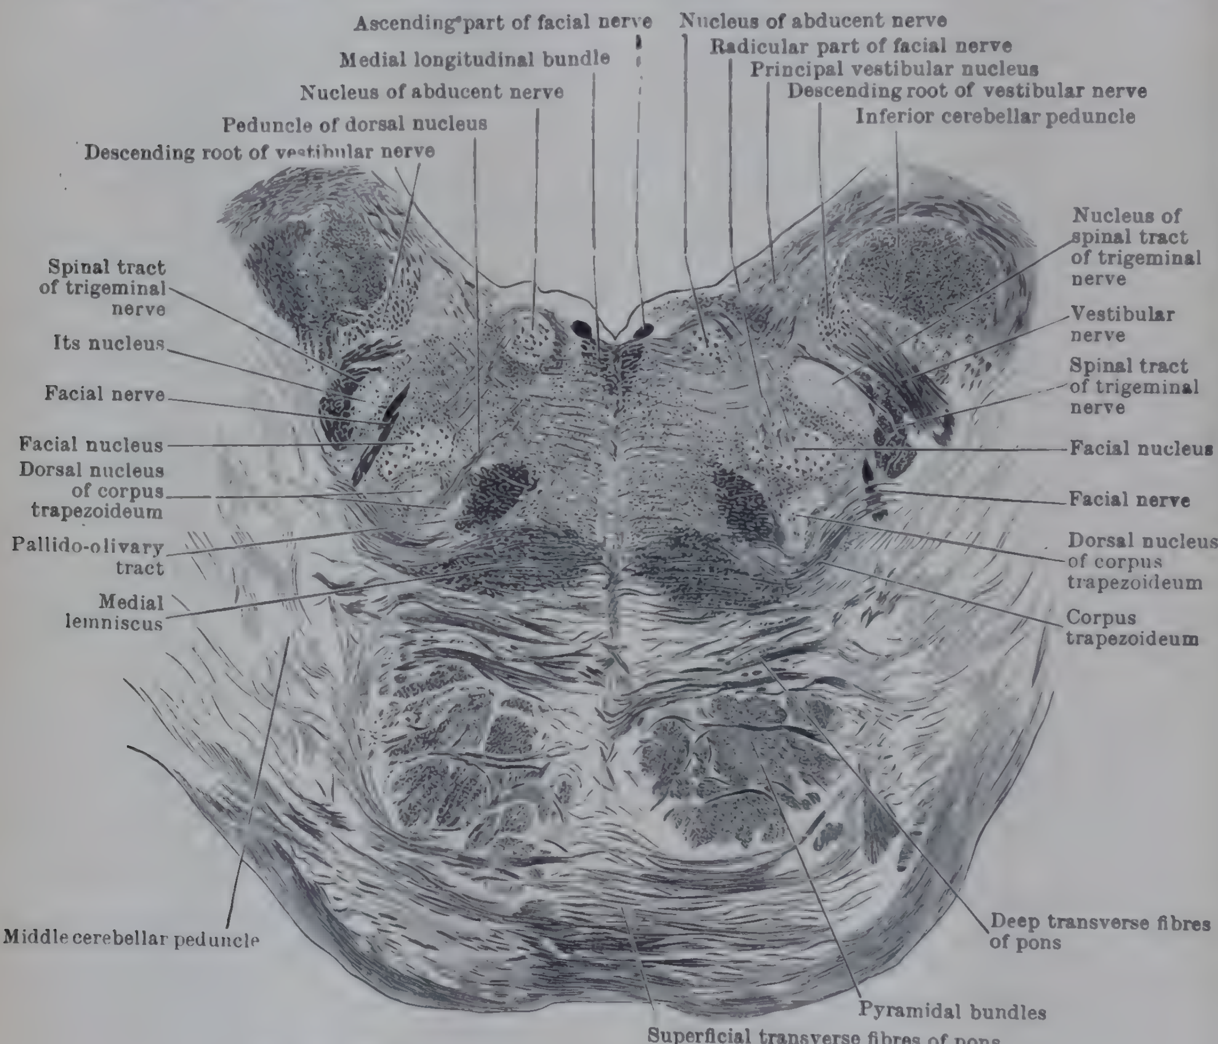

Fig. 781.—Section through the Lowest Part of the Pons.

of the medulla oblongata, exclusive of the pyramids (which are drawn forward into the basilar part).

Basilar Part of Pons.—This constitutes the chief bulk of the pons, and it is the part to which the name "pons" was originally applied by Varolius, as it appears to form a bridge between the hemispheres of the cerebellum. It is composed of: (1) **transverse fibres** arranged in coarse bundles; (2) **longitudinal fibres**, gathered together in massive bundles; and (3) a large amount of grey matter, termed the **nuclei pontis**, which fills up the interstices between the intersecting bundles of fibres.

The **longitudinal bundles**, to a large extent, consist of the same fibres which,

lower down, are gathered together in the two pyramids of the medulla oblongata. When the pyramids are traced upwards into the pons they are first a pair of compact bundles, and then are broken up by the transverse fibres of the pons into smaller bundles which are spread out over a wider area. At the upper border of the pons they again come together and form a pair of solid strands, each of which is continuous with the middle part of the corresponding basis pedunculi. Added to these bundles of the pyramid, there are many other fibres that enter the pons from the basis pedunculi to terminate in the nuclei pontis.

The **transverse fibres** are placed in front of the pyramidal bundles at the lower border of the pons. Farther up they increase in number, and many are seen breaking through the pyramids and also passing behind them. Laterally, these transverse fibres are collected together into one compact mass which enters the white core of the cerebellum as the **middle cerebellar peduncle**. In the median plane the transverse fibres of the two sides form a coarse decussation.

There is some analogy between the pyramidal portions of the medulla oblongata and the basilar part of the pons. In the medulla oblongata fine external arcuate fibres sweep over the surface of the pyramids. These resemble the transverse fibres of the pons, and, like them, reach the cerebellum—although by a different route, viz., the inferior peduncle. The nuclei pontis are represented also in the pyramidal part of the medulla oblongata by the arcuate nuclei, which are covered over by the external arcuate fibres, and even tend to penetrate into the pyramids. These arcuate nuclei, as already pointed out, are continuous with the nuclei pontis.

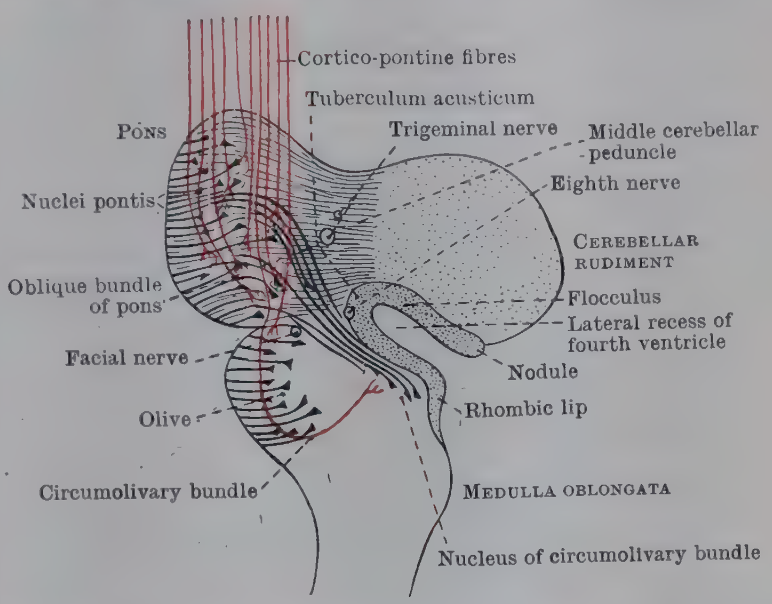

Fig. 782.—Diagram of Left Lateral Aspect of Fœtal Rhombencephalon representing some of the Cell-Groups and Fibre-Tracts.

Connexions of Longitudinal and Transverse Fibres.—When a transverse section through the upper part of the pons is compared with one close to its lower border, it becomes at once apparent that the numerous scattered bundles of longitudinal fibres which enter the basilar part of the pons from above, if brought together into one tract, would form a strand very much larger than the two pyramids. The reason is this: a large proportion of the fibres of the basis pedunculi—those forming its lateral and medial parts—are **cortico-pontine fibres**; they arise in the cerebral cortex and end in the nuclei pontis. The pyramidal fibres, which occupy the intermediate part of the basis pedunculi, also suffer loss when they descend into the hind-brain, because some of them end there by effecting synapses with the cells of the motor nuclei of the trigeminal, abducent, facial and hypoglossal nerves; but that accounts for only a very small part of the difference between the bulk of the basis and that of the pyramid.

The transverse fibres take origin as axons of the cells of the nuclei pontis. They cross the median plane and enter the middle peduncle of the opposite side, and thus reach the cerebellar cortex, where they end in ramifications around certain of the cortical cells. Some authorities believe that there are also fibres passing in the opposite direction, *i.e.*, from the cerebellum to the nuclei pontis; but there is some doubt concerning the existence of any such fibres. The middle peduncle thus may contain both efferent and afferent cerebellar fibres; but no fibres pass continuously through the pons from one middle peduncle into the other.

Corpus Trapezoideum.—This name is applied to a group of transverse fibres which traverse the lower part of the pons (Fig. 781). They are quite distinct from those which have been just described as entering the middle peduncle, and they

lie in the boundary between the dorsal and basilar parts of the pons, but encroaching considerably into the ground of the former. They arise from the cells of the terminal nuclei of the cochlear nerve, and constitute a tract which establishes certain central connexions for that nerve. They will be more fully described when we treat of the cerebral connexions of the auditory nerve.

Dorsal Part of Pons.—On the dorsal surface of the pons there is spread a thick layer of grey matter, covered with ependyma, which forms the floor of the upper or pontine part of the fourth ventricle. Beneath this grey matter the median raphe of the medulla oblongata is continued up into the pons, so as to divide its dorsal part into symmetrical halves.

In the *lowest part of the pons* the inferior cerebellar peduncle is placed on

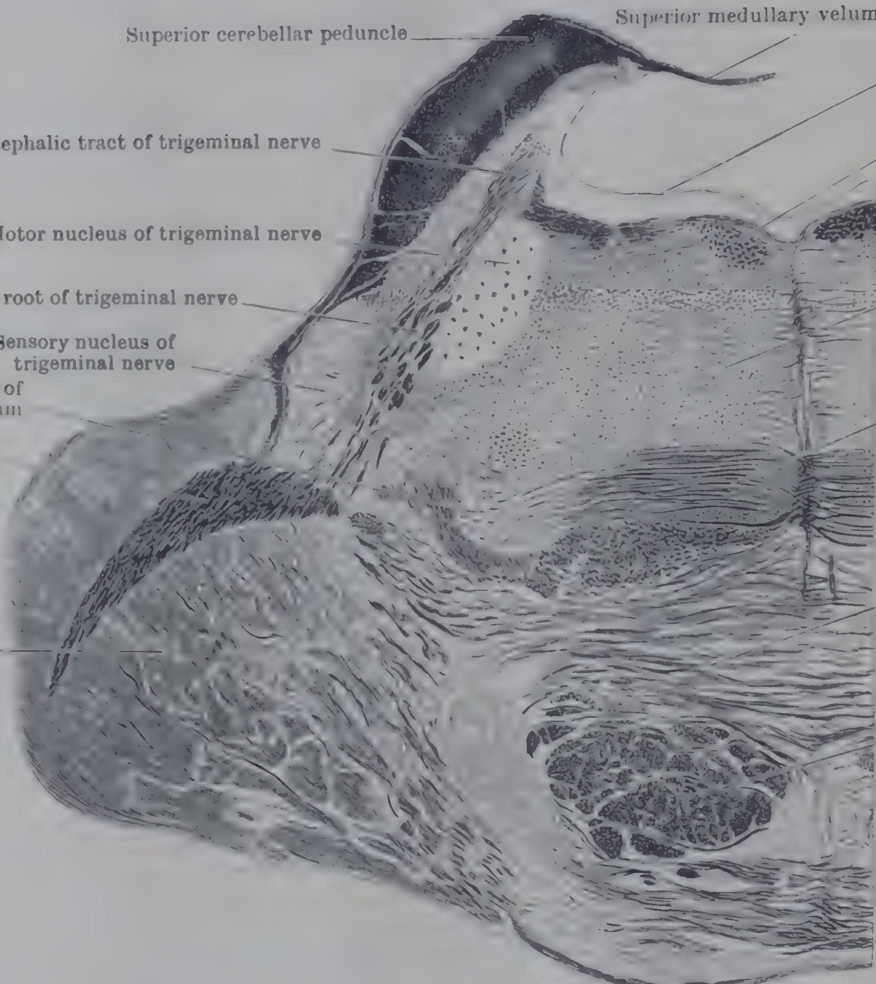

FIG. 783.—TRANSVERSE SECTION THROUGH PONS AT LEVEL OF TRIGEMINAL NUCLEI.

the lateral side of the dorsal part (Fig. 781). In transverse sections it appears as a large, massive, oval strand of fibres which inclines backwards into the cerebellum and thus leaves the pons. Between the inferior peduncle and the median raphe the dorsal part of the pons is composed of formatio reticularis, continuous with the same formation in the medulla oblongata. Thus, transverse fibres, curving in towards the raphe, and also longitudinal fibres, are seen breaking through the mass of grey matter which occupies the interstices of the intersecting bundles. To the naked eye the formatio reticularis appears uniformly grey, but its constituent parts are revealed by low powers of the microscope in properly stained and prepared specimens. Embedded in the formatio reticularis are various clumps of compact grey matter and certain definite strands of fibres. These we shall describe as we pass from the inferior peduncle towards the median raphe.

(1) **Spinal Tract of Trigeminal Nerve and its Nucleus.**—Close to the medial side of the inferior peduncle, but separated from it by the vesitibular nerve as it proceeds backwards through the pons, is seen a large crescentic group of coarse bundles of fibres. This is the spinal tract of the trigeminal nerve; and applied to

its medial, concave side there is a small mass of grey matter which is the direct continuation upwards of the substantia gelatinosa (Fig. 781).

(2) The **nucleus of the motor root of the facial nerve** comes next. It is a conspicuous, obliquely placed, ovoid clump of grey matter that lies close to the corpus trapezoideum. The root-fibres of the facial nerve stream backwards and medially from it towards the floor of the fourth ventricle. Passing forwards between the facial nucleus and the trigeminal sensory nucleus a solid nerve-bundle may be observed. This is the facial nerve, traversing the pons towards its place of emergence from the brain.

(3) Immediately medial to the facial nucleus, but partly sunk in the corpus trapezoideum, is the **dorsal nucleus of the corpus trapezoideum**, and some of the fibres of the corpus may be observed penetrating into its substance. In Man, it is a very small mass of grey matter. In sections through the part of the pons where it attains its greatest size, it appears in the form of two, or it may be three,

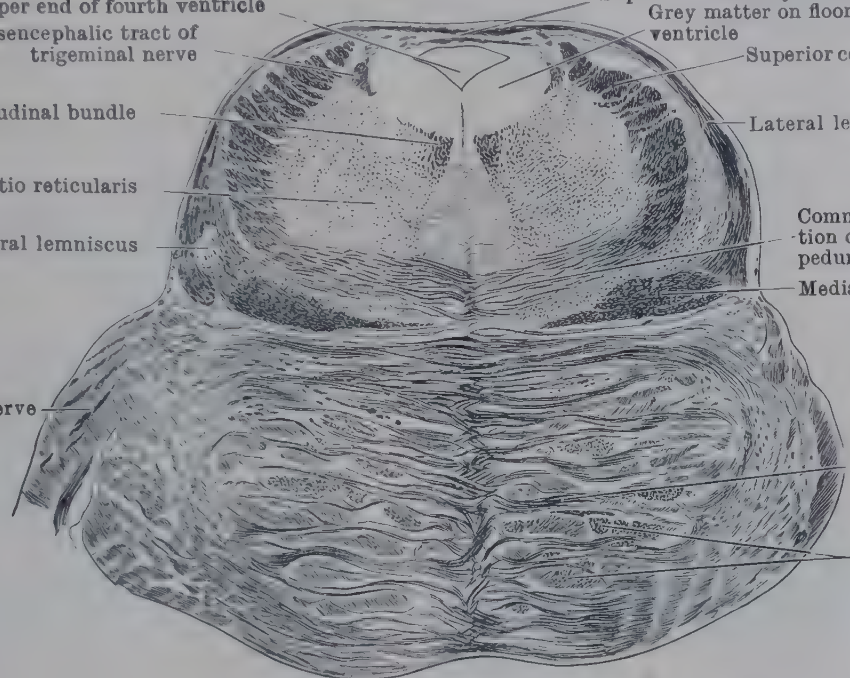

FIG. 784.—SECTION THROUGH PONS, ABOVE LEVEL OF THE MAIN TRIGEMINAL NUCLEI.

small isolated masses. It is intimately connected with the auditory fibres, and establishes manifold connexions between them and the nuclei of other nerves. A dense group of longitudinal fibres lies behind and medial to it; they constitute the **pallido-olivary tract**, to which we have already referred in discussing the olivary nucleus (Fig. 781).

(4) The **medial longitudinal bundle** and the **medial lemniscus** come next. As they proceed upwards through the pons, they occupy the same relative position as in the medulla oblongata. They are placed close to the median raphe and are separated from each other by the **tecto-spinal tract**. The **medial longitudinal bundle** lies immediately under cover of the grey matter of the floor of the fourth ventricle. The **medial lemniscus** is placed close to the corpus trapezoideum, many of whose fibres traverse it as they pass towards the median plane.

(5) The **nucleus of the abducent nerve** also forms a conspicuous object in sections through the lower part of the pons. In such sections it appears as a round mass of grey matter situated close to the lateral side of the medial longitudinal bundle and immediately under cover of the grey matter of the floor of the fourth ventricle. From its medial side numerous root-bundles of the abducent nerve pass out and proceed forwards between the medial lemniscus and the dorsal nucleus of the corpus trapezoideum. They occupy in the pons, therefore, a position similar to that occupied by the hypoglossal root-fibres in the medulla oblongata.

Up to the present only the lowest part of the dorsal portion of the pons has been described. As we proceed upwards and gain a point *above the level of*

the corpus trapezoideum, the floor of the ventricle becomes narrower, and the medial lemniscus becomes markedly increased in size by the addition of the fibres of the spino-thalamic tracts. On the other hand, many of the structures that have attracted attention lower down gradually disappear, while other objects make their appearance in the formatio reticularis.

The **superior cerebellar peduncle** is the group of fibres proceeding from the nuclei of the cerebellum to the red nucleus in the opposite side of the brain-stem and to the opposite thalamus. It is a very conspicuous object in sections through the middle and upper parts of the pons. In transverse section it has a semilunar outline, and as it emerges from the cerebellum it lies immediately on the lateral side of the fourth ventricle, towards which its concave aspect is turned (Fig. 783). Its dorsal border is joined with the opposite peduncle by the thin lamina of white matter termed the *superior medullary velum*, whilst its ventral border is sunk to a small extent in the dorsal part of the pons. As it is traced upwards it sinks deeper and deeper into the pons until it becomes completely submerged, with the exception of the dorsal border. It now lies on the lateral side of the reticular formation of the pons, and this position it maintains until the mid-brain is reached (Fig. 785).

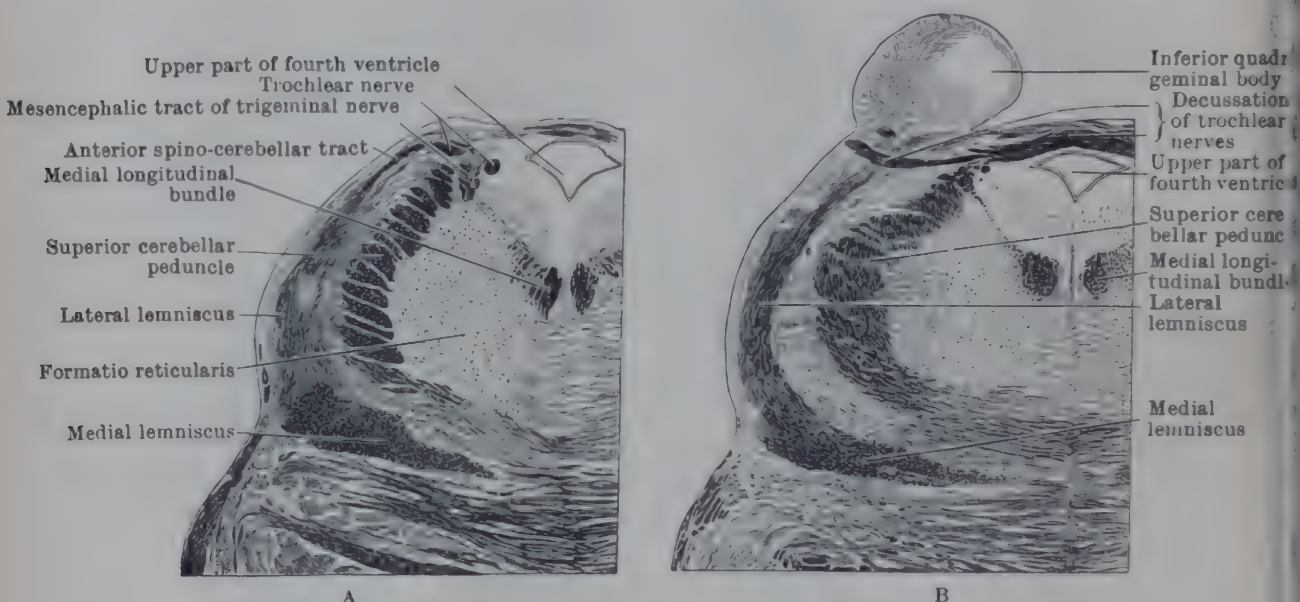

FIG. 785.—SECTIONS THROUGH DORSAL PART OF PONS CLOSE TO THE MID-BRAIN.
A is at a slightly lower level than B.

About *half-way up the pons* the main nuclei of the trigeminal nerve come into view. These nuclei are two in number on each side, viz., a large oval terminal nucleus for certain of the sensory fibres of the nerve and a nucleus of origin, equally conspicuous, for the motor fibres (Fig. 783). The **sensory nucleus** lies close to the lateral surface of the dorsal portion of the pons. The **motor nucleus** is placed on the medial side of the sensory nucleus, but rather nearer the floor of the fourth ventricle. At this level the spinal tract of the trigeminal nerve begins by the bending downwards of certain of the fibres of the sensory portion. The sensory and motor roots of the fifth nerve traverse the basilar part of the pons on their way to and from the nuclei.

Above the level of the nuclei of the trigeminal nerve a new tract of fibres comes into view—the **mesencephalic tract of the trigeminal nerve**. It is a small bundle of nerve-fibres, semilunar in cross-section, which lies close to the medial side of the superior peduncle and on the lateral and deep aspect of the grey matter on the floor of the fourth ventricle (Figs. 783-785).

On a slightly deeper plane than the mesencephalic tract of the fifth nerve, between it and the medial longitudinal bundle, and in close relation to the grey matter of the floor of the ventricle, there is the collection of pigmented cells which constitutes the **substantia ferruginea**.

The **medial longitudinal bundle**, as it is traced upwards, maintains the same position throughout, and as it ascends it becomes more clearly mapped out as a

definite and distinct tract. It lies close to the median raphe, and immediately subjacent to the grey matter of the floor of the fourth ventricle.

The **medial lemniscus**, as it ascends, undergoes striking changes in shape. In the lower portion of the pons its fibres, which in the medulla oblongata are spread out along the side of the median raphe, are collected together in the form of a loose bundle which occupies a wide field immediately behind the basilar portion of the pons. As it proceeds up, the fibres spread out laterally until a compact ribbon-like layer is formed which ascends between the dorsal and ventral parts of the pons (Figs. 784 and 785).

Above the level of the main trigeminal nuclei another flattened layer of fibres comes into view to the lateral side of the medial lemniscus. To it the name of **lateral lemniscus** is given. Its fibres spread laterally and backwards, and finally take up a position on the lateral surface of the superior cerebellar peduncle. Among the fibres of the lateral lemniscus a little knot of compact grey matter, termed the **nucleus of the lateral lemniscus**, comes into view (Fig. 785). It gives origin to many of the fibres of the lateral lemniscus.

CEREBELLUM

The **cerebellum** forms the largest subdivision of the hind-brain. It lies behind the pons and medulla oblongata and occupies the greater part of the posterior cranial fossa. Above it lies the tentorium cerebelli, which separates it

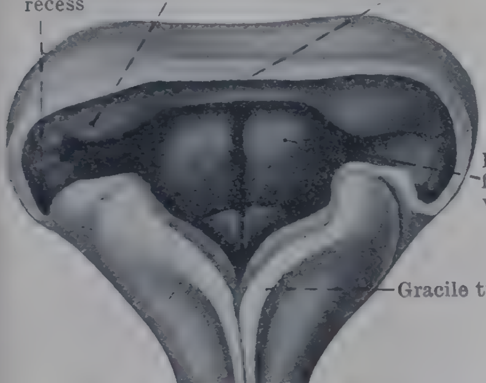

FIG. 786.—DORSAL ASPECT OF RHOMBENCEPHALON IN HUMAN EMBRYO. (His, 1904.)

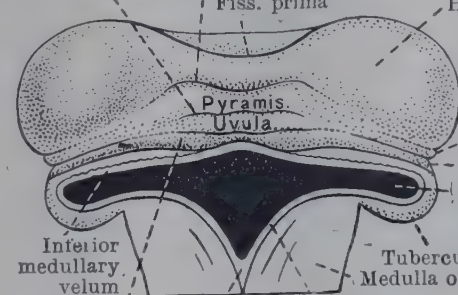

FIG. 787.—DORSAL ASPECT OF FŒTAL (FOURTH MONTH) CEREBELLUM, MEDULLA OBLONGATA AND FOURTH VENTRICLE.

from the posterior part of the cerebral hemispheres. Laterally the cerebellum is related to the temporal bone; behind and below it occupies a deep fossa of the occipital bone. In the dura mater of the posterior fossa there are various venous sinuses which are related to the cerebellum (Fig. 877, p. 977).

The whole organ is divisible for descriptive purposes into a pair of **hemispheres** united by a narrow median part called the **vermis** (Fig. 791). When viewed from above, the vermis projects as a low ridge but is not clearly separable from the hemispheres. Inferiorly (Fig. 792) the vermis lies in a deep gutter—**the vallecula**—between the hemispheres and is clearly demarcated from them by deep furrows. Anteriorly the cerebellum, as it faces the pons and medulla, is related to the fourth ventricle of the brain (Fig. 793).

DEVELOPMENT AND SUBDIVISION OF CEREBELLUM

It has been shown that the cerebellum is formed from two distinct rudiments, one on each side derived from the dorsal edge of the alar lamina close to the insertion of the eighth nerve. During the second month of intra-uterine life there is a rapid proliferation of the cells of the mantle layer of the cerebellar rudiments, which thus becomes considerably thickened (Fig. 786).

The accentuation of the pontine flexure brings the cerebellar rudiments into a transverse direction. The roof-plate that unites them becomes thickened by immigrant neuroblasts from the medial parts of the cerebellar rudiments; it thus

comes about that one organ is formed by the fusion of the two original rudiments in the roof-plate, and a dumb-bell shaped mass results (Fig. 787). On the lower aspect of this mass the inferior medullary velum and the choroid plexus of the fourth ventricle develop. In the third month, lateral bulgings of the cerebellar rudiment give the first evidence of cerebellar hemispheres (Fig. 787).

The basic plan of the adult human cerebellum is obscured to a considerable degree by the complexity of its fissuration. Hence, before attempting to describe its main divisions it is desirable to give a brief schematic account of the basic plan by reference to the presumed stages in the evolutionary development of the cerebellum. (For a general account of the structural organization of the cerebellum, see Dow, 1942.)

It has already been noted that the cerebellum is developed primarily as an extension and elaboration of part of the terminal nucleus of the vestibular nerve. In other words, it may be supposed that in its most primitive form the whole of

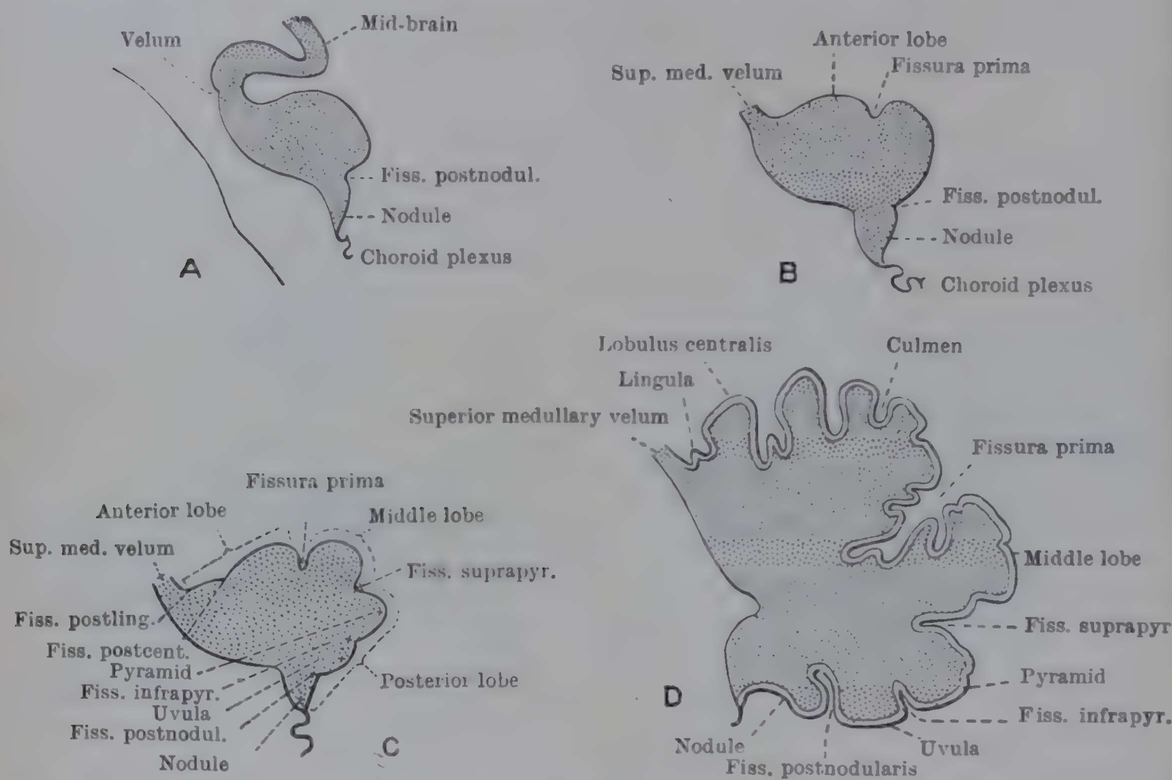

FIG. 788.—MEDIAN SAGITTAL SECTIONS OF FŒTAL CEREBELLA IN FOUR STAGES OF DEVELOPMENT. A and B, third month ; C, fourth month ; D, fifth month.

the cerebellum receives direct and indirect vestibular connexions and is therefore concerned entirely with functions of equilibration. In fishes generally, in which the semicircular canals and lateral lines play a very important rôle as a balancing and orientating mechanism in swimming, the primitive vestibular part of the cerebellum develops on each side a lateral expansion—the *auricular lobe* (Fig. 789 A). This expansion is retained in all mammals, including Man ; and in them it is termed the *flocculus* (Figs. 789, 792).

In the next phase of development (Fig. 789 B), the spino-cerebellar tracts make their appearance, conveying proprioceptive impulses on the basis of which the postural tone of the limb-muscles comes under the regulatory influence of the cerebellum. This leads to the differentiation of a new element, the "spinal cerebellum", which appears in the middle of the older "vestibular cerebellum" and divides it into anterior and posterior parts. The anterior part is represented by a small median lobule—the *lingula*—and the posterior part by a central thickening called the *nodule* and the laterally situated flocculi. The newer, spinal, part of the cerebellum also sends out on each side a lateral expansion—the *paraflocculus*—which lies in close topographical relation with the flocculus. It should be noted that the divisions which we have described are not to be quite sharply distinguished on the basis of fibre-connexions, for afferent fibres from

the spinal cord reach the lingula in addition to vestibular fibres, while direct vestibular connexions encroach to a slight degree on to the posterior part of the "spinal cerebellum".

A third phase in the development of the cerebellum is an expression of the increasing domination of the cerebral cortex in the central nervous system of the higher vertebrates. In all mammals the activities of the cerebellum are to some extent under the control of the fore-brain, and to effect this control descending fibres pass from most areas of the cerebral cortex down to the pons. Here they are relayed on to the cerebellum by fibres which take their origin in the nuclei pontis. The irruption of these *ponto-cerebellar fibres* into the cerebellum leads to the differentiation of yet another element, and this again makes its appearance in the middle of the older parts of the cerebellum. The new element, which becomes relatively larger and more elaborate as the cerebral cortex undergoes a progressive expansion, is termed the **lobus medius.** It is also sometimes referred to as the "neocerebellum", in contradistinction to the older and more primitive spinal and vestibular elements which are collectively termed the "palæocerebellum". The lobus medius consists of a central portion which enters into the formation of the vermis, and a pair of large lateral expansions which form the greater part of the hemispheres of the human cerebellum. It can be divided into two main parts, the larger *ansiform lobe* and the smaller *paramedian* or *tonsillar lobe.* Both these lobes become extremely complicated in higher mammals by an intricate system of fissures and folia, and by reference to some of the deeper fissures further topographical subdivisions can be defined.

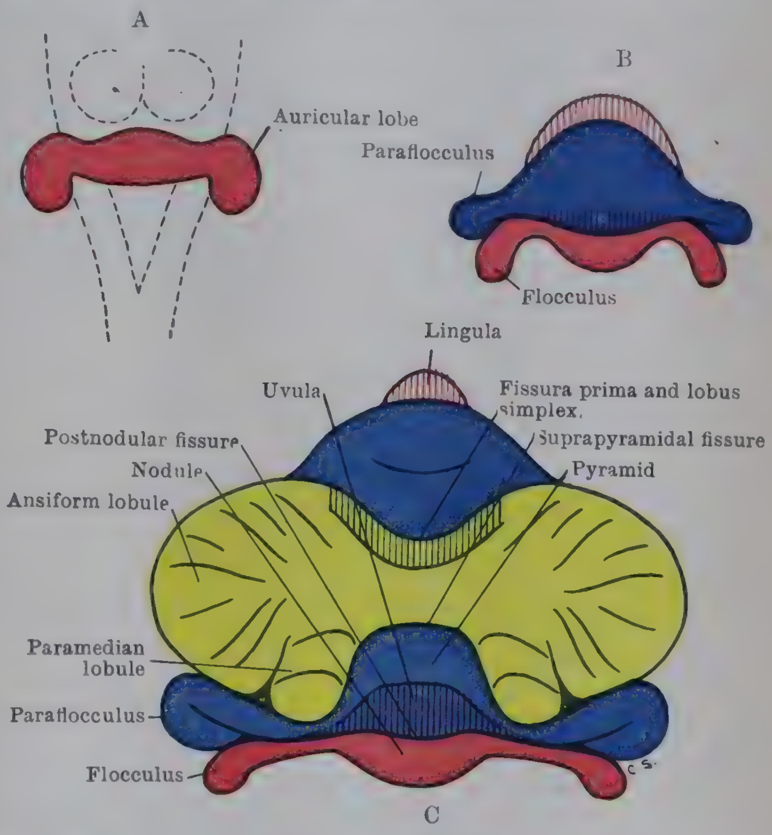

FIG. 789.—DIAGRAMS ILLUSTRATING EVOLUTIONARY DEVELOPMENT OF CEREBELLUM AND THE CONSTITUTION OF ITS THREE LOBES.

Red, Vestibular cerebellum ; *Blue,* Spinal cerebellum ; *Yellow,* Neocerebellum (lobus medius).

A. Hypothetical primitive cerebellum with vestibular connexions only ; B. Cerebellum of reptile showing addition of part that receives spino-cerebellar tracts ; C. Mammalian cerebellum showing addition of part (lobus medius) that receives cortical impulses by way of the pontine nuclei.

We can now appreciate the general plan on which the cerebellum is built in Man by reference to Figs. 788, 789, 794, 795. From these diagrams it is perfectly clear that the whole cerebellum is naturally divisible into three lobes—anterior and posterior lobes which are composed of the older vestibular and spinal elements, and the middle lobe or lobus medius. The anterior lobe is separated from the middle lobe by a deep fissure which makes its appearance very early in the embryonic development of the cerebellum. Hence it is termed the **fissura prima.** The anterior lobe is composed of the lingula in front and a larger portion behind which receives afferent connexions from the spinal cord. The middle lobe, as already noted, is distinguished from other parts of the cerebellum by the connexions whereby it is brought into functional relation with the cerebral cortex. It should be noted, however, that its anterior part (immediately behind the fissura prima) receives a few spino-cerebellar fibres which encroach upon it from the anterior lobe. This portion of the middle lobe is marked off from the main

part by a transverse fissure and forms a separate lobule, sometimes termed the *lobus simplex* (Fig. 789). The posterior lobe is divisible into a median part, which forms the inferior vermis in the human cerebellum, and a lateral expansion made up of the flocculus and paraflocculus on each side. The median part is separated into three segments by two transverse fissures. Behind and below is the nodule, which has already been mentioned. Separated from it by the post-nodular fissure is the *uvula*, while in front and above is the *pyramid*. The posterior lobe is marked off from the middle lobe by a relatively deep fissure—the **fissura suprapyramidalis.**

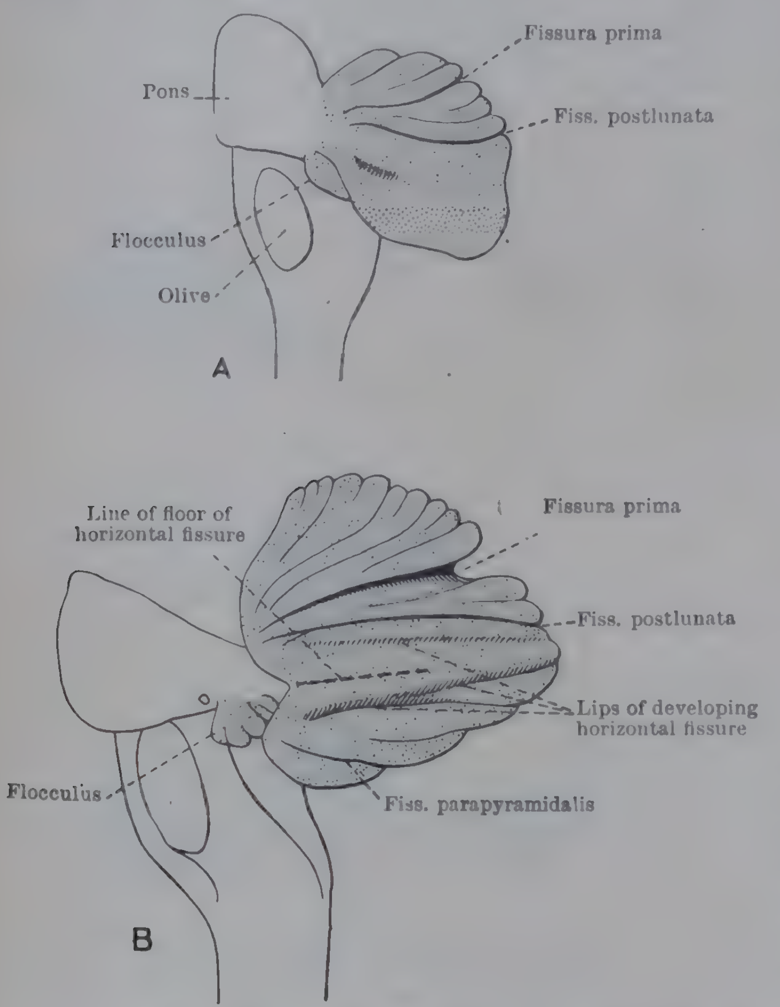

Fig. 790.—Left Lateral Aspect of Fœtal Rhombencephalon at Fourth (A) and Fifth (B) Months.
The cerebellum is stippled.

The fissura suprapyramidalis has been reasonably termed the fissura secunda because of the part it plays with the fissura prima in separating the cerebellum into its three main lobes. Unfortunately, however, the term *fissura secunda* has been applied by various authorities to other fissures in the posterior lobe so that its use is likely to lead to confusion.

The subdivisions of the cerebellum which we have noted have much more than a purely morphological significance. Their different fibre-connexions are an expression of correspondingly different functions, and these differences, again, are reflected in the disorders which arise when they are affected by injury or disease. Hence, the recognition of the three main lobes of the human cerebellum will be found of great assistance in the appreciation of the clinical syndromes related to cerebellar lesions. The nodule and floccular lobes are entirely vestibular in their connexions. Lesions of this part of the cerebellum, therefore, give rise to disturbances of equilibrium without affecting the reflex mechanisms of the spinal cord. Lesions of the spinal part of the cerebellum lead to disturbances of postural mechanisms in relation to the fact that the normal cerebellar control of the distribution of reflex muscular tonus is thrown out of gear. Lastly, lesions affecting the middle lobe, or neocerebellum, always lead to gross defects of voluntary movements, which become inco-ordinate, jerky, and inaccurate.

In the light of what has been said in the previous paragraphs we can now turn our attention to a more detailed consideration of the adult human cerebellum (Figs. 791-795). On the upper surface the deep fissura prima can usually be recognized without difficulty. In front of it lies the **anterior lobe** of the cerebellum. An ill-defined ridge in the median plane marks the position of the superior vermis, while on each side the anterior lobe enters into the composition of the corresponding cerebellar hemisphere. The lingula is an extension forwards of the superior vermis on the surface of the superior medullary velum. It appears as a thin tongue of grey matter (cerebellar cortex) crossed transversely by a few shallow fissures, and it is bounded on each side by the superior cere-

bellar peduncle. The remainder of the anterior lobe can be subdivided (somewhat indistinctly) into the *central lobule*, with lateral expansions termed the *alæ*,

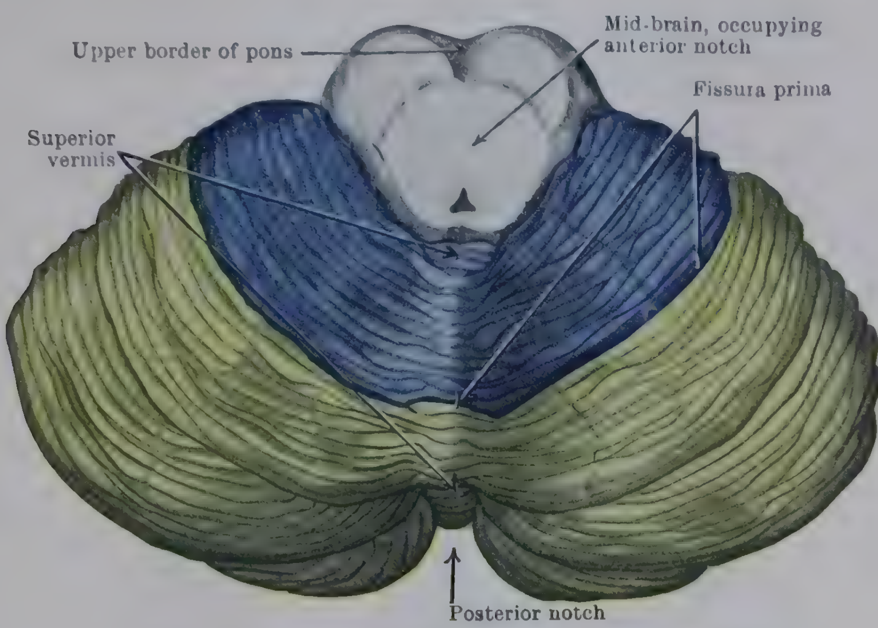

FIG. 791.—SUPERIOR SURFACE OF THE CEREBELLUM.
The anterior lobe is coloured *blue*, the middle *yellow*.

and (immediately above the *fissura prima*) the *culmen* with lateral expansions termed the *anterior lunate lobules*.

The **middle lobe** forms by far the greater part of the bulk of the cerebellum (Figs. 794, 795), in conformity with the pronounced development of the cortico-ponto-cerebellar connexions in the human brain. In the median plane it enters

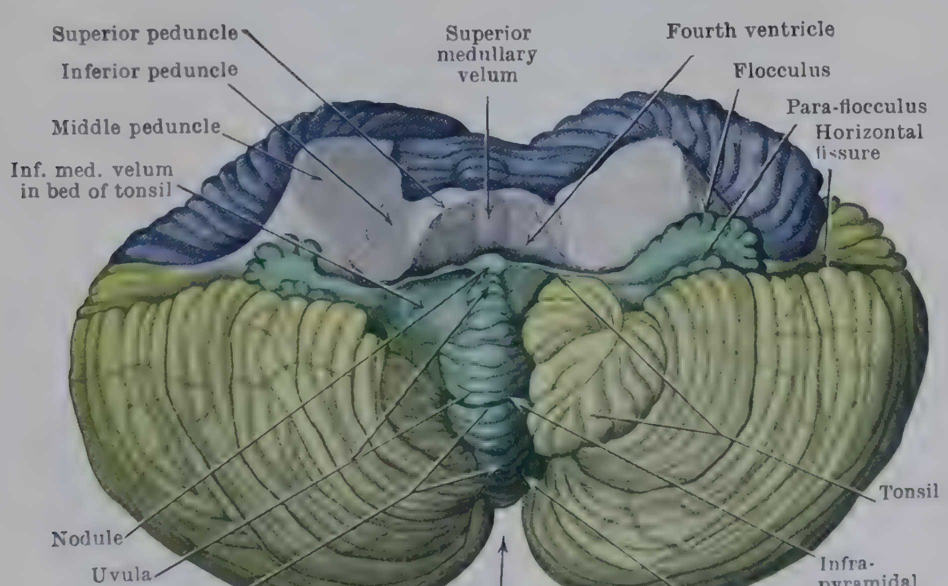

FIG. 792.—INFERIOR SURFACE OF THE CEREBELLUM.
The right tonsil has been removed so as to display more fully the inferior medullary velum. The anterior lobe is coloured *blue*, the middle *yellow*, and the posterior *green*.

into the formation of the vermis of the cerebellum, and this, again, has been topographically subdivided from before back into the *lobulus clivi*, *lobulus folii*, and *lobulus tuberis*. The lateral expansions of the middle lobe form most of the cerebellar hemispheres. Each is divided into upper and lower parts by a deep fissure—the **horizontal fissure**. On the superior surface a curved fissure (post-lunate fissure) separates the *posterior lunate lobule* (or lobus simplex) from the *ansiform lobule* behind. The ansiform lobule extends round on to the inferior surface of the cere-

bellum where it is separated by the retro-tonsillar fissure from the *tonsillar lobule.* The tonsil forms a rather circumscribed rounded lobule, situated at the antero-

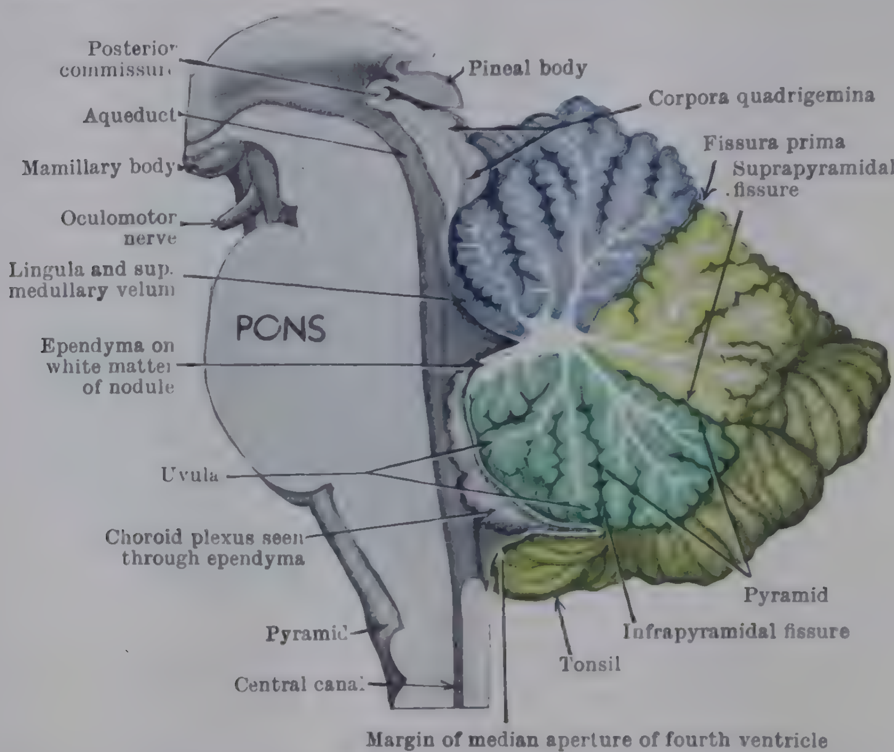

FIG. 793.—MEDIAN SECTION THROUGH BRAIN-STEM AND CEREBELLUM, SHOWING ARBOR VITÆ OF VERMIS AND THE FOURTH VENTRICLE.

The anterior lobe of the cerebellum is coloured *blue*, the middle *yellow*, and the posterior *green.*

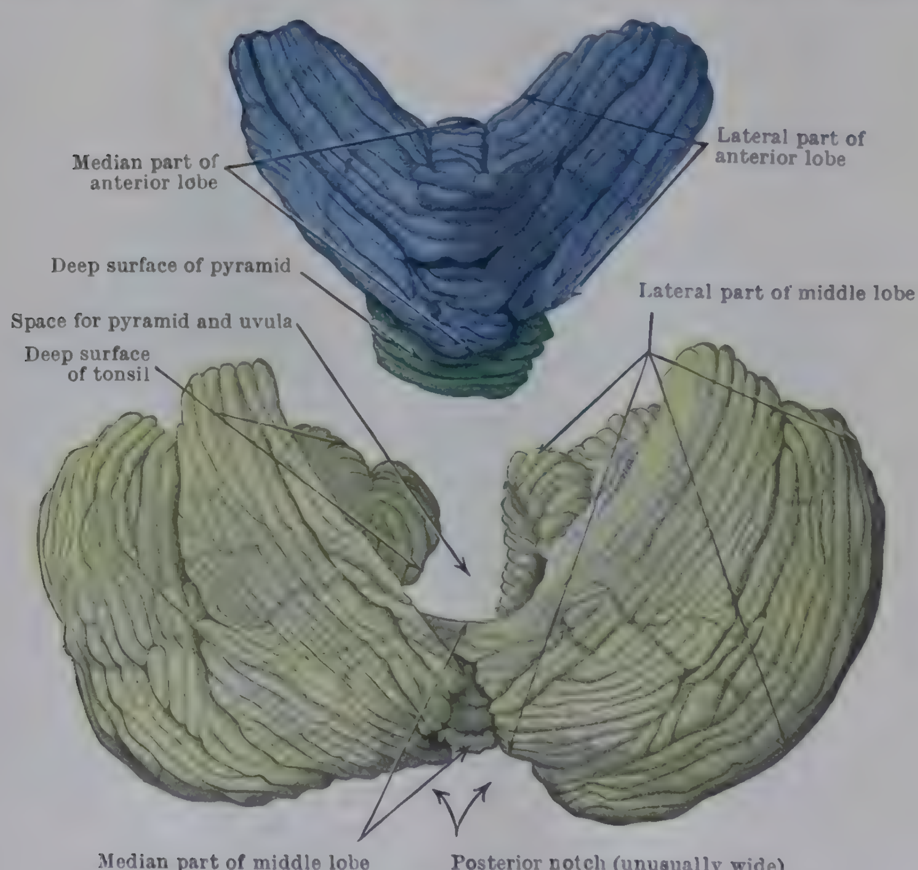

FIG. 794.—DISSECTION OF THE CEREBELLUM, SEEN FROM ABOVE, TO SHOW THE RELATION OF THE THREE LOBES.

medial part of the inferior surface of the cerebellum. Close to its lateral margin the cerebellum is marked by a broad shallow groove where it lies in contact with the

margin of the foramen magnum in the skull. In its position in the body the tonsillar lobules actually bulge down through the foramen magnum so that they are clearly seen when looking up through the vertebral canal.

The **posterior lobe** of the cerebellum in the human brain is relatively small (Fig. 795). The *pyramid, uvula,* and *nodule* can be defined without difficulty as component parts of the inferior vermis. The *flocculus* is evident as a small foliated lobule lying immediately below the eighth nerve at the point where it enters the brain-stem and behind the lateral recess of the fourth ventricle. It is connected with the nodule by a thin lamina of white matter which becomes continuous with

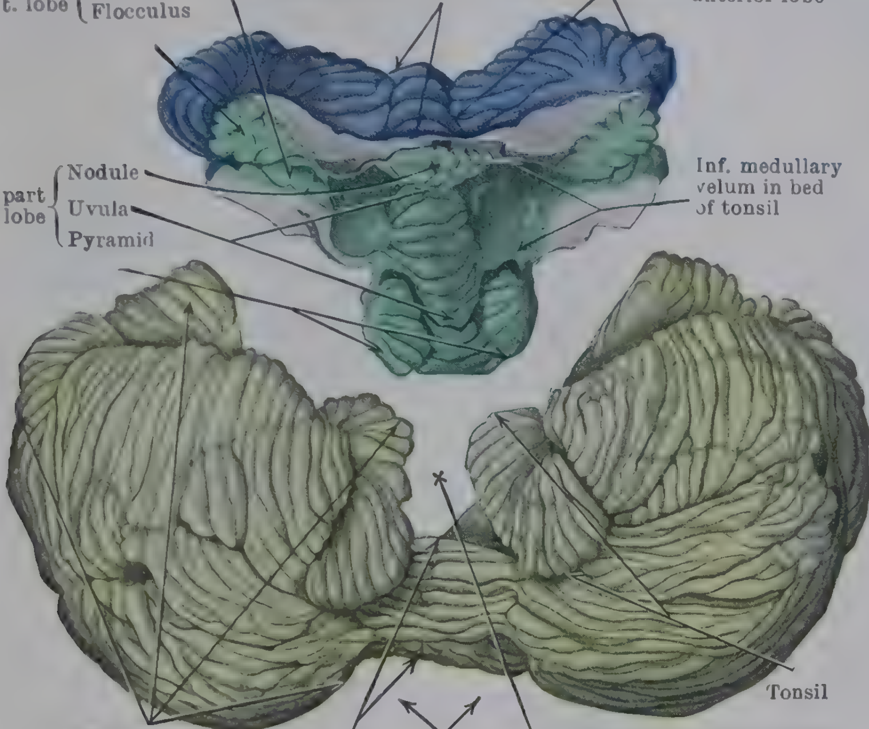

FIG. 795.—DISSECTION OF THE CEREBELLUM, SEEN FROM BELOW, TO SHOW THE RELATION OF THE THREE LOBES.

The anterior lobe is coloured *blue*, the posterior *green*, and the middle lobe, which has been detached from the others and moved backward, is *yellow*.

the upper part of the inferior medullary velum, and lies immediately above and in front of the tonsil. This lamina contains afferent and efferent fibres which link the flocculus with other parts of the cerebellum and with the vestibular nuclei. Closely attached to the flocculus is seen the *paraflocculus*, a minute lobule which in Man is undoubtedly vestigial. The paraflocculus is relatively much larger in most mammals, and in marine mammals its development is even exuberant. There is some evidence to show that it is concerned with the regulation of tone in those muscles which control the tendency to roll in the lateral direction—that is, around the long axis of the body. Hence in Man, in whom the long axis is vertical instead of horizontal, it is perhaps to be expected that the paraflocculus would be relatively insignificant.

STRUCTURE AND CONNEXIONS OF CEREBELLUM

Arrangement of Grey and White Matter of Cerebellum. — The white matter of the cerebellum forms a solid compact mass in the interior, and over it is spread a continuous and uniform layer of grey matter—the cerebellar cortex. In each hemisphere the white central core is more bulky than in the vermis, in which the central white matter is reduced to a relatively thin bridge thrown across

between the two hemispheres. When sagittal sections are made through the cerebellum, the grey matter on the surface stands out clearly from the white matter in the interior. Further, from all parts of the surface of the central core stout stems of white matter are seen projecting into the lobules of the cerebellum. From the sides of these white stems secondary branches proceed at various angles, and from these again tertiary branches are given off. Over the various lamellæ of white matter thus formed the grey cortex is spread, and the fissures on the surface show a corresponding arrangement, dividing up the organ into lobes, lobules, and folia. When the cerebellum is divided at right angles to the general direction of its fissures and folia, a highly arborescent appearance is presented by the cut surface. To this the term **arbor vitæ** is applied (Fig. 793).

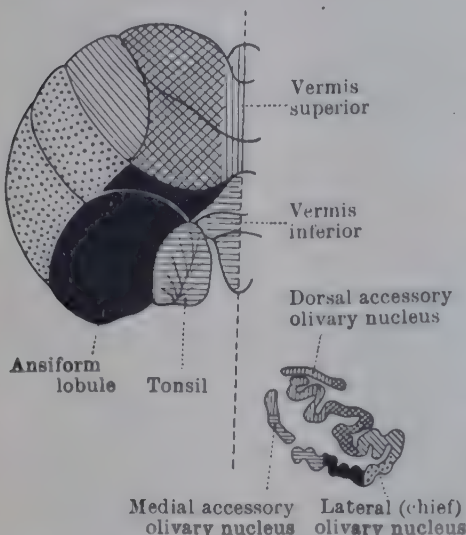

Fig. 796.—Diagram to indicate the Parts respectively of the Right Olivary Nuclei in the Medulla Oblongata and of the Left Half of the Cerebellum, which are linked together by Olivo-Cerebellar Fibres. (After Holmes & Stewart, 1908.)

Dentate Nucleus and other Nuclei in the White Matter of Cerebellum.—Embedded in the midst of the white matter which forms the central core of each hemisphere there is an isolated nucleus which presents a strong resemblance to the olivary nucleus of the medulla oblongata. It is called the **dentate nucleus**, and it consists of a corrugated lamina of grey matter folded on itself so as to enclose, in a flask-like manner, a portion of the central white matter (Figs. 797 and 799). This grey capsule is not completely closed. It presents an open mouth, termed the hilum, which is directed medially and upwards, and out of this streams a stout fasciculus of fibres which form the greater part of the superior cerebellar peduncle.

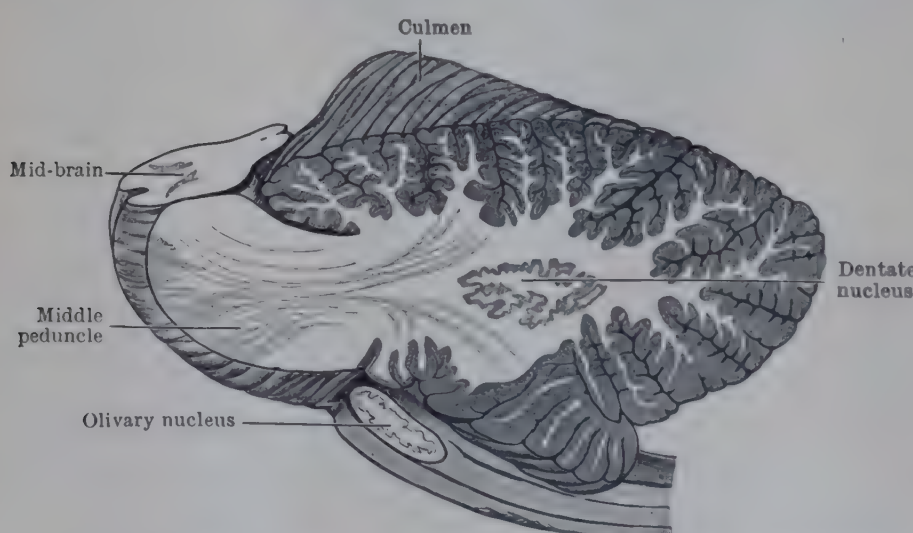

Fig. 797.—Sagittal Section through Left Hemisphere of Cerebellum. Showing the arbor vitæ and the dentate nucleus.

Three small additional masses of grey matter are present on each side of the median plane in the central white matter of the cerebellum. They are termed the nucleus emboliformis, the nucleus globosus, and the nucleus fastigii. The **nucleus emboliformis** is a small lamina of grey matter which lies just medial to the hilum of the dentate nucleus. The **nucleus globosus** lies medial to the nucleus emboliformis and on a slightly deeper horizontal plane. The **nucleus fastigii** or **roof nucleus** is placed in the white substance of the vermis close to the median plane and its fellow of the opposite side. It is, therefore, situated on the medial aspect of the nucleus globosus.

Cerebellar Peduncles.—These are three in number on each side, viz., the middle, the inferior, and the superior (Figs. 770, 799). The fibres of which they are composed all enter or emerge from the white medullary centre of the cerebellum, and they comprise the afferent and efferent connexions whereby the cerebellum is related functionally to the brain-stem and spinal cord.

The **middle peduncle** is much the largest of the three and has already been

described on pp. 884 and 899. It enters the cerebellar hemisphere on the lateral aspect of the other two peduncles. The lips of the anterior part of the horizontal fissure are separated widely to give it admission (Fig. 792). Within the cerebellar hemisphere its fibres are distributed in great bundles to all that part of the grey cortex which belongs to the neocerebellum.

The **inferior peduncle** ascends for a short distance on the dorsal surface of the pons and then turns sharply backwards to enter the cerebellum between the other two peduncles.

The **superior peduncle**, as it issues from the cerebellum, lies close to the medial side of the middle peduncle (Figs. 798, 799). Its farther course upwards towards the inferior quadrigeminal body has been previously described (pp. 885 and 902).

Connexions established by the Peduncular Fibres.—The fibres of the **middle peduncle** represent the second stage of the connexion between the cerebral hemisphere

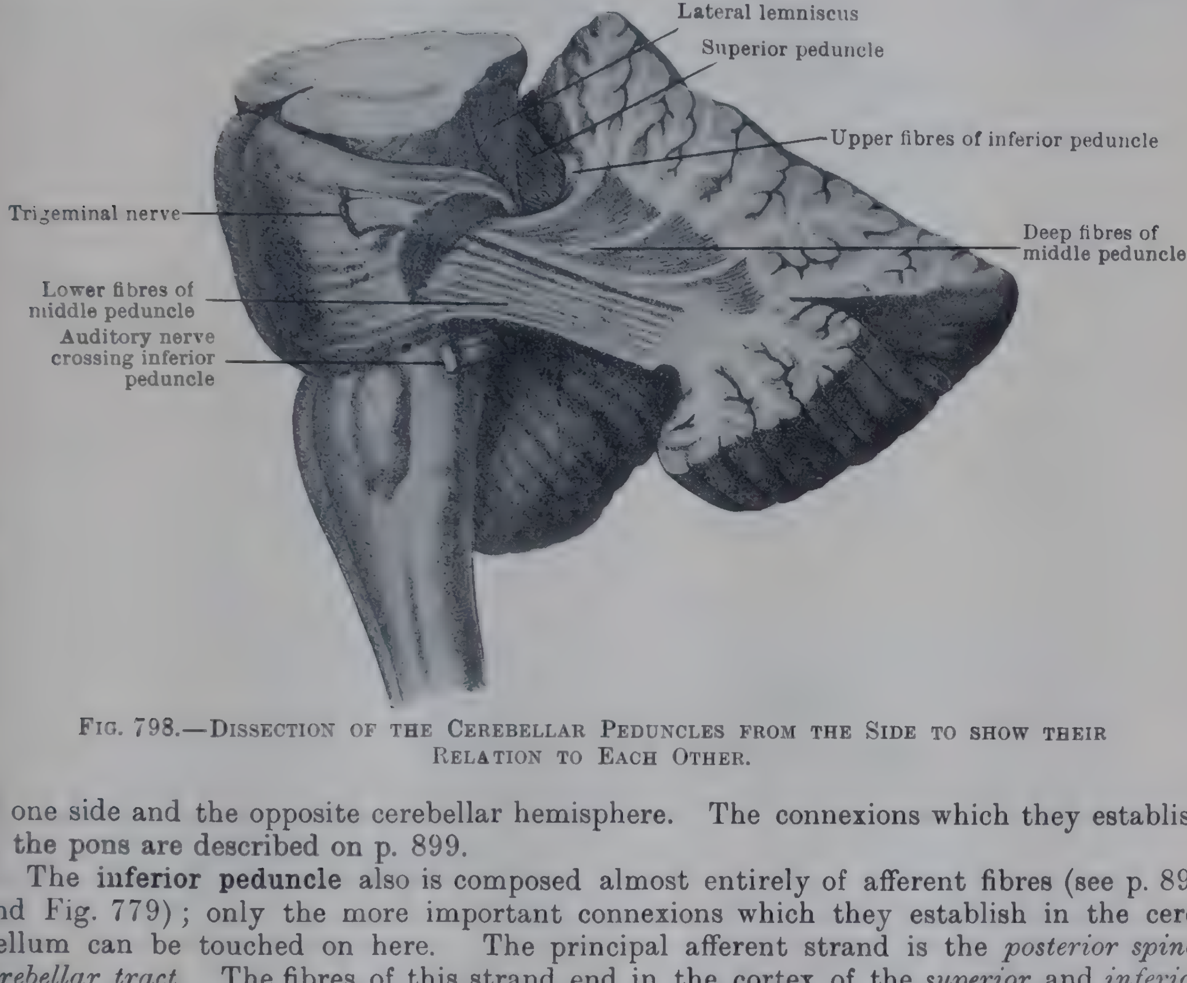

Fig. 798.—Dissection of the Cerebellar Peduncles from the Side to show their Relation to Each Other.

of one side and the opposite cerebellar hemisphere. The connexions which they establish in the pons are described on p. 899.

The **inferior peduncle** also is composed almost entirely of afferent fibres (see p. 896 and Fig. 779); only the more important connexions which they establish in the cerebellum can be touched on here. The principal afferent strand is the *posterior spino-cerebellar tract*. The fibres of this strand end in the cortex of the *superior* and *inferior vermis* on both sides of the median plane and partly in the lobus simplex of the middle lobe. The *olivo-cerebellar tract* is also afferent. Its fibres take origin from the accessory olivary nuclei as well as all parts of the olivary nucleus itself, and they terminate in the cortex of the opposite cerebellar hemisphere and the vermis. The projection of the olivary nuclei on to the cerebellar cortex is of a very precise nature, each portion of the nuclei being related to a definite area of the cortex (Fig. 796). Some of the fibres from the accessory olivary nuclei are said to end in the dentate nucleus, but of this there is some doubt.

The significance of the olivo-cerebellar fibres is quite obscure. However, as indicated on p. 891, they probably transmit impulses which have their origin in the subcortical motor centres of the fore-brain (particularly the globus pallidus of the corpus striatum) and play a part in regulating the tone of muscles involved in voluntary movements. The fibres which take origin from the accessory cuneate nucleus reach the vermis of the anterior and posterior lobes. Lastly, fibres from the medial vestibular nucleus (and also direct vestibular fibres) enter the cerebellum by way of the inferior peduncle to reach the nodule and floccular lobes and the uvula.

The **superior peduncle** is mainly composed of efferent fibres; most of these spring from the cells of the dentate nucleus and other nuclei of the cerebellum, and pass to the red nucleus and thalamus of the opposite side. According to Ramón y Cajal

collateral branches which spring from these fibres descend to the motor nuclei in the medulla oblongata and spinal cord.

A bundle of fibres is also described as passing alongside the superior peduncle to reach the cerebellum from the tegmentum of the mid-brain. They probably arise

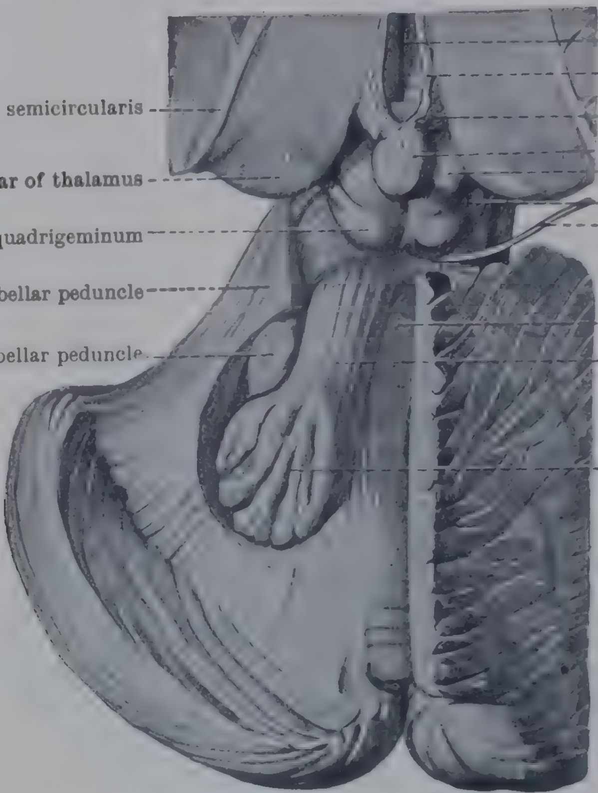

Fig. 799.—Dissection from above to show Dentate Nucleus, Cerebellar Peduncles and Lateral Lemniscus (between Inferior Corpus Quadrigeminum and Middle Cerebellar Peduncle).

from the superior corpus quadrigeminum (tecto-cerebellar fibres) and convey to the cerebellum impulses from the lower visual centres of the opposite side.

The **anterior spino-cerebellar tract** also enters the cerebellum alongside the emerging superior peduncle. It has been noticed in connexion with the lateral white column of the spinal cord (p. 871). The fibres which compose it are carried upwards through the formatio reticularis grisea of the medulla oblongata and the dorsal portion of the pons. In this part of its course the fibres are scattered and do not form a compact strand. Reaching the upper end of the pons the tract turns backwards across the superior peduncle, and proceeds in it to reach the cerebellum. Its fibres are distributed to the cortex of the superior vermis, being limited in their distribution almost entirely to the anterior lobe of the cerebellum.

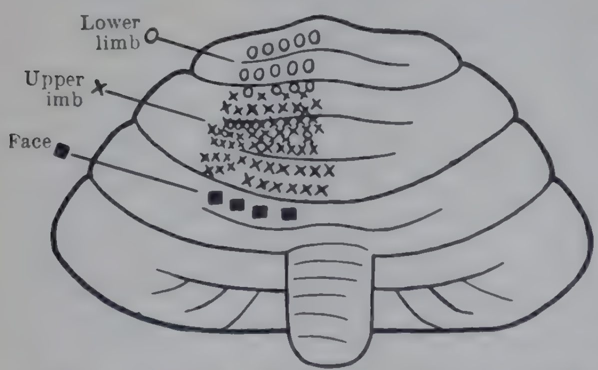

Fig. 800.—Diagram of Projection Areas of Afferent Cerebellar Impulses from Limbs and Face on the Cerebellar Cortex of the Monkey (Adrian, *Brain*, 1943).

For many years, anatomists and physiologists have sought evidence for functional localization in the cerebellum—in the sense that different areas of the cortex are related to different regions of the body—but with inconclusive results. Recently, however, Adrian (1944), with the help of a special electro-physiological technique, has demonstrated (in the monkey) that this form of localization does in fact exist. Afferent cerebellar impulses are projected on to the cerebellar cortex on the upper surface of the cerebellum in such a way that those from the lower limb reach the lobus centralis, those from the upper limb the culmen, and those from the face-region (conveyed presumably through the trigeminal nuclei) reach the lobus simplex immediately behind the fissura prima (Fig. 800). For a discussion of the general question of functional localization in the cerebellum, with bibliography, see Fulton (1949).

Minute Structure of Cerebellar Cortex

A cerebellar folium is composed of a central core of white matter covered with a layer of grey matter. The grey cortex is arranged into two very evident layers—a superficial **molecular layer** and a subjacent **granular layer**. Between these strata a single layer of large cells, termed the **cells of Purkinje**, is disposed in the form of a very nearly continuous sheet. The cells of Purkinje constitute the most characteristic constituents of the cerebellar cortex.

The **cells of Purkinje** are most numerous on the summit of a folium. At the bottom of a fissure they become fewer in number, and, therefore, looser in their arrangement. Each consists of a large flask-shaped cell-body, the narrow end of which projects into the molecular layer, whilst the thicker, deeper end rests on the granular layer. From the deep end arises a **single axon**, which passes down through the granular layer and assumes its medullary sheath almost immediately. From the axon a few collateral branches soon arise, which, taking a recurrent course, enter the molecular layer, to end in connexion with certain of the adjoining cells of Purkinje. They appear to constitute a reinforcing mechanism whereby the activity of any one cell can call adjacent cells into action.

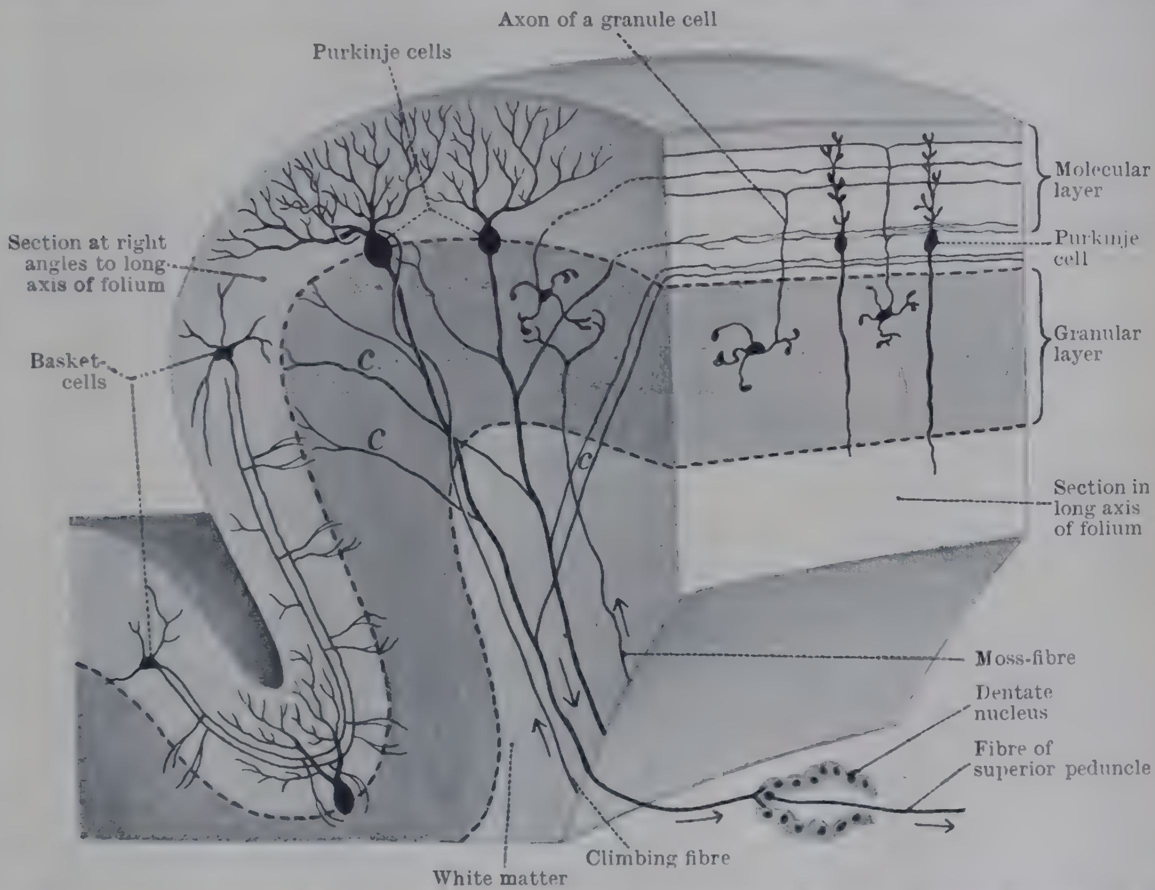

Fig. 801.—Diagram to show Minute Structure of a Cerebellar Folium. The surface to the right shows a section in the long axis of a folium and that to the left is a section at right angles to the long axis of a folium. C=recurrent collaterals from the axons of Purkinje cells.

The **dendrites** spring from the narrow end of the cell in the form of either one or perhaps two stout stalks. They ascend into the molecular layer, branching and rebranching until an arborescent arrangement of extraordinary richness and extent results. The dendritic branches extend throughout the entire thickness of the molecular layer, and the branching takes place in one plane only—transverse to the long axis of the folium. Consequently, it is only when transverse sections through a folium are made that the full dendritic effect is obtained (Fig. 801); in sections made parallel to the long axis of the folium the cells are seen in profile, and are observed to occupy quite a narrow area. The branching of the dendrites of a cell of Purkinje may, therefore, be compared to **the branching of a fruit-tree trained against a wall.**

Terminating in relation to each cell of Purkinje is an afferent fibre which ascends to the cortex from the white substance of the cerebellum. These fibres form fine ramifications which climb up the dendritic processes of each cell of Purkinje, intertwining with them in a very intimate manner, very much like the tendrils of a climbing plant. They are termed **climbing fibres** (Fig. 801).

In the **molecular layer** the cells are not very numerous, and of these the most

characteristic are the **basket-cells** which lie in the deeper part of the layer. In addition to numerous dendrites the basket-cell gives off an axon which runs transversely, as regards the long axis of the folium, between the planes of adjacent dendritic arborizations of the cells of Purkinje. At first very fine, the axons gradually become coarse and thick, and at intervals they give off collaterals which run towards the bodies of the cells of Purkinje. Reaching these, they break up into a great number of fine terminal branches which enclose the cells of Purkinje, as well as the short non-medullated portions of their axons, in a close basket-work of fine filaments.

The **granular layer** is, for the most part, composed of large numbers of small granule-like cells closely packed together. Each of them has a rather large nucleus, with a very small amount of surrounding cytoplasm. From the cell-body three or four, or perhaps five, dendrites and one axon proceed. The **dendrites** are short and radiate out from different aspects of the cell-body. They end in tufts of claw-like twigs which either embrace or are otherwise in contact with neighbouring granule-cells. The granule-cells, therefore, are brought into intimate connexion with one another. The **axon** passes into the molecular layer, in which it ends, at a varying distance from the surface, by dividing into two branches. These diverge so sharply from each other that they form almost a right angle with the parent stem, and they run parallel to the long axis of the folium, threading their way among the branches of the various dendritic processes of the cells of Purkinje and entering into the closest contact with them. When it is borne in mind that the number of granule-cells is very great, and that each sends an axon into the molecular layer, the important part which these fibres, with their longitudinal branches, take in building up the molecular layer will be understood. They are found pervading its entire thickness—from the surface down to the bodies of the cells of Purkinje.

Ending in the granular layer are numerous afferent fibres which ascend from the white substance of the cerebellum and divide into a relatively large number of terminal branches. These branches end in tufts of thickened terminals which have a rather moss-like appearance. Hence the fibres are termed **moss-fibres**, and each one enters into synaptic relation with a large number of granule-cells (Fig. 801).

The **functional implications** of the minute structure of the cerebellar cortex now require consideration. It will be noted that there are two types of afferent fibre, the "climbing" and the "moss" fibres. There is still some doubt regarding the origin of these fibres. According to Cajal the climbing fibres are the terminals of pontine and vestibular fibres while the spino-cerebellar and olivo-cerebellar fibres form the moss-terminals. On the other hand, Dow (1942) takes the view that the climbing fibres are the terminals of the olivo-cerebellar tracts, while the mossy fibres are derived from the vestibular, spinal and pontine systems. Yet another view has been recently put forward, that the climbing fibres are chiefly, if not entirely, derived from the cerebellar nuclei. The impulses conveyed by the *climbing fibres* must be extremely localized in the cortex, for each fibre ends in relation to a single cell of Purkinje. Moreover, the axon of each cell of Purkinje descends straight to the dentate nucleus, whence it is relayed to the red nucleus and thalamus of the opposite side by fibres of the superior cerebellar peduncle. Hence there seems to be an anatomical basis for some form of punctate localization of function in the cerebellar cortex, at least so far as impulses conveyed by the climbing fibres are concerned.

In contrast with this, the impulses conveyed by the *moss-fibres* must be diffused very widely in the cerebellar cortex, mainly in a transverse direction, for they are carried up into the molecular layer by the axons of the granule-cells, which here bifurcate to form the parallel fibres. From this disposition it may be inferred that, if there is any localization in the cerebellar cortex with regard to afferent impulses from the spinal cord, it is presumably a localization in an antero-posterior direction. This, in fact, has been demonstrated to be the case by Adrian (see p. 912). The question whether there is a functional localization in the cerebellum, in the sense that different lobules of the cerebellum are concerned on the efferent side with muscular activities in correspondingly different parts of the body, has been the source of much controversy. Although a small lesion of the cerebellum may produce quite widespread defects of muscular activity in the body, clinical evidence does suggest a motor localization of a very general type.

MID-BRAIN

The **mid-brain** or **mesencephalon** is the short part of the brain-stem which connects the cerebrum with the parts in the posterior cranial fossa; and, in its normal position in the skull, it occupies the notch in the tentorial process of dura

mater. It is about three-quarters of an inch in length, and it consists of a dorsal part called the **tectum**, and a much larger ventral part—the two **cerebral peduncles**.

The cerebral peduncles can be seen to some extent on the base of the brain, where they bound the posterior part of the interpeduncular fossa (see p. 878).

The mid-brain is tunnelled lengthwise by a narrow passage, called the **aqueduct**, which connects the third ventricle above with the fourth ventricle below (Fig. 764, p. 879).

Tectum.—This name is applied to that part of the mid-brain which forms the roof of the cerebral aqueduct. Its free surface is heaped up into two pairs of rounded eminences called the **corpora quadrigemina** (Figs. 766 and 802). The **superior pair** are larger and broader than the **inferior pair**, but they are not so well defined nor are they so prominent. A longitudinal and a transverse groove separate the corpora from one another. The longitudinal groove occupies the median plane and extends upwards to the posterior commissure of the brain. The upper part of the groove widens out into a shallow depression in which the **pineal body** rests. From the lower end of the same groove a short but well-defined ridge—the **frenulum veli**—passes to the superior medullary velum, which lies immediately below the inferior corpora quadrigemina. The transverse groove curves round below each of the superior pair of corpora and separates them from the inferior pair. It is also continued in an upward and forward direction on the side of the mid-brain.

The quadrigeminal bodies are not marked off laterally from the sides of the mid-brain, for each has in connexion with it, on that aspect, a prominent strand which is prolonged upwards and forwards towards the thalamic region of the fore-brain. These strands are called the **brachia quadrigemina**, and they are separated from each other by a continuation of the transverse groove that separates the two pairs of corpora.

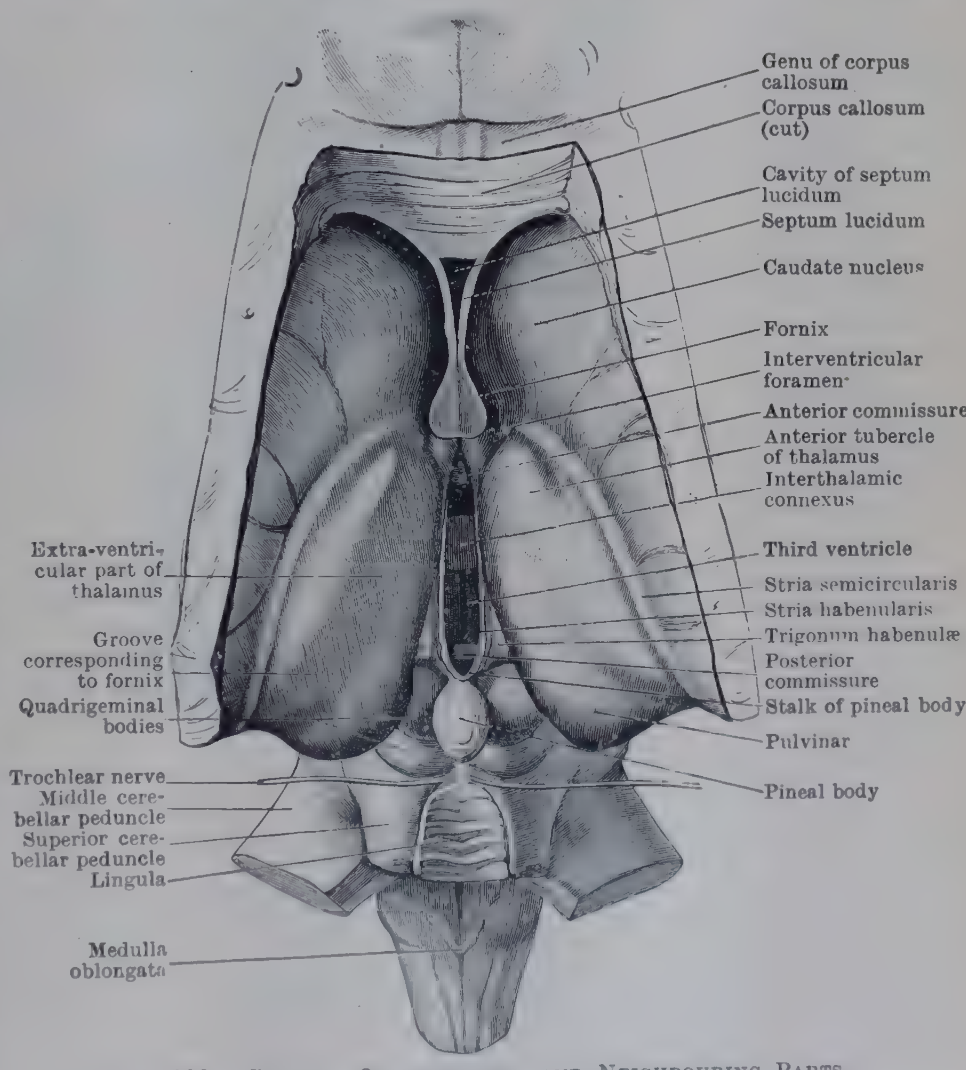

Fig. 802.—Corpora Quadrigemina and Neighbouring Parts.

The **medial geniculate body** is closely associated with the brachia. Strictly speaking, this is not a part of the mesencephalon; it is really a portion of the thalamus of the fore-brain which has been pushed back as the result of the expansion of other thalamic elements; and it has become applied to the side of the mid-brain and secondarily fused with it. It is a small, sharply defined oval eminence which lies on the lateral side of the upper part of the mid-brain under shelter of the pulvinar of the thalamus.

The **inferior brachium**, proceeding upwards and forwards from the inferior corpus, advances towards the medial geniculate body and disappears under cover of it (Fig. 803).

The **superior brachium** is carried upwards and forwards between the overhanging thalamus and the medial geniculate body. A superficial examination of the mid-brain is sufficient to show that while a large part of this strand disappears under cover of the lateral geniculate body (Fig. 831, p. 950) a portion of it is a continuation of the lateral root of the optic tract. The lateral geniculate body is

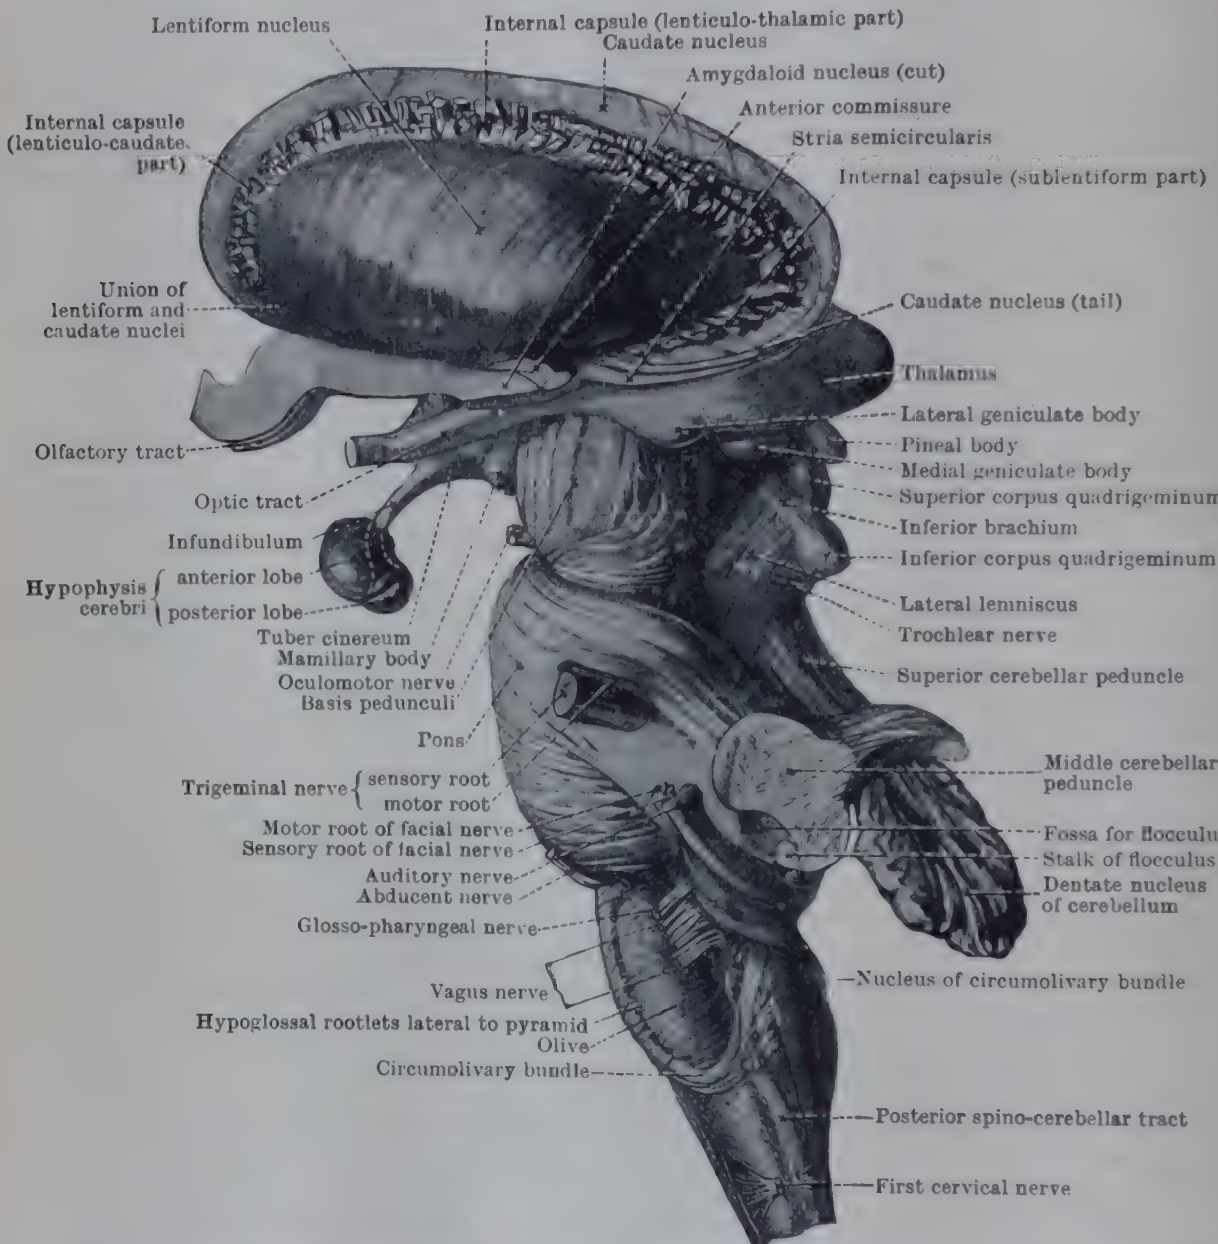

FIG. 803.—LEFT LATERAL ASPECT OF BRAIN AFTER REMOVAL OF THE CEREBRAL HEMISPHERE (EXCEPT CORPUS STRIATUM) AND THE CEREBELLUM (EXCEPT DENTATE NUCLEUS).

an ill-defined prominence at the posterior end of the optic tract; it belongs to the thalamus, and, as its name implies, it lies lateral to the medial geniculate body.

Cerebral Peduncles.—The cerebral peduncles (Figs. 803 and 813) appear on the base of the brain as a pair of large rope-like strands which emerge from the cerebral hemispheres and disappear below by plunging into the basilar portion of the pons. At the place where each peduncle emerges from the corresponding side of the cerebrum it is crossed by the optic tract.

Each cerebral peduncle is composed of three parts:—(1) a dorsal tegmental part (**tegmentum**), which is prolonged upwards into the region below the thalamus (hypothalamus and subthalamus); (2) a ventral portion (**basis pedunculi**), which, when traced upwards into the cerebrum takes up a position on the lateral side of the thalamus and is continuous with the internal capsule of the brain; and (3) an

intervening conspicuous layer of deeply pigmented tissue—the **substantia nigra.** When the base of the brain is examined it is the basis pedunculi which is seen, and it is observed to be white in colour and streaked in the longitudinal direction. It may be noted that in the tegmentum the longitudinally arranged fibres are, in large part, fibres which are ascending towards the thalamus; the basis pedunculi, on the other hand, is composed entirely of longitudinal strands of fibres which are descending from the cerebral hemisphere.

On the surface of the mid-brain the separation between the tegmental and basal portions of the cerebral peduncle is clearly indicated by a medial and a lateral groove. The **medial sulcus** is the more distinct of the two. It faces into the interpeduncular fossa, and through it the roots of the oculomotor nerve emerge.

The **lateral sulcus** extends from the thalamus to the groove between the superior and middle cerebellar peduncles, and the medial geniculate body is lodged at its upper end.

A close inspection of the lateral surface of the tegmental part of the mid-brain, below the level of the brachia, will reveal a faintly marked bundle of fibres curving obliquely upwards and backwards to reach the inferior corpus quadrigeminum (Fig. 803). It contains fibres of the **lateral lemniscus,** coming to the surface at the lateral sulcus and sweeping over the subjacent superior cerebellar peduncle to gain the inferior corpus quadrigeminum and medial geniculate body. They transmit auditory impulses to these structures from the hind-brain.

Internal Structure of Mid-Brain

When transverse sections are made through the mid-brain the aqueduct is seen to be surrounded by a thick layer of grey matter—the **central grey matter of the aqueduct.** Behind this, there is the **tectum** with its *corpora quadrigemina*; in front and laterally there are the **cerebral peduncles,** each divided into *tegmentum, substantia nigra* and *basis pedunculi.* (Fig. 804.)

Central Grey Matter and Aqueduct of Mid-Brain.—The aqueduct is not quite three-quarters of an inch in length, has a variable outline in transverse section, and is much nearer the back than the front of the mid-brain. It is lined with ependymal epithelium, and outside this is the thick layer of central grey matter, which is continuous below with the grey matter of the floor of the fourth ventricle, and above with grey matter on the floor and sides of the third ventricle. Scattered more or less irregularly throughout the central grey matter are numerous nerve-cells of varying form and size, whilst in addition to these there are definite clusters of cells which constitute the nuclei of origin of the trochlear and oculomotor nerves, and the terminal nucleus of the mesencephalic tract of the trigeminal nerve. The position and relations of these nuclei will be given later.

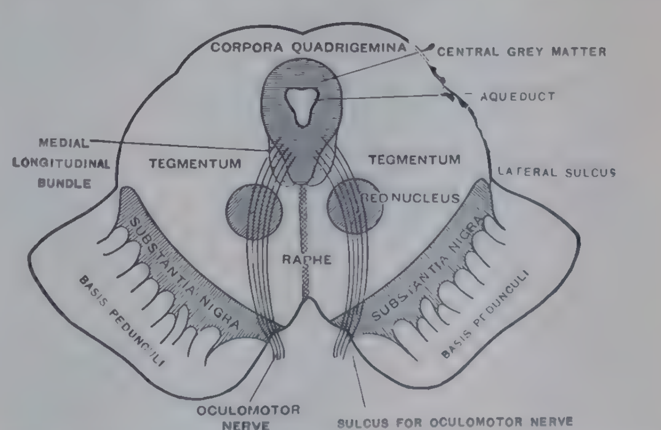

Fig. 804.—Diagrammatic Transverse Section through Upper Part of Mid-Brain.

Inferior Quadrigeminal Bodies.—Each inferior corpus quadrigeminum is composed largely of a mass of grey matter which is oval in transverse section (Fig. 805). This central nucleus is, to a large extent, encapsulated by white matter. Numerous cells of various sizes are scattered throughout it, and the whole mass is pervaded by an intricate interlacement of fine fibres, many of which are derived from the lateral lemniscus.

In transverse sections through this region, the lateral lemniscus is seen to abut against the lateral margin of the central nucleus of the inferior quadrigeminal body. Many of the fibres of this tract enter it at once and become dispersed

amongst its cells; others sweep over its dorsal surface, so as to give it a superficial covering; whilst a third group is carried medially in front of it in the form of a thin layer that marks it off from grey matter of the aqueduct (Fig. 808). In this manner, therefore, the inferior quadrigeminal body becomes partially circumscribed by the fibres of the lateral lemniscus.

The intimate connexion thus exhibited between the fibres of the lateral lemniscus and the nucleus of the inferior corpus quadrigeminum is very significant. The lateral lemniscus, to a large extent, comes from the nuclei of termination of the cochlear nerve of the opposite side, though some also come from the same side. We must associate, therefore, the inferior corpus quadrigeminum and also the medial geniculate body, which likewise receives fibres from the lateral lemniscus, with the nervous mechanism of hearing.

This view regarding the inferior quadrigeminal body is supported both by experimental and by morphological evidence. Speaking broadly, it may be stated that the inferior corpora quadrigemina become prominent only in mammals, and they are correlated with the development of a spirally wound and well-developed cochlea. It is probable that at least some of the fibres of the ventral supra-optic decussation (Gudden's commissure) connect with the cells of the inferior corpus quadrigeminum (see p. 952).

Superior Quadrigeminal Bodies.—The superior quadrigeminal body has a more complicated structure (Fig. 806). Superficially, it is coated with a very thin layer of white matter which is termed the **stratum zonale.** Underneath this there is a layer of grey matter, called the **stratum griseum,** which, in transverse section, exhibits a crescentic outline and rests in a cap-like manner upon the subjacent part of the eminence. The succeeding two strata, which respectively receive the names of **stratum opticum** and the **stratum lemnisci,** present this feature in common, that they are composed of grey matter traversed by numerous fibres. The source from which the fibres are derived is different, however, in each case.

Nerve-fibres reach the superior corpus quadrigeminum through (1) the lemnisci and (2) the superior brachium.

The stratum lemnisci is partly composed of the terminals of the spino-tectal tract of the spinal cord. It contains also cortico-tectal fibres which take origin from the area striata and the area peri-striata of the occipital region of the cerebral cortex; these enter the tectum of the mid-brain by way of the superior brachium, and they convey impulses which enable the visual cortex to influence the oculomotor nuclei through the superior corpus quadrigeminum. In most animals many of the fibres of the optic tract end in the superior quadrigeminal body, but in the human brain these are very considerably reduced. As they penetrate into the substance of the superior corpus quadrigeminum, these mesencephalic fibres of the optic tract form the white matter of the stratum opticum. They ultimately terminate in this stratum, and in the stratum griseum which lies superficial to it.

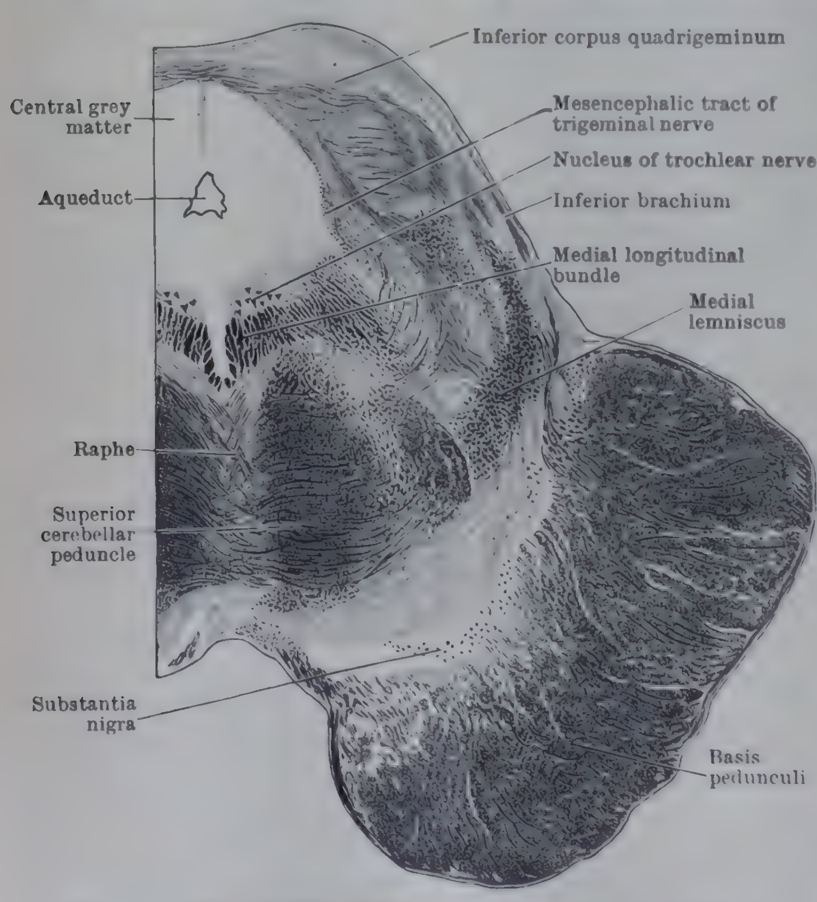

FIG. 805.—TRANSVERSE SECTION OF MID-BRAIN AT LEVEL OF INFERIOR CORPUS QUADRIGEMINUM.

Under cover of the upper and lateral margins of the superior corpus quadri-

geminum is an ill-defined collection of small cells named the **pretectal nucleus.** This nucleus is of some importance since it is the terminal station for those optic fibres which are concerned with the pupillary reflex (Fig. 835). This reflex is still present after the experimental destruction of the superior corpora quadrigemina. From the pretectal nucleus retinal impulses are relayed to the oculomotor nucleus of the same and opposite sides.

Posterior Commissure.—This is a slender band of white matter which extends transversely across the roof of the aqueduct at the point where the aqueduct opens into the third ventricle. The posterior commissure is mainly formed of commissural fibres which connect the superior corpora quadrigemina, the pretectal nuclei, and the medial longitudinal bundles of the two sides. It also contains fibres which proceed from the pretectal nucleus of one side to the oculomotor nucleus of the other.

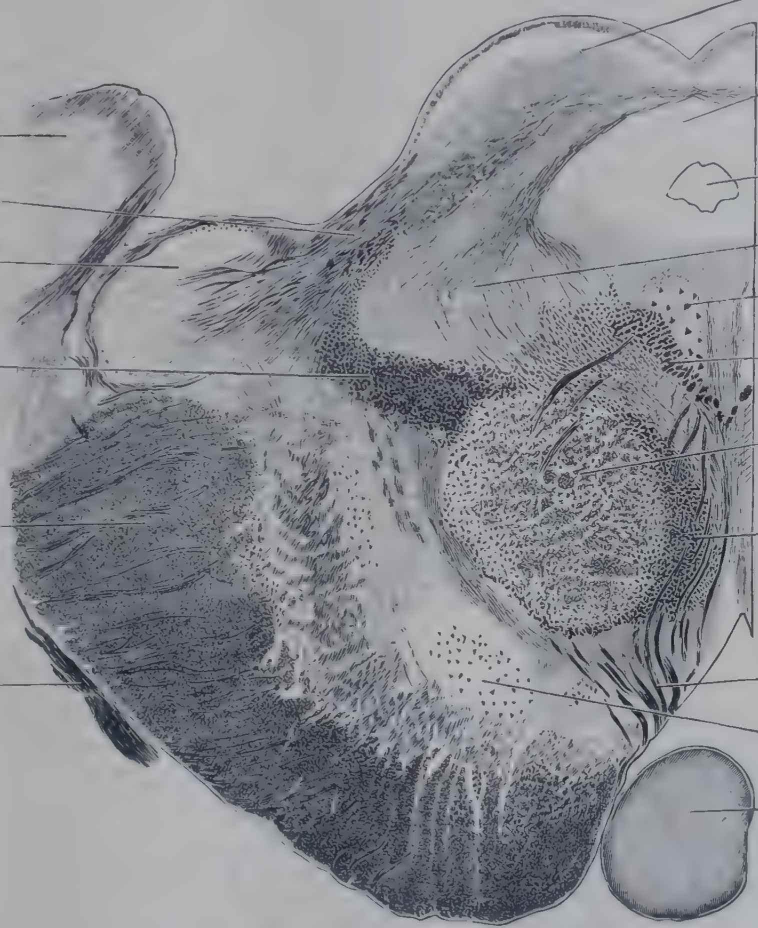

Fig. 806.—Transverse Section of Mid-Brain at Level of Superior Corpus Quadrigeminum.

Tegmentum.—The tegmentum of the mid-brain may be regarded as the continuation upwards of the dorsal portion of the pons. It consists, therefore, of fine bundles of longitudinal fibres intersected by arching fibres which take a transverse and curved course. The interstices between these bundles are occupied by grey matter containing irregularly scattered nerve-cells. Posteriorly the tegmentum is continuous, at the side of the central grey matter, with the bases of the corpora quadrigemina, whilst anteriorly it is separated from the basis pedunculi by the substantia nigra. In the median plane of the tegmentum there is a prolongation upwards of the median raphe of the pons, although, in the lower part, this is much obscured by the decussation of the superior cerebellar peduncles. The two longitudinal strands, termed the **medial longitudinal bundle** and the **medial lemniscus,** are prolonged upwards throughout the entire length of the mid-brain; and they present the same relations to the tegmentum as in the lower parts of the brain—the longitudinal bundle being placed behind the lemniscus.

The tegmentum is divisible into two parts: (1) a lower part subjacent to the inferior corpora quadrigemina, and largely occupied by the decussation of the superior cerebellar peduncles (Fig. 807); and (2) an upper part subjacent to

the superior corpora quadrigemina, and traversed by the emerging bundles of the oculomotor nerves. Each half of the upper part contains a large and striking nuclear mass, termed the **red nucleus** (Fig. 806). The lower part of the central grey matter contains the nuclei of the trochlear nerves; the upper part contains the nuclei of the oculomotor nerves.

Superior Cerebellar Peduncles—As the superior cerebellar peduncles leave the pons and sink into the tegmentum they undergo a complete decussation subjacent to the inferior corpora quadrigemina and the central grey matter (Figs. 805, 806, and 807); the decussation is completed at the level of the upper borders of the inferior corpora quadrigemina. Having crossed to the opposite side, each peduncle proceeds upwards into the upper part of the tegmentum, where it encounters the red nucleus. A large number of its fibres plunge into this nucleus and come to an end in connexion with its cells. Many of the fibres, however, are carried around the nucleus, forming a capsule for it (Fig. 806), and are prolonged into the thalamus to end in connexion with the cells of the ventral nucleus of the thalamus. The superior peduncle is, therefore, a great efferent tract which issues from the dentate nucleus of the cerebellum, crosses the median plane in the lower part of the mid-brain, and ends in the red nucleus and the ventral part of the thalamus of the opposite side.

Substantia Nigra.—When seen in transverse section, the **substantia nigra** appears as a slightly curved dark-brown band between the basis pedunculi and the tegmentum. It consists of a mass of grey matter in the midst of which there are large numbers of deeply pigmented nerve-cells. This remarkable pigment—a melanin—is commonly regarded as a by-product of the cellular activity of the substantia nigra, for it increases with age. It is not found in the homologues of the substantia nigra of many mammals, and in the human subject it is not present at birth, but develops only in the second or third year. In the adult the large cells of the substantia nigra and those of the globus pallidus contain more iron than any other nuclear territories of the nervous system. The substantia nigra begins at the upper border of the pons and extends upwards into the subthalamus (see p. 945). Its margins come to the surface at the medial and the lateral sulci of the mid-brain, and its medial part is traversed by the emerging rootlets of the oculomotor nerve. It is not equally thick throughout. The surface turned towards the tegmentum is concave and uniform; the opposite surface is convex and made irregular by the presence of numerous slender prolongations of the substance into the basis pedunculi.

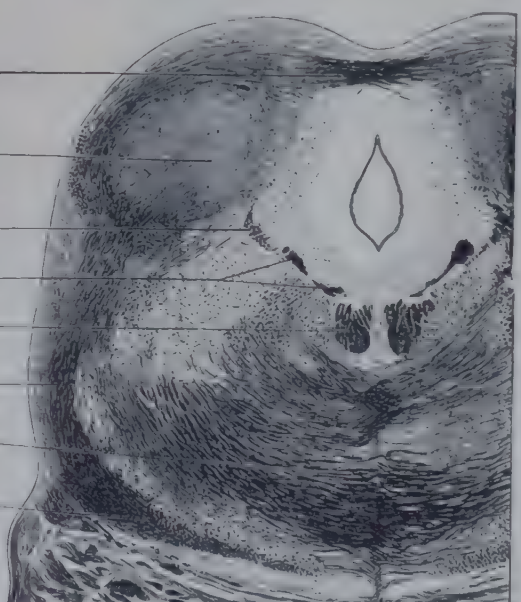

Fig. 807.—Section through Inferior Corpus Quadrigeminum and Tegmentum below the Level of Nucleus of Trochlear Nerve. The decussation of the superior cerebellar peduncles and the course of the trochlear nerve in the central grey matter are seen.

The functional significance of the substantia nigra remains obscure, but the investigation of the damage to the brain in such affections as encephalitis lethargica ("sleepy sickness") has directed particular attention to the substantia nigra and revealed that lesions affecting it are associated with such symptoms as increased muscular tone and involuntary rhythmic movements.

The substantia nigra receives fibres from the globus pallidus and possibly from the red nucleus, and it evidently forms a part of the so-called extra-pyramidal motor system (see p. 970). There is also experimental evidence that it gives rise to ascending fibres which terminate in the caudate nucleus. Other connexions of the substantia nigra have been described, but they are not yet certainly established.

Red Nucleus.—The red nucleus is a rounded nuclear mass, of a reddish tint in the fresh brain, which lies in the upper part of the tegmentum, and in the path of the superior cerebellar peduncle. In transverse section it has a circular outline. It begins at the level of the lower border of the superior corpus quadrigeminum and it extends upwards as far as the subthalamus. The emerging bundles of the oculomotor nerve pass through it on their way to the surface. The relation which the fibres of the opposite superior cerebellar peduncle present to it has been described.

In most mammals the red nucleus consists mainly of a group of large cells that emit fibres, called the **rubro-spinal tract**, which, after crossing to the other side, descend in the tegmentum to reach the lateral white column of the spinal cord (Fig. 755, p. 868). In Man the large-celled element and the rubro-spinal tract become reduced to small proportions, and, as already noted, the tract probably reaches down only to the upper part of the cord. In the higher mammals, and especially in the human brain, a very large element, composed of small cells, develops in front of the older, large-celled element, and forms the major part of the red nucleus. The small-celled element receives descending fibres from the frontal cortex of the cerebral hemisphere, and also from the globus pallidus of the corpus striatum (pallido-rubral fibres). It gives off fibres which end in the reticular substance of the mid-brain and hind-brain. The progressive development of the small-celled element of the red nucleus is simply an expression of the fact that, in higher mammals, the nucleus becomes increasingly dominated by the cerebral cortex. This tendency reaches its highest expression in Man.

Medial Longitudinal Bundle.—This is a very conspicuous tract of longitudinal fibres which extends throughout the whole length of the medulla oblongata, pons, and mid-brain, in the formatio reticularis or dorsal part of each. Below, at the level of the decussation of the pyramids, it becomes continuous with the anterior intersegmental tract of the spinal cord (p. 870); by its opposite end, it establishes intricate connexions in the region immediately above the mid-brain. Throughout its whole length it lies close to the median plane and its fellow of the opposite side. In the mid-brain it is applied to the front of the central grey matter, whilst in the pons and medulla oblongata it is situated immediately subjacent to the grey matter of the floor of the fourth ventricle. One of its most salient features is the intimate association which it presents with the three motor nuclei from which the nerves for the supply of the muscles of the eyeball take origin, viz., the oculomotor nucleus, the trochlear nucleus, and the abducent nucleus. The first two of these are closely applied to its medial and dorsal aspect, whilst the abducent nucleus is placed on its lateral side. Into each of these nuclei it sends many collaterals, and probably also some of its constituent fibres, and they end around the nuclear cells. It would appear, therefore, that one of the most important functions of the strand is to link together those nuclei, and thus enable them to act in harmony with each other. The most important element in the medial longitudinal bundle, however, consists of fibres that come from the vestibular nucleus and proceed to the oculomotor group of nuclei of both sides as well as to both nuclei of the accessory nerve in the medulla oblongata and spinal cord. These connexions provide the anatomical basis for the reflex movements

Fig. 808.—Section through Inferior Corpus Quadrigeminum and Tegmentum of Mid-Brain at a slightly Lower Level than Fig. 807.

of the eye and neck which are elicited by impulses arising in the semicircular canals.

It is evident that it is a brain-tract of high importance from the fact that it is present in all vertebrates, and, further, that its fibres assume their medullary sheaths at an extremely early period. In fishes, amphibians and reptiles, it is one of the largest bundles of the brain-stem. In Man, its fibres medullate between the sixth and seventh months of intra-uterine life, and at the same time as the fibres of the anterior intersegmental tract of the spinal cord, with which it stands in connexion.

Lateral Lemniscus.—The lateral lemniscus is a definite tract of longitudinal fibres which lies in the upper part of the dorsal division of the pons, and extends upwards through it and through the tegmentum of the mid-brain near their lateral surface. It is formed in large part by the fibres of the corpus trapezoideum

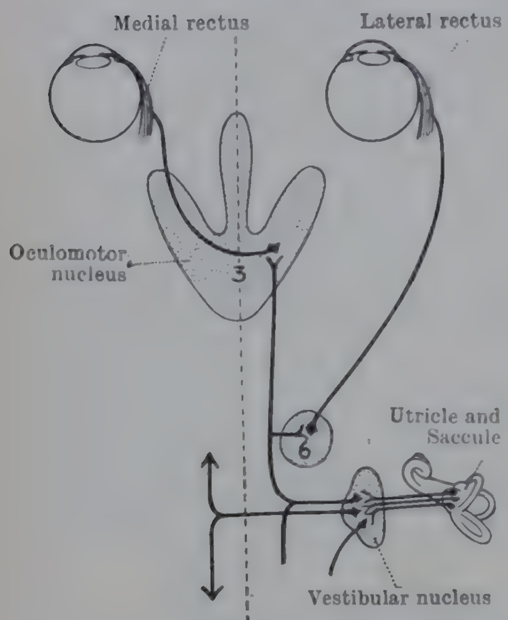

Fig. 809.—Plan of some of the Vestibular Elements in the Medial Longitudinal Bundle.

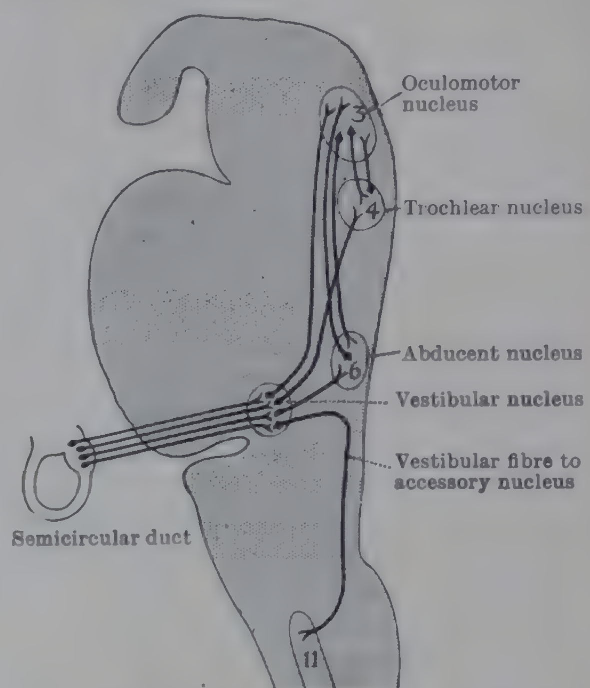

Fig. 810.—Profile Plan of Important Elements in the Medial Longitudinal Bundle.

in the lower part of the pons turning abruptly upwards and taking a course towards the quadrigeminal region. But the details of the arrangement and connexions of this important fasciculus must be left for fuller consideration when we are discussing the central connexions of the auditory nerve. It should be mentioned that, intermingled with the auditory fibres and forming a part of the lateral lemniscus (so far as the latter is defined topographically) are certain other fibres, *e.g.*, tecto-pontine fibres and spino-tectal fibres.

Medial Lemniscus.—The medial lemniscus has already been followed through the medulla oblongata and pons, and its position in each of these portions of the brain-stem has been defined (pp. 895 and 903). In the lower part of the tegmentum of the mid-brain it is carried up in the form of a more or less flattened band in front of the decussating superior cerebellar peduncles. To its lateral side, and forming an angle with it (as seen in transverse section), is the lateral lemniscus (Figs. 784 and 785), and at that level there is no clear demarcation between the two tracts. In the upper part of the mid-brain the appearance of the red nucleus in the tegmentum causes the medial lemniscus to take up a more lateral and dorsal position, so that it now comes to lie subjacent to the medial geniculate body (Fig. 806). At this level it exhibits a crescentic outline in transverse section, and the lateral lemniscus has to a large extent disappeared from its lateral aspect.

The main part of the medial lemniscus takes origin in the lower part of the medulla oblongata from the gracile and cuneate nuclei of the opposite side (p. 894).

Seeing that the posterior white column of the spinal cord ends in these nuclei, the medial lemniscus may be considered to be the functional continuation of this column upwards into the brain. Other fibres arise from the terminal nuclei of the trigeminal nerve of the opposite side. At the lateral margin of the main part of the medial lemniscus are situated the spino-thalamic fibres which convey exteroceptive impulses from the spinal cord. They form a diffuse bundle which is sometimes termed the "*spinal lemniscus*". Intermingled with them are spino-tectal fibres, and in the mid-brain these pass dorsally to reach the superior corpus quadrigeminum. The medial lemniscus and "spinal lemniscus" proceed into the ventral nucleus of the thalamus, and there their fibres end.

Interpeduncular Nucleus and Fasciculus Retroflexus.—Immediately above the pons a small collection of nerve-cells is found in the median plane, wedged in between the two cerebral peduncles. It is all that is found in the human brain to represent a large nucleus that projects into the interpeduncular fossa in many lower animals. In this **interpeduncular nucleus** ends the **fasciculus retroflexus**—a tract of fibres which comes from the habenular nucleus of the epithalamus.

Decussations of Tegmentum.—Three decussations of bundles of fibres take place in the tegmentum—the decussations of the superior cerebellar peduncles, of the tecto-spinal tracts, and of the rubro-spinal tracts. The **decussation of the superior cerebellar peduncles** has been described already (p. 920). If the region ventral to the medial longitudinal bundles is examined in the upper part of the mid-brain, two groups of decussating fibres will be observed in the interval between the red nuclei—one dorsal to the other. The dorsal one is the **decussation of the tecto-spinal tracts**; the other is the **decussation of the rubro-spinal tracts**; both of these pairs of tracts cross the median plane immediately after their origin, decussating with their fellows, and descend in the opposite half of the brain-stem to the spinal cord—the tecto-spinal from the superior corpora quadrigemina, the rubro-spinal from the red nuclei.

Basis Pedunculi.—The basis pedunculi is slightly crescentic in outline in transverse section, and stands quite apart from its fellow. It is composed of a compact mass of longitudinally directed fibres, all of which arise in the cortex of the cerebrum and pursue an unbroken corticifugal course into and through the basis pedunculi. These fibres may be classified into two distinct sets, viz., cortico-pontine and pyramidal.

In their course downwards the **cortico-pontine fibres** are all arrested in the basilar part of the pons and end among the cells of the nuclei pontis. These tracts hold a very definite position in the basis pedunculi. Thus, it has been established that the fibres from the temporal and occipital areas of the cortex form the lateral fifth of the basis pedunculi, whilst those from the frontal and parietal areas occupy the medial fifth.

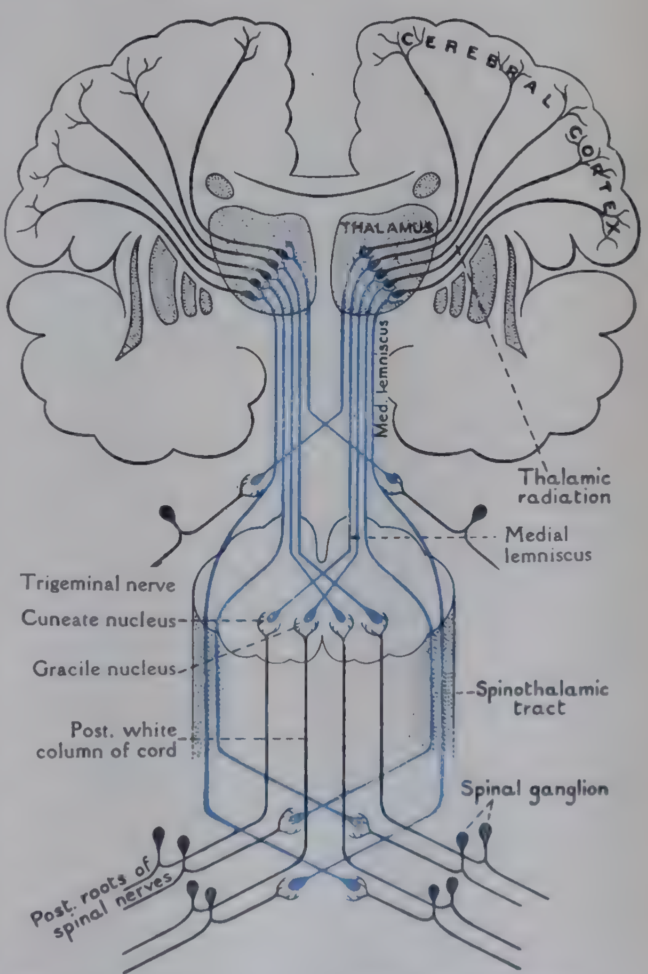

FIG. 811.—DIAGRAM OF CONNEXIONS OF MEDIAL LEMNISCUS AND OF THALAMO-CORTICAL FIBRES.

The **pyramidal fibres** constitute the great motor tract from the cerebral cortex. They occupy the middle three-fifths of the basis. This tract differs from the cortico-pontine strands in being carried downwards through the basilar part of the pons and on the front of the medulla

oblongata into the spinal cord, which it enters in the form of the *anterior* and *lateral cerebro-spinal tracts.* On its way through the mid-brain, pons, and medulla oblongata it sends fibres across the median plane to the various motor nuclei on the opposite side of those sections of the brain-stem; these may be termed *cortico-nuclear fibres.*

Development of Mid-Brain

Even in the early embryo the mesencephalon is the smallest section of the brain-tube, although the disproportion in size between it and the other primitive divisions of the brain is not nearly so marked as in the adult. Owing to the cephalic flexure, the mid-brain for a

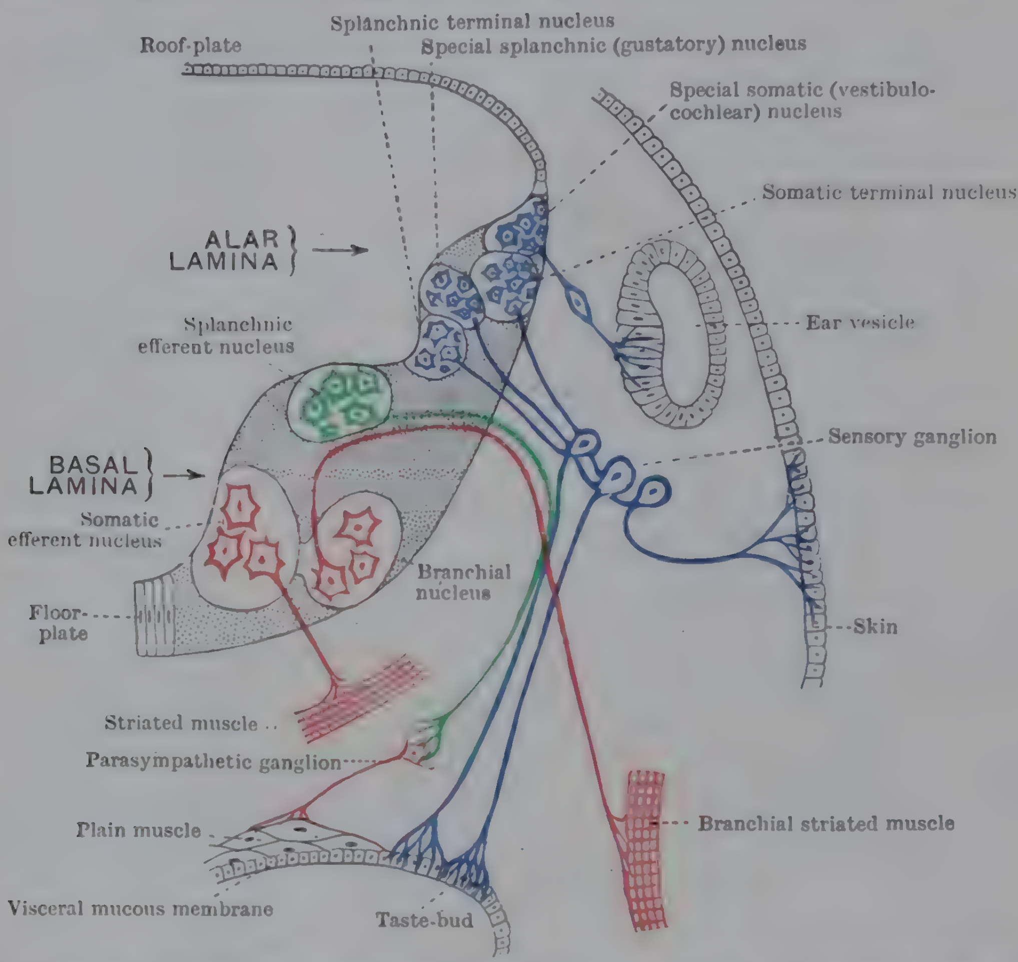

Fig. 812.—Diagram representing in Transverse Section of Fœtal Hind-Brain the Different Kinds of Components found in the Cranial Nerves and the position of their Nuclei of Origin or Termination.

time occupies the summit of the head. Later it becomes completely covered over by the expanding cerebral hemispheres.

The corpora quadrigemina are derived from the alar laminæ of the side-walls of the brain-tube, whilst the basal laminæ thicken and ultimately form the cerebral peduncles. The original cavity of the mid-brain becomes relatively narrowed down to form the aqueduct.

For a considerable time the cavity of the mid-brain remains relatively large, and the lower part of its dorsal wall is carried downwards in the form of a diverticulum or recess which overlaps the cerebellar plate. About that time, also, the dorsal wall shows a median fold or ridge. Both of those conditions are transitory. As the corpora quadrigemina take shape, the median ridge disappears and is replaced by the median longitudinal groove which separates the quadrigeminal bodies. Only its lower part is retained, and that is represented by the frenulum veli of the adult brain. The diverticulum of the cavity gradually becomes reduced, and finally disappears as the aqueduct assumes form.

DEEP CONNEXIONS OF CRANIAL NERVES ATTACHED TO MEDULLA OBLONGATA, PONS, AND MID-BRAIN

There are twelve pairs of cranial nerves, of which the lower eight are attached to the medulla oblongata and pons. From above downwards these eight are named the trigeminal (fifth), the abducent (sixth), the facial (seventh), the auditory (eighth), the glosso-pharyngeal (ninth), the vagus (tenth), the accessory (eleventh), and the hypo-

glossal (twelfth). Two others—the trochlear (fourth) and oculomotor (third)—spring from the mid-brain. The hypoglossal, the accessory, the greater part of the facial, the abducent, the motor root of the trigeminal, the trochlear, and the oculomotor are efferent nerves; the auditory and the sensory root of the trigeminal are purely afferent nerves; the vagus and the glosso-pharyngeal are composed of both efferent and afferent fibres; and the sensory root of the facial nerve contains not only afferent fibres but also the efferent, parasympathetic preganglionic fibres which later pass into the chorda tympani. In all these cases (with the exception of the mesencephalic tract of the trigeminal) afferent fibres arise from ganglionic cells

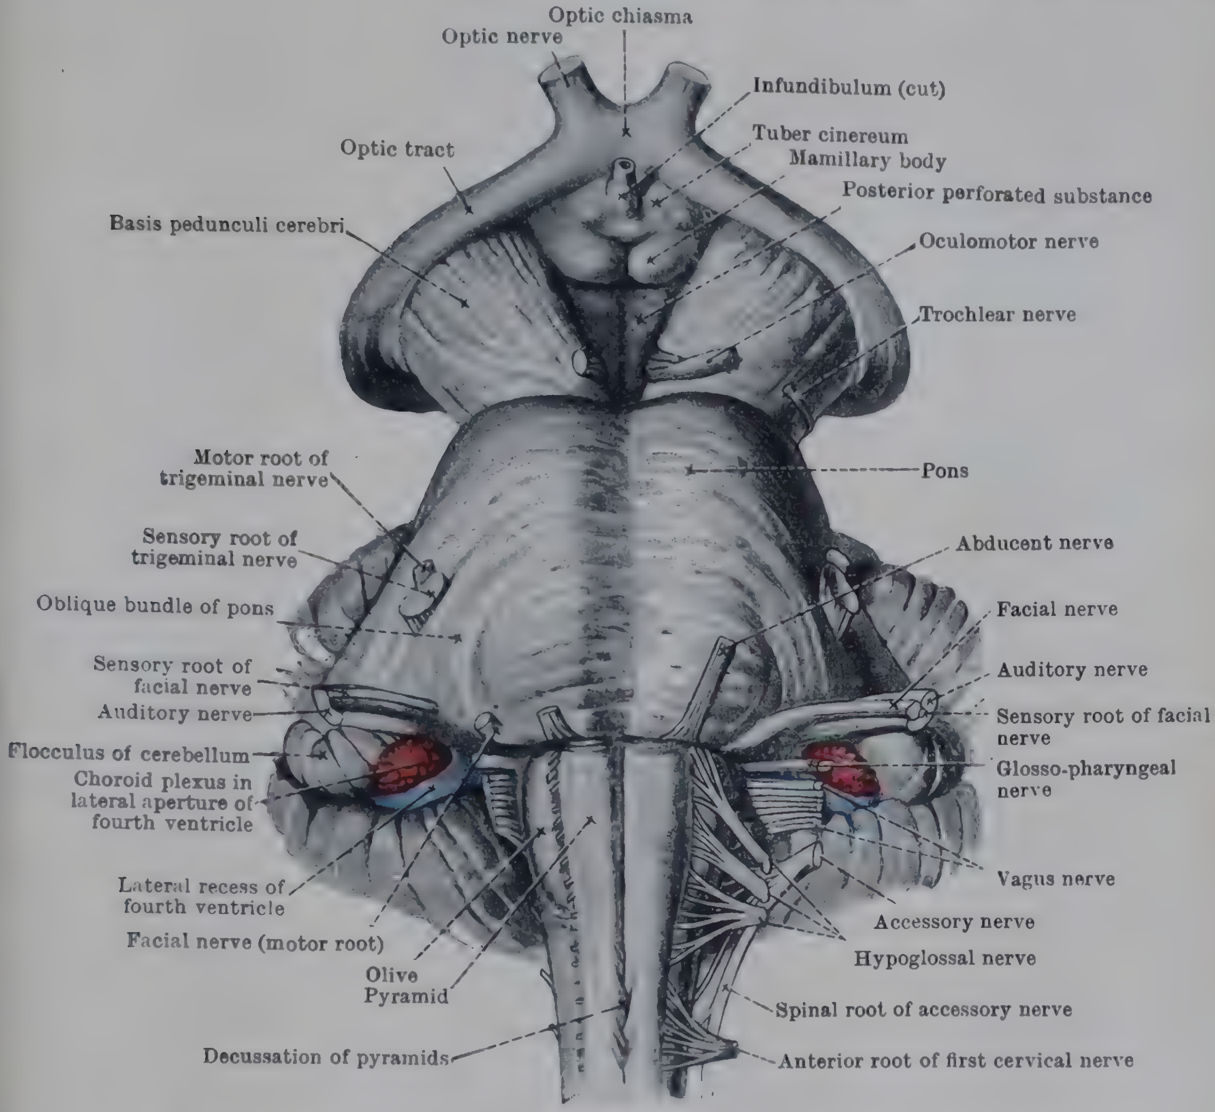

FIG. 813.—ANTERIOR SURFACE OF BRAIN-STEM, SHOWING THE NERVE-ROOTS.

placed outside the brain and penetrate the brain-stem, to end in connexion with the cells of certain **nuclei of termination**. Efferent fibres, on the other hand, take origin within the brain as the axons of cells which are grouped together in certain places in the form of **nuclei of origin**.

Nuclei of Origin, or Motor Nuclei.—In the spinal cord the nuclei of origin are represented by elongated columns of cells which run more or less continuously through successive spinal segments in the anterior grey column, and from them the series of efferent anterior nerve-roots take origin. In the medulla oblongata, pons, and mid-brain the nuclei of origin, or, in other words, the motor nuclei of the individual nerves, become, for the most part, discontinuous, and are represented by certain isolated clumps of compact grey matter in which are placed the clusters of cells from which the efferent fibres of the nerves arise. The nucleus ambiguus, however, which consists of a column of cells from which root-fibres of the upper part of the accessory, of the vagus, and also of the glosso-pharyngeal are derived, is an exception to this rule. At the decussation of the pyramids, the anterior grey column of the spinal cord is broken up by the intercrossing bundles into a

detached head, and a basal part which remains in relation with the antero-lateral aspect of the central canal. Certain of the efferent nuclei of the medulla oblongata, pons, and mid-brain lie in the line of the basal portion of the anterior grey column close to the median plane. They are the **somatic motor nuclei** of the brain-stem and are met with at different levels. This group comprises the hypoglossal nucleus, the abducent nucleus, and, in the mid-brain, the trochlear nucleus and part of the oculomotor nucleus. Other motor nuclei of origin are present in the form of isolated clumps or columns of grey matter which lie at different levels in the medulla oblongata and pons in a more lateral and ventral situation. They are the nucleus ambiguus of the accessory, vagus, and glosso-pharyngeal, the motor nucleus of the facial nerve, and the nucleus of the motor root of the trigeminal nerve. Since these nuclei give origin to fibres which innervate musculature derived from the pharyngeal or branchial arches in the embryo, they may be termed **branchial nuclei** (p. 844).

In addition to these two columns of motor nuclei there is a third efferent column of **splanchnic nuclei** represented by the dorsal nucleus of the vagus and glosso-pharyngeal nerves, and similar nuclei from which autonomic fibres arise and leave the brain with the facial and oculomotor nerves.

The different nuclei of origin of the efferent fibres which belong to the various cranial nerves, both somatic and branchial, are connected with the motor area of the cerebral cortex by cortico-nuclear fibres of the pyramidal tract which enter the nuclei and end in association with their cells.

Terminal Nuclei.—The general scheme of arrangement of the **terminal nuclei** has already been explained (Fig. 812); its details will be further elucidated as the various nerves are considered seriatim.

The axons of many of the cells of the nuclei of termination enter the formatio reticularis as arcuate fibres, and, after crossing the median plane, are carried upwards in the formatio reticularis of the opposite side to establish direct connexions with the thalamus and, indirectly through it, with the cerebral cortex. Others pass to the motor nuclei, to the cerebellum, or other groups of nerve-cells, to form connexions necessary for the performance of reflex actions.

Hypoglossal Nerve.—The nucleus of origin of the hypoglossal nerve—the motor nerve of the tongue—lies in the substance of the medulla oblongata. It is composed of several groups of large multipolar cells which closely resemble the cells in the anterior grey column of the spinal cord, and is pervaded by an intricate network of fine fibres. In form it is a slender rod about 18 mm. in length. It extends from a point immediately above the decussation of the pyramids up to the level of the striæ medullares. The lower part is in front of the central canal of the medulla close to the median plane in that part of the central grey matter which is continuous with the basal part of the anterior grey column of the spinal cord. The upper part is in the grey matter in the floor of the fourth ventricle, subjacent to the medial part of the surface area named the **hypoglossal triangle** (see p. 887). Within the nucleus the axons of the cells arrange themselves in converging bundles of fine fibres and leave through the front of the nucleus as the rootlets of the nerve. The nerve-bundles thus formed traverse the entire antero-posterior thickness of the medulla oblongata to emerge on the surface in linear order between the olive and the pyramid.

In the substance of the medulla oblongata the rootlets of the hypoglossal pass between the olivary nucleus and the medial accessory olivary nucleus, and many of them on their way to the surface pierce the ventral lamina of the olivary nucleus. After they emerge they at first collect to form a series of definite bundles like the anterior nerve-roots of three or four spinal nerves (Fig. 813). These subsequently unite to form two trunks which always pierce the dura mater separately, and the trunks then unite to form the single hypoglossal nerve. This arrangement is an expression of the composite nature of the hypoglossal nerve, for developmentally it is formed by the fusion of three or four segmental nerves.

No decussation between the nerves of opposite sides takes place in the medulla oblongata, but commissural fibres pass between the two nuclei (Kölliker). Further,

numerous cortico-nuclear fibres from the opposite side enter the nucleus and end in connexion with its cells. The nucleus is thus brought into connexion with the motor area of the cerebral cortex of the opposite side.

Accessory Nerve.—The accessory nerve also is a motor nerve, and it arises by a spinal and a cranial root.

The fibres of the **spinal root** emerge as a vertical row of bundles through the side of the spinal cord from the level of the fifth cervical nerve upwards; they unite to form a stem that ascends between the anterior and posterior roots of the cervical nerves and enters the skull through the foramen magnum. The root-fibres take origin in a column of cells situated in the anterior grey column close to its lateral margin and immediately behind the nerve-cells which give rise to the fibres of the anterior roots of the upper five cervical nerves. The cells of the accessory nucleus are large, multipolar, and in every respect similar to the motor cells of the spinal nerves. The axons from these cells leave the posterior surface of the nucleus in converging groups to form the root-bundles of the nerve. These, in the first place, proceed straight backwards in the anterior grey column. Reaching the bay between the two columns of grey matter, they turn sharply laterally into the white matter and traverse the lateral white column to gain their points of exit from the cord. At the decussation of the pyramids additional rootlets proceed from the detached head of the anterior grey column.

It should be noted that many of the fibres which take origin from the lower part of the spinal nucleus do not at once emerge on the surface of the spinal cord, but ascend for some distance in the white matter alongside the base of the anterior grey column. These fibres constitute the *intraspinal root* of the accessory nerve.

The fibres of the **cranial root** arise in the medulla oblongata. As they proceed laterally from their nucleus they cross in front of the spinal tract of the trigeminal nerve; this distinguishes them from the fibres of the vagus, for the vagal fibres pass through the tract or behind it. The nucleus of origin of the cranial rootlets is the **nucleus ambiguus**, which, at a higher level, gives motor fibres to the vagus and glosso-pharyngeal nerves.

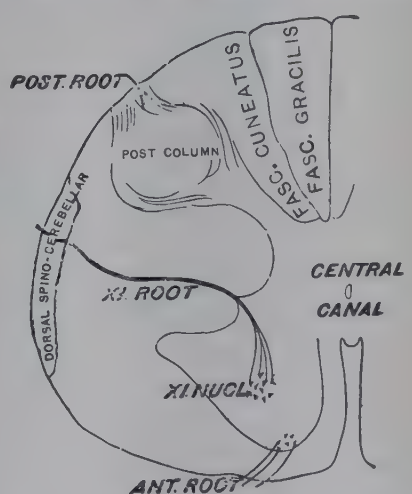

Fig. 814.—Diagram of Spinal Origin of Accessory Nerve. (After Bruce, 1892.)

The part of the accessory nerve which takes origin in the spinal cord supplies the sterno-mastoid and trapezius muscles. The cranial portion joins the vagus, and through the recurrent laryngeal nerves it supplies all the intrinsic muscles of the larynx except the crico-thyroid (see p. 1040).

Collaterals and fibres of the opposite lateral cerebro-spinal tract end in connexion with the cells of origin of the accessory nerve, and thus bring its nucleus into connexion with the motor area of the cerebral cortex.

Vagus and Glosso-Pharyngeal Nerves.—The vagus and glosso-pharyngeal nerves have similar connexions with the brain, and they may therefore be studied together. The greater part of both nerves is composed of afferent fibres which arise outside the brain-stem from ganglionic cells placed in relation to the nerve-trunks. Both nerves possess efferent fibres also, which spring from two special nuclei of origin situated within the medulla oblongata and termed respectively the **dorsal** or **splanchnic nucleus** and the **nucleus ambiguus**, which is a **branchial nucleus**. The afferent ganglionic fibres of the vagus and glosso-pharyngeal enter the brain by a series of roots which penetrate the medulla oblongata along the front of the inferior cerebellar peduncle. Within the medulla oblongata they separate into two sets, viz., a series of bundles (composed chiefly of vagus fibres, *i.e.*, afferent splanchnic) which end in grey matter closely related to the dorsal nucleus of the vagus and glosso-pharyngeal nerves, and another series of bundles (composed chiefly of glosso-pharyngeal fibres, *i.e.*, taste-fibres) which join a conspicuous longitudinal tract of fibres called the **tractus solitarius**.

The **dorsal nucleus** (Figs. 774, p. 891, and 779, p. 895) of the vagus and glosso-pharyngeal nerves contains motor cells which give origin to efferent fibres.

Immediately lateral to it is a slender column of grey matter (sometimes called the "dorsal sensory nucleus of the vagus") in which terminate afferent fibres of the vagus, and possibly also of the glosso-pharyngeal nerve. The dorsal nucleus proper (*i.e.*, the motor nucleus) is almost as long as the nucleus of the hypoglossal nerve, with which it is closely related. Above, it reaches as high as the striæ medullares, whilst its inferior end falls slightly short of that of the hypoglossal nucleus. In specimens stained by the Weigert-Pal method the two nuclei offer a marked contrast. The hypoglossal nucleus has a dark hue, owing to the enormous

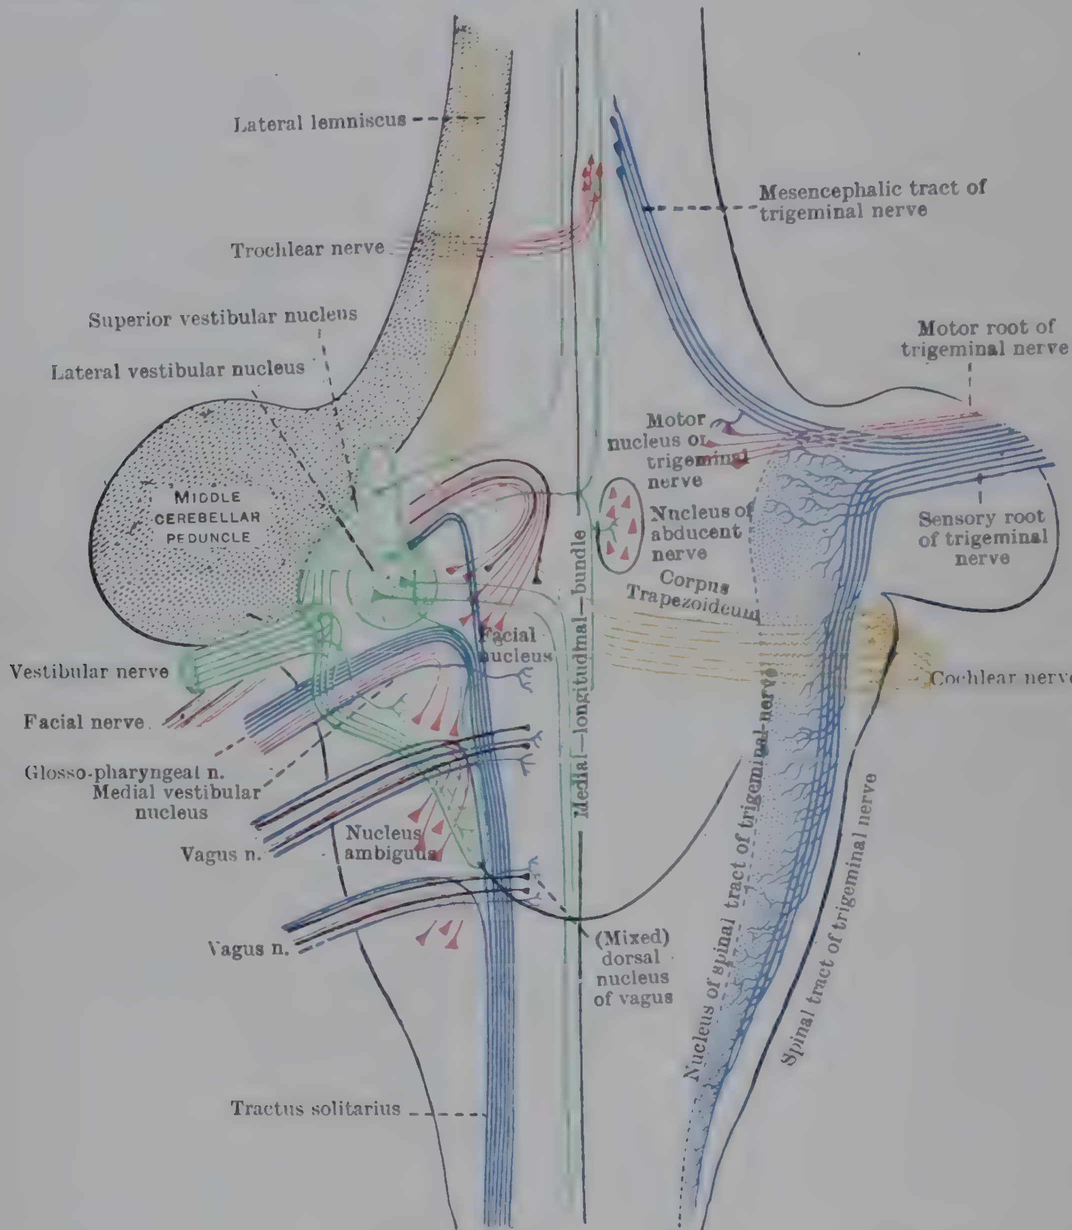

FIG. 815.—DIAGRAM OF DEEP CONNEXIONS OF VAGUS, GLOSSO-PHARYNGEAL, AUDITORY, FACIAL, ABDUCENT, AND TRIGEMINAL NERVES.

numbers of fine fibres which twine in and out among its cells; the vago-glossopharyngeal dorsal nucleus is pale, from the scarcity of such fibres within it. Its cells, like those of all splanchnic efferent nuclei, are much smaller than the cells of the nucleus ambiguus. In the lower half of the medulla oblongata the dorsal vago-glossopharyngeal nucleus lies in the central grey matter lateral to the central canal and immediately behind the hypoglossal nucleus; in the upper part it lies in the grey matter of the floor of the fourth ventricle immediately to the lateral side of the hypoglossal nucleus and subjacent to the vagal triangle (see p. 887).

All the fibres which arise from the dorsal splanchnic nucleus are very fine, and in sections of the vagus nerve can readily be distinguished from the coarser fibres which come from the nucleus ambiguus, and also from the medium-sized sensory fibres, which spring from the ganglia placed on the nerves. The fine fibres

from the dorsal nucleus are distributed (indirectly, *i.e.*, after being interrupted in a peripheral ganglion) to the involuntary striated muscle of the œsophagus, and the plain muscle of the œsophagus, stomach, and respiratory system.

The **nucleus ambiguus** (Figs. 774, 779, 815) gives origin to the branchial motor fibres of the glosso-pharyngeal, vagus and accessory nerves. It has already been noted that the motor fibres of the accessory nerve which arise in the nucleus eventually join the vagus nerve and are distributed with its branches. All of the fibres that pass into the glosso-pharyngeal nerve end in the stylo-pharyngeus muscle and the superior constrictor muscle of the pharynx; the vagal branches are distributed to the muscles of the soft palate (except the tensor palati), to the muscles of the pharynx (except the stylo-pharyngeus), and to the crico-thyroid muscle. The cells of the nucleus ambiguus are large, multipolar, and similar in every respect to the large cells in the anterior grey column of the spinal cord. They are arranged in a slender column seen best in the upper half of the medulla oblongata. There the nucleus can easily be detected, in transverse sections, as a small area of compact grey matter in the formatio reticularis grisea, midway between the dorsal accessory olive and the nucleus of the spinal tract of the trigeminal nerve. It therefore lies more deeply in the substance of the medulla oblongata than the dorsal vago-glosso-pharyngeal nucleus. It can be traced downwards as low as the level of the sensory decussation, and upwards as high as the level of entrance of the cochlear nerve. The axons of its cells emerge from the dorsal aspect of the nucleus, and in the first instance pass backwards towards the floor of the fourth ventricle; then, bending suddenly laterally and forwards, they join the afferent roots of the vagus and the glosso-pharyngeal nerves, and emerge from the brain in company with them. The origin of the cardiac fibres of the vagus is not certainly known; there is some evidence that they arise, not from the dorsal splanchnic efferent nucleus, but from a group of slightly larger cells alongside the nucleus ambiguus.

Sensory Nuclei of Glosso-Pharyngeal and Vagus (Splanchnic and Gustatory Components).—The cells in the column of grey matter, lateral to the dorsal (motor) nucleus, which acts as a *nucleus of termination* are spindle-shaped in form and similar to those found in the posterior grey column in the spinal cord. The greater number of the afferent fibres of the vagus nerve, and a small proportion of the afferent fibres of the glosso-pharyngeal nerve, end around these cells in fine terminal arborizations. A small part of the upper portion of the nucleus may be said to belong to the glosso-pharyngeal nerve and the remainder to the vagus nerve.

The **tractus solitarius** (Figs. 773, p. 889; 774, p. 891; and 779, p. 895) is a cylindrical bundle of longitudinal fibres which forms a very conspicuous object in transverse sections through the medulla oblongata. It begins at the upper end of the medulla oblongata and can be traced downwards through its whole length. The relations of the tractus solitarius are not the same in all parts of its course. It lies immediately to the lateral side of the dorsal vago-glossopharyngeal nucleus—rather in front of it in the upper part of the medulla, and behind it in the lower part. Throughout its entire length it is intimately associated with a column of gelatinous grey substance, called the **nucleus of the tractus solitarius**, which is its nucleus of termination. Most of the fibres of the tractus solitarius are derived from the glosso-pharyngeal nerve; only a few of the afferent fibres of the vagus enter it, but fibres of the sensory root of the facial also enter it at its upper extremity. As the fibres of the three nerves join the fasciculus they immediately turn downwards, and at different levels they come to an end in the associated nucleus.

As the afferent rootlets of the vagus and the glosso-pharyngeal nerves traverse the substance of the medulla oblongata in a backward and medial direction to reach the tractus solitarius and the dorsal nucleus of termination, they pass through the spinal tract of the trigeminal nerve and the nucleus of that tract. As the afferent root of the vagus passes through the spinal tract and its nucleus (which is somatic sensory in nature), it gives off to that nucleus its own somatic sensory branches, the peripheral ends of which constitute the *auricular branch*, distributed to the skin on the back of the auricle. The other afferent fibres in the glosso-pharyngeal and vagus nerves include taste-fibres, sensory fibres from the pharynx, larynx, and other parts of the respiratory and alimentary systems, and other splanchnic afferent fibres. Although

there is no sharp demarcation between the terminal nuclei of these various components, it is probable that the taste-fibres proceed to the nucleus of the tractus solitarius, the splanchnic afferent fibres to the dorsal nucleus, and the somatic afferent fibres to the nucleus of the spinal trigeminal tract.

Auditory Nerve.—As this is a nerve of special sense it will be left for consideration after the rest of this series.

Facial Nerve (Figs. 815 and 816).—The facial nerve is a mixed nerve with two separate roots—sensory and motor.

The **motor root** is so much the larger that the term **facial nerve** is often applied to it alone. It emerges through the lower border of the pons a little medial to the auditory nerve. The **sensory root** is a very slender cord that lies between the auditory nerve and the motor root—but nearer the former than the latter (Fig. 813)—and it sinks into the upper end of the medulla oblongata. The two roots run alongside the auditory nerve from the pons to the internal auditory meatus.

The fibres of the sensory root arise in the temporal bone from the cells of the ganglion of the facial nerve. These, like the cells of a spinal ganglion, are unipolar—the single process in each case dividing into a peripheral and a central branch. The group of peripheral fibres is represented partly by the greater superficial petrosal nerve and chorda tympani nerve. The central fibres form the sensory root; they penetrate the brain, and, passing either through or behind the spinal tract of the trigeminal nerve, they finally reach the upper part of the column of grey matter in connexion with the tractus solitarius, and in that they end. The sensory root has therefore the same terminal connexions as the glossopharyngeal nerve.

The motor nucleus of the facial nerve contains elements serially homologous with both the nucleus ambiguus and the dorsal vago-glossopharyngeal nucleus. It is composed partly of the larger cells characteristic of the former and the smaller cells distinctive of the latter. The axons of the larger cells innervate the striated muscles of the face, whereas the splanchnic fibres from the smaller cells pass to the sphenopalatine, otic, and submandibular ganglia (as their preganglionic fibres), and are concerned with the regulation of the secretory activity of the large salivary glands and other glands around the mouth; these secretory fibres of the seventh nerve leave the brain with its sensory root which is therefore not composed wholly of afferent fibres.

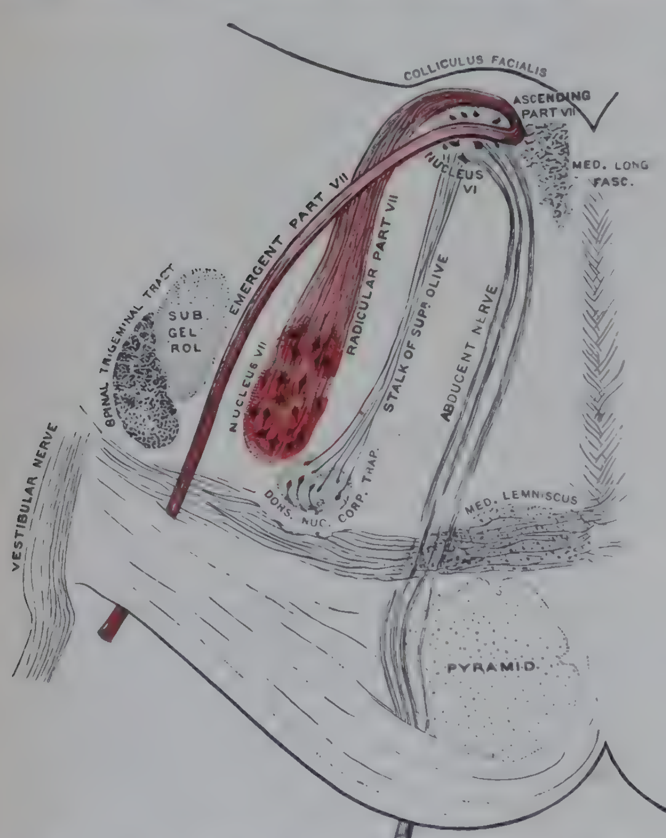

Fig. 816.—Diagram of Intrapontine Course of Facial Nerve.

SUB. GEL. ROL. refers to the nucleus of the spinal trigeminal tract.

The facial nucleus is situated close to the place where the nerve emerges from the brain, but the nerve does not at once pass to the point of exit. It pursues a long and devious path within the pons before it finally reaches the surface. This intrapontine part of the nerve may be divided into three parts, viz.: (1) a radicular part, (2) an ascending portion, and (3) an emergent part.

The **radicular part of the facial nerve** (Fig. 816) is composed of a large number of fine, loosely arranged bundles of fibres which issue from the lateral and dorsal aspect of the nucleus and proceed backwards and slightly medially through the pons. Reaching the floor of the fourth ventricle they curve medially,

and the bundles which lie highest up sweep over the lower part of the nucleus of the sixth nerve. Close to the median plane they turn sharply upwards and are collected into a solid nerve-bundle. This **ascending part** (Figs. 815 and 816) proceeds upwards immediately beneath the ependyma of the ventricular floor on the dorsal surface of the medial longitudinal bundle, and along the medial side of the abducent nucleus for a distance of about five millimetres; it then bends laterally, and curves a second time over the dorsal surface of the abducent nucleus, and this bend bulges the floor of the ventricle, producing the **colliculus facialis** (Fig. 816 and Fig. 770, p. 886). The nerve having thus made a curved loop over the dorsal aspect of the abducent nucleus, its **emergent part** now begins (Figs. 815, 816). This part takes an oblique course laterally, forwards and downwards to its place of exit at the lower border of the pons; and, on its way, it passes between its own nucleus and the spinal tract of the trigeminal nerve.

Ending in the facial nucleus, in fine terminal arborizations around its cells, there are: (1) many cortico-nuclear fibres from the pyramidal tract of each side; (2) fibres from the spinal tract of the fifth nerve; (3) fibres from the corpus trapezoideum, etc. The nucleus is thus brought into connexion with the motor area of the cerebral cortex, with the trigeminal nerve (the sensory nerve of the face), and with the auditory nerve.

The peculiar course of the efferent fibres of the facial nerve within the pons is the result of a migration of the motor nucleus which has occurred during embryonic (and also during evolutionary) development. In the embryo the facial nucleus develops alongside the abducent nucleus. The latter, controlling one of the eye-muscles, receives most of its afferent impulses from the medial longitudinal bundle (descending from the optic centres in the superior corpus quadrigeminum), and therefore it remains alongside the medial longitudinal bundle and perhaps moves slightly upwards, *i.e.*, towards the mid-brain. The facial nucleus, however, receives most of its stimuli from the nucleus of the spinal tract of the trigeminal nerve and from cortico-nuclear fibres, and therefore, as the walls of the metencephalon thicken during their growth, this nucleus comes to occupy a position between the trigeminal nucleus and the pyramidal tract (Fig. 816), and so migrates along a course which remains mapped out by its emerging fibres.

Abducent Nerve (Figs. 781 and 816).—The abducent nerve is a small motor nerve which emerges from the brain at the lower border of the pons above the lateral border of the pyramid of the medulla oblongata. It is the nerve of supply to the lateral rectus muscle of the eyeball. Its **nucleus** of origin is a small oval mass of grey matter, containing large multipolar cells, which lies in the lower part of the pons, close to the median plane and immediately subjacent to the grey matter of the floor of the fourth ventricle. Its position can be easily indicated on the ventricular floor, seeing that it is placed subjacent to the facial colliculus and immediately above the level of the striæ medullares. Its peculiar and intimate relation to the intrapontine portion of the facial nerve has already been indicated.

The axons of the multipolar cells of the nucleus emerge from the medial side of the nucleus in several bundles which proceed through the whole dorso-ventral thickness of the pons towards the place of exit. As they pass forwards they incline downwards and slightly laterally. In the dorsal part of the pons they proceed forwards on the medial side of the dorsal nucleus of the corpus trapezoideum, whilst in the basilar part of the pons they keep for the most part to the lateral side of the pyramidal bundles, although several of the nerve-rootlets pierce these on their way to the surface.

It appears probable that certain of the axons of the cells of the abducent nucleus enter the medial longitudinal fasciculus and proceed upwards in it to end in the oculomotor nucleus of the opposite side. Fibres and collaterals from the basis pedunculi enter the nucleus, and, ending around the cells, bring the nucleus into connexion with the motor area of the cerebral cortex. A slender bundle of fibres connects it with the dorsal trapezoid nucleus, and is called the *pedicle* of that nucleus (named "stalk of sup^{r}. olive" in Fig. 816).

Trigeminal Nerve.—The trigeminal nerve strikes its roots deeply into the brain and establishes a connexion with it which extends from the upper part of

the mid-brain to the level of the second cervical nerve. No other cranial nerve presents so extensive a connexion (Fig. 815). It has two roots—a large afferent or sensory root and a small efferent or motor root; both roots appear close together on the surface of the pons, rather nearer its upper than its lower border, and in the same line as the facial, and glosso-pharyngeal and vagus nerves (Fig. 813).

The **sensory root** is composed of fibres which arise outside the brain from the cells of the trigeminal ganglion. They end within the brain in a tadpole-shaped nucleus, the swollen body of which is situated in the pons and is termed the main sensory nucleus of the trigeminal nerve: the tail is a long column of grey matter which is directly continuous below with the substantia gelatinosa of the spinal cord.

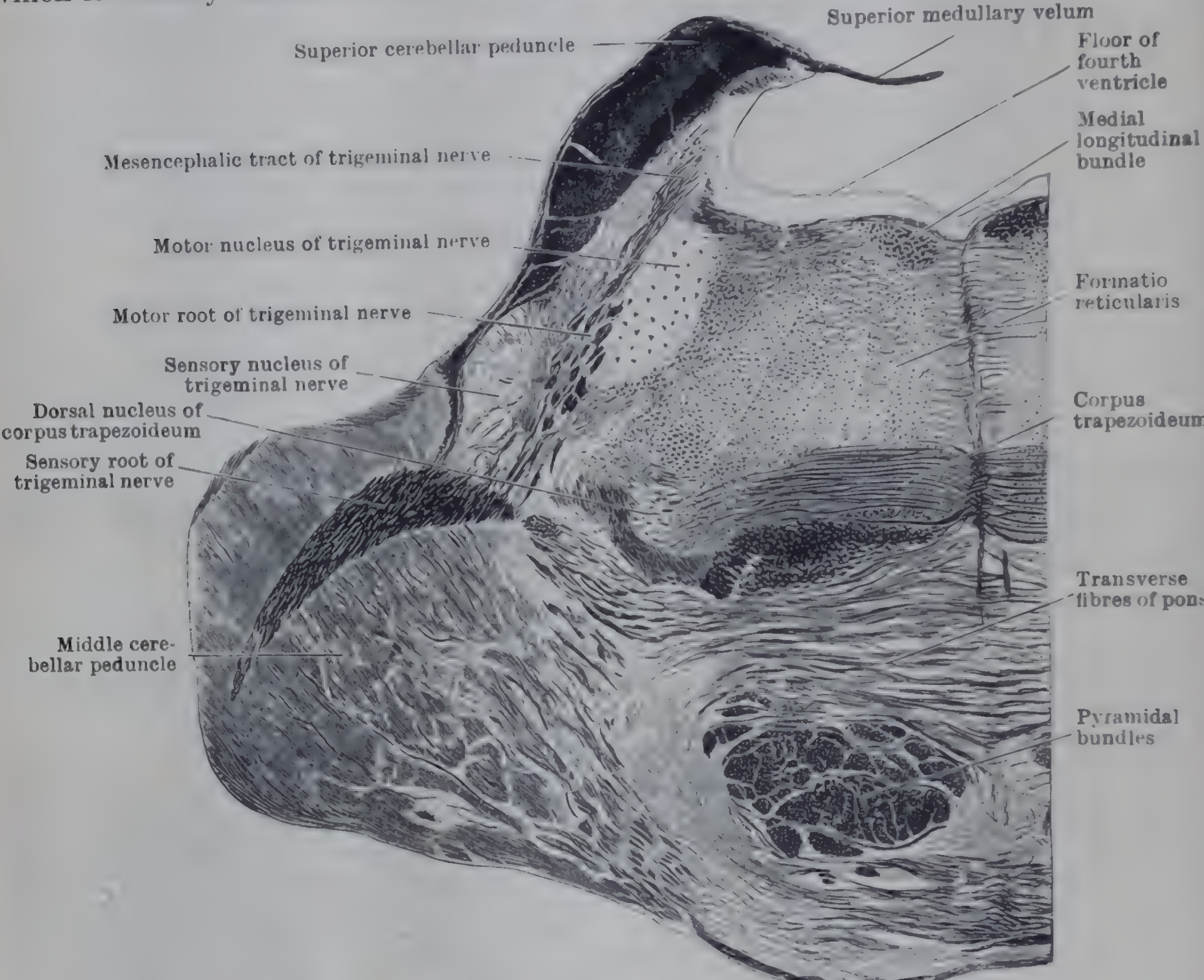

FIG. 817.—SECTION THROUGH PONS AT LEVEL OF NUCLEI OF TRIGEMINAL NERVE.

The **main sensory nucleus** (Fig. 817) is an oval mass of grey matter placed half-way up the pons in the lateral part of its dorsal portion. It lies close to the surface immediately subjacent to the submerged margin of the superior cerebellar peduncle. It is directly continuous with the substantia gelatinosa, and may be regarded as being merely its enlarged upper end.

The fibres of the sensory root, on reaching the sensory nucleus, divide (in the same way as the fibres of the entering posterior roots of the spinal nerves) into ascending and descending branches (Fig. 815). The ascending fibres are short, and almost immediately enter the main sensory nucleus and end within it; the descending fibres turn sharply downwards and form the **spinal tract**. This tract descends on the lateral side of the nucleus in which its fibres terminate—the **nucleus of the spinal tract of the fifth nerve**. Fibres constantly leave it to enter the nucleus, so that the farther the spinal tract proceeds the smaller does it become, until, in the upper part of the spinal cord, about the level of the first or second spinal nerve, it disappears altogether.

The spinal tract of the trigeminal nerve is a conspicuous object in sections through the pons and medulla oblongata. In the pons it traverses the dorsal part—first between the

emergent part of the facial nerve and the vestibular nerve, and then, lower down, between the inferior cerebellar peduncle and the nucleus of the facial nerve (Fig. 781). In cross-sections it presents a well-defined semilunar or curved piriform outline. In the upper part of the medulla oblongata it lies on the front of the inferior peduncle, and is therefore nearer the surface at this level (Fig. 779, p. 895); here, it is traversed and broken up into bundles by the olivo-cerebellar fibres and the roots of the glosso-pharyngeal and vagus nerves. Finally, it comes to the surface and its fibres are spread over the area on the side of the medulla oblongata known as the **tubercle of the fifth nerve.** (Fig. 778, p. 894).

The **motor root of the trigeminal nerve** is distributed chiefly to the muscles of mastication, and derives its fibres from the motor nucleus.

The **motor nucleus** (Fig. 817) lies in the lateral part of the dorsal division of the pons, close to the medial side of the main sensory nucleus, but slightly nearer the floor of the fourth ventricle. It is serially homologous with the motor nuclei of the branchial group, namely, the facial nucleus and the nucleus ambiguus. It does not become displaced so far forwards as these nuclei, because its chief source of sensory impulses—the terminal nucleus of the trigeminal afferent fibres—is placed alongside it, and there is no need for any definite migration (Fig. 815).

The **mesencephalic tract of the fifth nerve** takes origin from a column of loosely arranged pear-shaped unipolar cells placed in the extreme lateral part of the grey matter around the aqueduct. As this tract is traced downwards it gradually increases in size by the accession of new fibres, and it is crescentic in transverse section (Figs. 783, p. 900; 784, p. 901; and 785, p. 902). In the lower part of the mid-brain it lies on the medial side of the superior cerebellar peduncle; and the trochlear nerve, on its way to the surface, runs downwards in the concavity of its medial side. In the upper part of the pons it continues its course downwards on the lateral and deep aspect of the grey matter in the floor of the fourth ventricle. Finally, reaching the level of the nuclei of the trigeminal nerve, the fibres of the mesencephalic tract turn forwards and run in close association with the *motor root.* Experimental observations have shown fairly conclusively that the mesencephalic tract is made up of sensory fibres derived from the dental and palatine nerves.

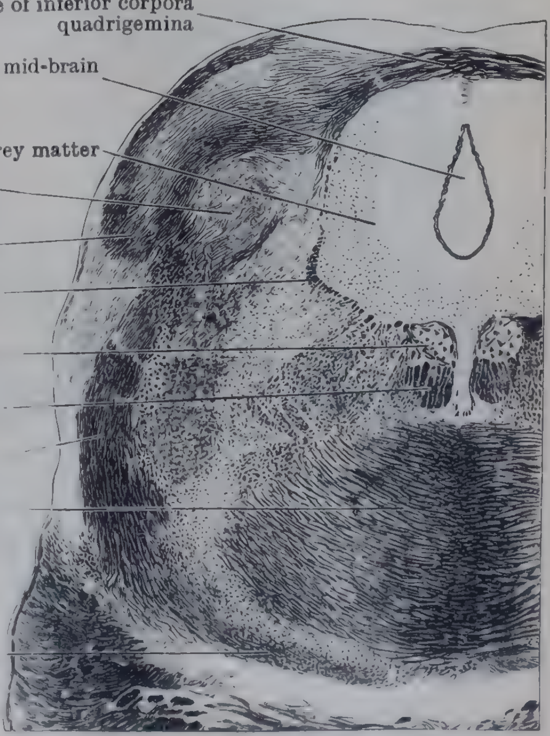

Fig. 818.—Section through Inferior Corpus Quadrigeminum and Tegmentum of Mid-Brain at Level of Middle Part of Trochlear Nucleus.

The reason why the afferent nature of the tract was not suspected until recent times is no doubt the fact that its fibres arise, not in some ganglion outside the central nervous system, like other afferent nerves, but from cells inside the mid-brain. The neural crest in the mesencephalic region must presumably have been drawn into the neural tube during development and given rise to this sensory nucleus of origin (*not* a terminal nucleus) within the central nervous system.

Trochlear Nerve.—The trochlear nerve supplies the superior oblique muscle of the eyeball. It emerges through the back of the brain-stem, at the upper part of the superior medullary velum, immediately below the lower border of the inferior corpus quadrigeminum (Fig. 799, p. 912). Its **nucleus** is a small oval mass of cells, placed in the ventral part of the central grey matter, at the level

of the upper part of the inferior corpus quadrigeminum. The close association of this nucleus with the medial longitudinal bundle has already been referred to. It is sunk deeply in a bay which is hollowed out on the dorsal and medial aspect of the tract. The nerve has a course of some length within the mid-brain. The axons of the cells leave the lateral aspect of the nucleus, and curve backwards and laterally in the central grey matter until they reach the medial surface of the mesencephalic tract of the trigeminal nerve. There they are gathered together into one or two round bundles, which, bending sharply, turn downwards at a right angle and descend on the medial side of the trigeminal tract. When the region below the inferior corpus quadrigeminum is reached, the nerve makes another sharp bend. This time it turns medially, enters the upper end of the superior medullary velum, and here decussates with its fellow of the opposite side. Having thus crossed the median plane, the trochlear nerve emerges at the medial border of the superior cerebellar peduncle. The course of the trochlear nerve in the central grey matter may be traced by examination in the order given of Fig. 818, Fig. 819, Fig. 785, p. 902, and Fig. 799, p. 912.

Oculomotor Nerve.—The oculomotor nerve supplies the levator palpebræ superioris, all the extrinsic muscles of the eyeball (with the exception of the superior oblique and the lateral rectus) and also two muscles within the eyeball, viz., the sphincter pupillæ and the ciliary muscle. The **nucleus** of origin is in the ventral part of the central grey matter subjacent to the superior corpus quadrigeminum (Fig. 806, p. 919). In length it measures from 5 to 6 mm. Its relation to the medial longitudinal fasciculus (Fig. 806) is even more intimate than that of the trochlear nucleus. It is closely applied to the dorsal and medial aspect of this strand; many of its cells occupy a position in the intervals between the nerve-bundles of the tract, and some are seen even in front of it. The axons of the cells leave the nucleus in numerous bundles which describe a series of curves as they proceed forwards through the medial longitudinal fasciculus, the tegmentum, red nucleus, and medial margin of the substantia nigra, to emerge finally from the brain-stem along the bottom of the medial sulcus of the mid-brain.

Fig. 819.—Section through Inferior Corpus Quadrigeminum and Tegmentum of Mid-Brain at Level of Lower Part of Trochlear Nucleus.

The oculomotor nucleus is made up of two main components—a large-celled somatic element which supplies extrinsic ocular muscles, and a small-celled visceral element which innervates intrinsic muscles. The somatic element is arranged as a longitudinal column of cells on each side of the median plane. In the upper part of the nucleus there is also a median group of cells which is probably concerned with the innervation of the medial rectus muscle; hence it is sometimes called the "nucleus of convergence". The lateral columns are often seen in transverse section to be subdivided into more or less well-defined and rather variable clusters of cells, but the significance of these groups is uncertain. It is generally supposed that they bear some relation to the several branches of the oculomotor nerve and the muscles which they supply, but there is considerable divergence of opinion regarding the topographical representation of these muscles. In the accompanying diagram (Fig. 820) one interpretation of this topographical

representation is shown, but in actual histological preparations it is not possible to define such groups anatomically.

On the basis of clinical observation, there is reason to believe that the cells from which the superior rectus and levator palpebræ superioris are innervated are situated dorsally, for tumours which exert pressure on the region of the oculomotor nucleus from above commonly lead to a paralysis of these muscles first. There is also indirect evidence that the cells which are concerned with the innervation of the inferior rectus muscle are situated in the ventral part of the oculomotor nucleus.

Whilst the majority of the fibres in an oculomotor nerve arise from the cell-groups on its own side of the median plane, it has been satisfactorily established that a certain proportion of its fibres are derived from the nucleus of the opposite side, thus forming a crossed connexion and giving rise to a median decussation. The whole oculomotor nucleus, and particularly that part which is concerned with the innervation of the medial rectus muscle, is connected, through the medial longitudinal fasciculus, with the abducent nucleus, from which proceeds the nerve of supply for the lateral rectus muscle. The harmonious action of the medial and lateral recti in producing the conjugate movements of the eyeballs is thus explained.

The oculomotor nucleus is connected: (1) with the occipital part of the cerebral cortex by fibres which reach it through the optic radiation; (2) with the vestibular, trochlear, and abducent nuclei (and probably with other nuclei) by fibres which come to it through the medial longitudinal fasciculus; (3) possibly with the facial nerve by fibres which pass out from it into the medial longitudinal fasciculus (p. 896); (4) with the fibres which convey retinal impulses indirectly through the pretectal nucleus and the superior corpus quadrigeminum.

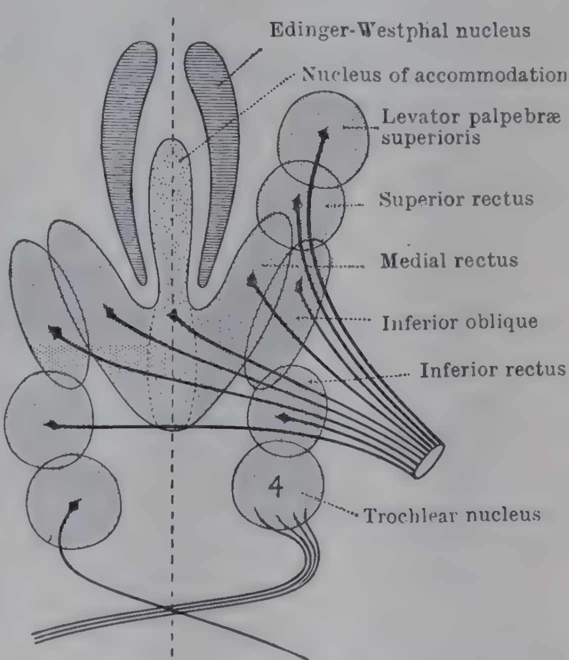

Fig. 820.—Diagram of the Oculomotor and Trochlear Nuclei. (After Brouwer, 1918.)

It is important to recognize that although the main part of the oculomotor nucleus belongs to the somatic group, which also includes the trochlear, abducent, and hypoglossal nuclei, it includes also a representative (the Edinger-Westphal group of small cells) of the column of general splanchnic efferent nuclei (parasympathetic) in series with those of the facial, glosso-pharyngeal, and vagus nerves. Its axons pass out with the other fibres of the oculomotor nerve and enter the ciliary ganglion, where they end in relationship with the cells that innervate the ciliary muscle and the sphincter pupillæ. The third, fourth, and sixth cranial nerves, which supply motor fibres to the extrinsic muscles of the eye, contain also proprioceptive afferent fibres, but their termination in the brain-stem is uncertain.

Auditory Nerve.—The **eighth cranial nerve** is a thick composite bundle that enters the brain at the lower border of the pons. Its fibres spring from bipolar ganglionic cells within the internal ear or its immediate neighbourhood (see section dealing with the Organs of Sense). One group of them forms the **spiral ganglion**, the peripheral branches of which are distributed to the spiral organ in the cochlea: another group constitutes the **vestibular ganglion**, which distributes fibres to the ampullæ of the semicircular ducts, the utricle, and the saccule. Although the central processes of the cells in the two ganglia accompany one another and are known collectively as the auditory nerve, they probably remain distinct throughout, in their mode of termination in the brain as well as in their peripheral distribution. Reaching the brain, the auditory nerve divides into two parts, viz.,

the cochlear nerve and the vestibular nerve, which have different connexions, corresponding to their distinct functions. At the pons, the two nerves embrace the inferior cerebellar peduncle—the vestibular nerve entering the pons on the medial side of the peduncle, whilst a large part of the cochlear nerve sweeps round its lateral surface. Special nuclei of termination require to be studied in connection with each of the two divisions.

The **cochlear nerve** is composed of finer fibres than the vestibular nerve, and they acquire their medullary sheaths at a later period. It is the true nerve of hearing, and its fibres end in two nuclei which are intimately related to the inferior cerebellar peduncle. One of them, called the **dorsal cochlear nucleus**, is a piriform mass placed on the back of the inferior peduncle—between it and the flocculus. The other, termed the **ventral cochlear nucleus**, is placed on the antero-lateral aspect of this peduncle in the interval between the dorsal part of the cochlear nerve and the vestibular nerve, after they have separated from each other. The fibres of the cochlear nerve enter these two nuclei and end around

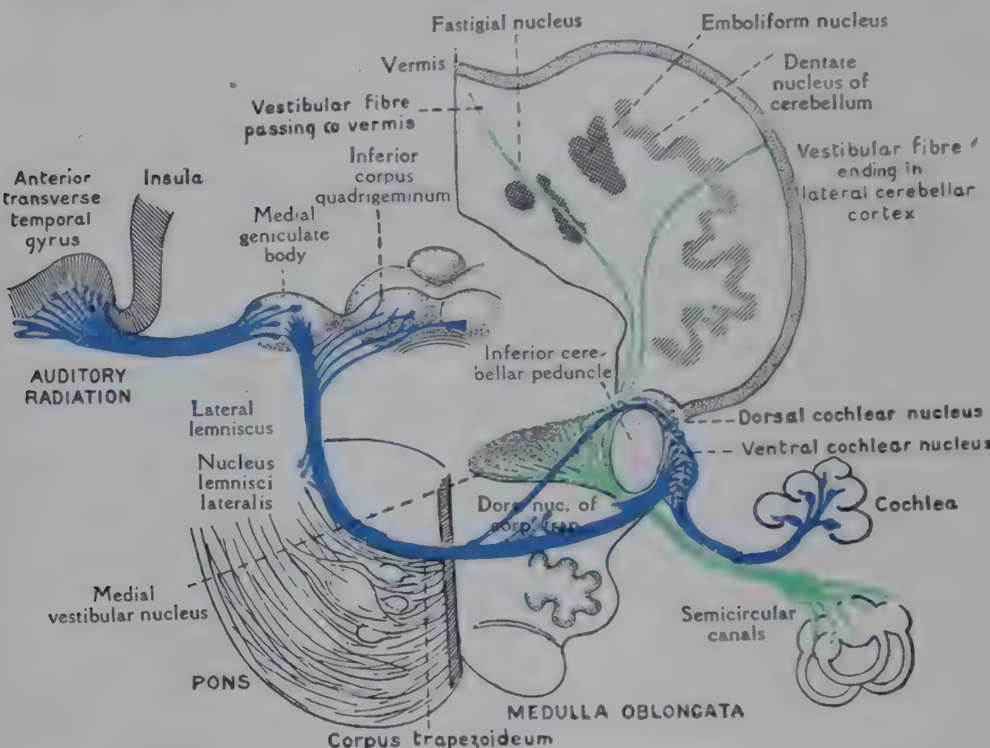

FIG. 821.—CENTRAL CONNEXIONS OF COCHLEAR AND VESTIBULAR NERVES.

the cells in arborizations which are characterized by their fineness and their intricate arrangement.

The **vestibular nerve** enters the brain at a slightly higher level than the cochlear nerve. It proceeds backwards through the pons between the inferior cerebellar peduncle, which lies on its lateral side, and the spinal tract of the trigeminal nerve, which is placed on its medial side. Its fibres end in a series of terminal nuclei—medial, lateral, superior, and inferior—and in the cerebellar cortex.

The **medial nucleus** (Figs. 781, p. 898; and 821) is the principal one. It is a large diffuse nuclear mass which lies in the floor of the fourth ventricle subjacent to the vestibular area (Fig. 770, p. 886). It is situated, therefore, in both the pons and the medulla oblongata to the lateral side of the foveæ. In transverse section it is prismatic in outline, and its surface is crossed by the striæ medullares.

When the vestibular nerve enters the brain on the medial side of the inferior peduncle, its fibres bifurcate to form ascending and descending branches. The latter pass downwards in separate bundles and form the **descending tract of the vestibular nerve** (Figs. 781, p. 898; 779, p. 895; and 815, p. 928). This proceeds through the lower part of the pons into the medulla oblongata, in which it may be traced as far as the level of the sensory decussation. The **inferior nucleus** is

associated with the descending tract; it is a column of grey matter containing sparsely strewn nerve-cells around which the fibres end in fine arborizations.

Some of the ascending fibres end in the **lateral nucleus.** This nucleus is composed of a number of large and conspicuous multipolar nerve-cells scattered amidst the bundles of the vestibular nerve. As it is traced upwards the nucleus gradually inclines backwards, and finally it occupies a place in the side-wall of the fourth ventricle. It attains its greatest size at the level of the emerging part of the facial nerve, and this upper part is termed the **superior nucleus.** Other ascending fibres pass without interruption into the cerebellum to terminate in

the cortex of the anterior and posterior lobes. In their course many of these fibres pass through the nucleus fastigii, and many writers describe them as terminating in this nucleus; but, according to Ramón y Cajal, they merely traverse it on their way to the cerebellar cortex.

From the lateral nucleus a strand of fibres passes medially to reach the medial longitudinal bundle, of which it forms one of the most important constituents. Some of these fibres pass upwards to the nuclei of the oculomotor, trochlear, and abducent nerves and form the basis for reflex movements of the eye which are produced by vestibular stimuli; others downwards, probably to the nucleus of the accessory nerve, which is concerned in regulating the movements of the head. Other fibres arise from the lateral nucleus and pass directly to the spinal cord without passing through the medial longitudinal bundle; they form the **vestibulo-spinal tract**, which passes downwards in the anterior white column and distributes fibres to the various motor nuclei in the anterior grey column of the spinal cord (Fig. 755, p. 868).

The **superior nucleus** also emits a group of fibres which pass directly to the mid-brain, chiefly to the oculomotor and trochlear nuclei.

Central Connexions of the Cochlear Nerve.—The cochlear nuclei are brought into connexion with the inferior corpus quadrigeminum and the medial geniculate body of the opposite side by the fibres of the corpus trapezoideum and the lateral lemniscus.

The fibres of the cochlear nerve end in the cochlear nuclei. From the cells of these nuclei two tracts arise, viz., a **ventral tract**, the fibres of which form the corpus trapezoideum, and a **dorsal tract** which lies near the floor of the fourth ventricle.

The **corpus trapezoideum** (Figs. 781 and 817) is formed of the axons of the cells of the ventral cochlear nucleus, as well as the axons of certain of the cells of the dorsal nucleus. In the midst of the corpus trapezoideum are lodged large cells which are known

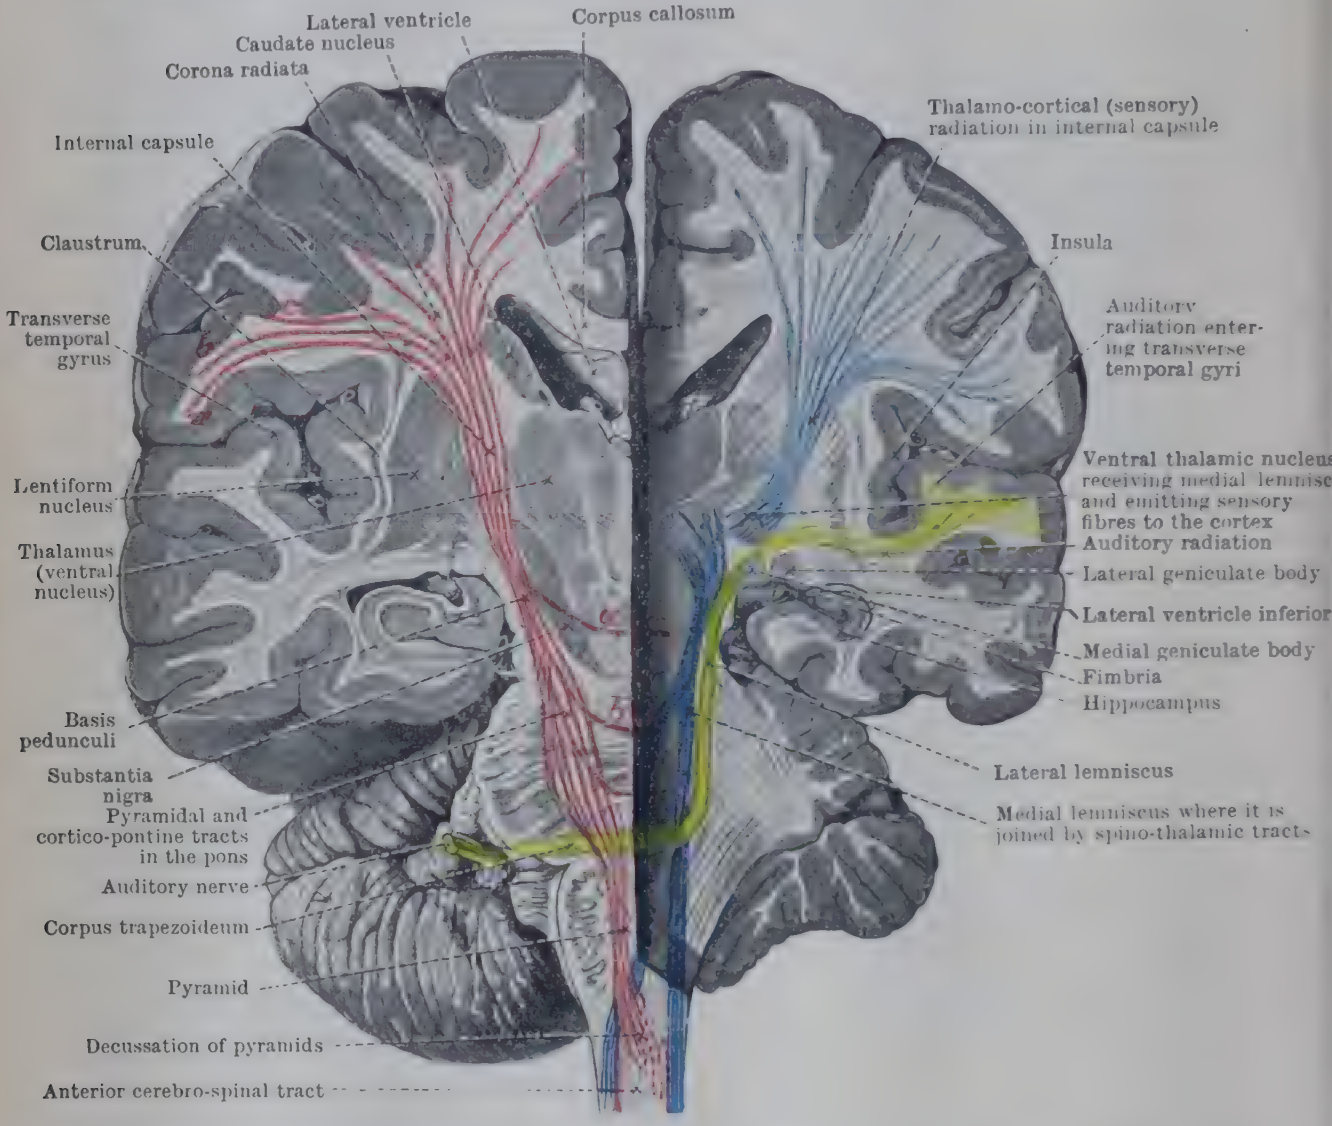

FIG. 823.—CORONAL SECTIONS OF BRAIN TO SHOW THE WHOLE OF THE CENTRAL AUDITORY PATH.

as the *ventral nucleus of the corpus trapezoideum*, and these give off axons which join the strand with which they are associated. Many of the fibres of the corpus trapezoideum end in a small mass of grey matter called the **dorsal nucleus of the corpus trapezoideum** which is placed immediately behind the trapezoid body. Most of the trapezial fibres cross the median plane and decussate with the corresponding fibres of the opposite side. Reaching the opposite dorsal trapezoid nucleus, more fibres leave the trapezoid body, and almost immediately after that the strand bends upwards and forms the **lateral lemniscus** (Figs. 784, p. 901; 785, p. 902). But still another nucleus is interposed in its path, viz., the **nucleus of the lateral lemniscus**. There some fibres are dropped, whilst from the nuclear cells others are acquired, and the lateral lemniscus then proceeds upwards until it reaches the inferior corpus quadrigeminum and the medial geniculate body, in which its fibres end.

The connexion between the cochlear nuclei and the inferior quadrigeminal body is not altogether with that of the opposite side, as the foregoing description and the diagram (Fig. 821) would lead one to infer. Some fibres pass directly to the inferior

corpus quadrigeminum of the same side, and some also reach the corresponding medial geniculate body.

From the medial geniculate body there proceeds a tract to an area of cerebral cortex in the upper surface of the temporal lobe (within the lips of the lateral sulcus of the cerebral hemisphere) which is marked by small convolutions called the transverse temporal gyri. The whole nervous apparatus of hearing is thus linked on to the cerebral cortex, and the successive neurons which build up the entire chain are therefore: (1) in the cochlea of the internal ear the bipolar cells of the spiral ganglion emit axons that terminate in the brain; (2) from the nerve-cells of the cochlear nuclei fibres arise and for the most part cross to the lateral lemniscus of the opposite side, proceeding to (3) the medial geniculate body, from which fibres pass to the cerebral cortex.

All the axons of the cells of the dorsal trapezoid nucleus do not join the trapezoid strand. Many pass backwards in a group called the **pedicle of the dorsal trapezoid nucleus** to end in the nucleus of the abducent nerve (Fig. 816, p. 930), and, through the medial longitudinal bundle, in the nuclei of the trochlear and oculomotor nerves. In this way the organ of hearing is brought into connexion with the nuclei through which the movements of the eye are controlled.

PROSENCEPHALON OR FORE-BRAIN

The fore-brain vesicle in the embryo is subdivided, more or less arbitrarily, into two parts—an anterior termed the **telencephalon**, and a posterior called the **diencephalon**, which forms the greater part of the walls of the third ventricle. The extreme anterior part of the third ventricle belongs to the telencephalon; it includes the layer of grey matter, known as the **lamina terminalis**, which forms the anterior extremity of the primitive neural tube (Fig. 829).

Development of Parts derived from Fore-Brain

The lateral wall of the telencephalon grows out on each side to form a diverticulum which ultimately constitutes the cerebral hemisphere, and thus, from a very early period, the primitive position of that part of the side-wall is indicated by the interventricular foramen—an aperture of communication between the cavity of the cerebral hemisphere and the third ventricle (Fig. 836).

The lateral wall of the diencephalon undergoes a thickening, the main part of which forms the thalamus. It arises as a large oval swelling which gradually approaches its fellow of the opposite side, and thus diminishes the width of the third ventricle. Finally, the two bodies sometimes come into contact in the median plane and cohere over an area corresponding to the interthalamic connexus. This may occur about the end of the second month.

On the posterior part of the thalamic thickening there appear on the surface two small elevations—the lateral and medial geniculate bodies. With the expansion of the thalamus as a whole these bodies become pushed farther back. It thus comes about that in the adult brain the medial geniculate body seems to hold a position on the lateral aspect of the mid-brain, whilst the lateral geniculate body, viewed from the surface, appears on the lower surface of the posterior pole of the main part of the thalamus.

Above the thalamus, a smaller thickening of the lateral wall of the diencephalon appears close to the roof of the third ventricle. This is the epithalamus. From it are developed the pineal body, its peduncle, and the habenular region. These parts are relatively much more evident in the embryonic brain than in the adult. The pineal body appears to be developed as a diverticulum of the posterior part of the roof of the diencephalon, but in reality it is a derivative of the alar lamina. Viewed from the dorsal aspect of the brain-tube, this diverticulum shows, in the first instance, as a rounded elevation, from each side of which a broad ridge runs forwards. The ridge becomes the stria habenularis, whilst in the region of its junction with the pineal elevation the trigonum habenulæ takes shape. The pineal diverticulum ultimately becomes solid, but a small portion of the original cavity is retained as the pineal recess of the third ventricle.

The floor of the diencephalon contributes to the formation of the hypothalamus. This is separated from the thalamic swelling by a sulcus—the hypothalamic sulcus—which is still to be recognized in the adult brain. The hypothalamus shows several elevations from which are derived the mamillary bodies, the tuber cinereum, and the cerebral part of the hypophysis. In front of the tuber cinereum are seen the optic chiasma and the optic recess. The anterior wall of the recess is formed by the lamina terminalis. The mamillary body forms, in the first instance, a relatively large ventral bulging of the floor of the brain-tube. As development goes on, this bulging becomes relatively small, and about the fourth month the single projection

becomes divided into a pair of tubercles. The infundibulum and the posterior or cerebral lobe of the hypophysis are developed as a hollow downgrowth of the floor of the third ventricle (Fig. 836). A portion of the original cavity is retained in the upper part of the infundibulum, and constitutes the infundibular recess in the floor of the third ventricle.

The **optic nerve** is formed by the growth of fibres backwards from the retina in the wall of the original optic stalk, whilst the chiasma takes form by the passage of fibres across the median plane in front of the infundibulum and behind the optic recess. These fibres are derived from the optic nerve. The optic recess of the third ventricle marks the spot where the optic vesicle was originally attached to the inferior and lateral part of the fore-brain, and in the adult it therefore represents a portion of the primitive cavity of the tubular stalk of the optic vesicle. In the course of development the optic nerve-fibres, which appear in the stalk of the optic vesicle to form the optic nerve, seek an attachment much farther back, and through the optic tract they are even carried as far as the mid-brain.

The **roof of the fore-brain** remains thin, and does not proceed to the development of nervous elements, although its posterior part becomes invaded by nervous tissue to form the pineal body and the posterior commissure. In front of these structures the roof of the fore-brain remains ependymal and constitutes the roof of the third ventricle. Along each side of the median plane it becomes invaginated into the third ventricle to form the choroid plexus (Figs. 829, 838). The posterior commissure appears as a transverse thickening at the bottom of the groove which lies in the roof of the early brain-tube below the pineal diverticulum.

Parts derived from Diencephalon

Under this heading we have to consider: (1) the **thalamus**; (2) the **epithalamus**, which comprises the pineal body and the habenular region; and (3) the **hypothalamus.**

Thalamus.—The thalamus is the principal structure in this section of the brain

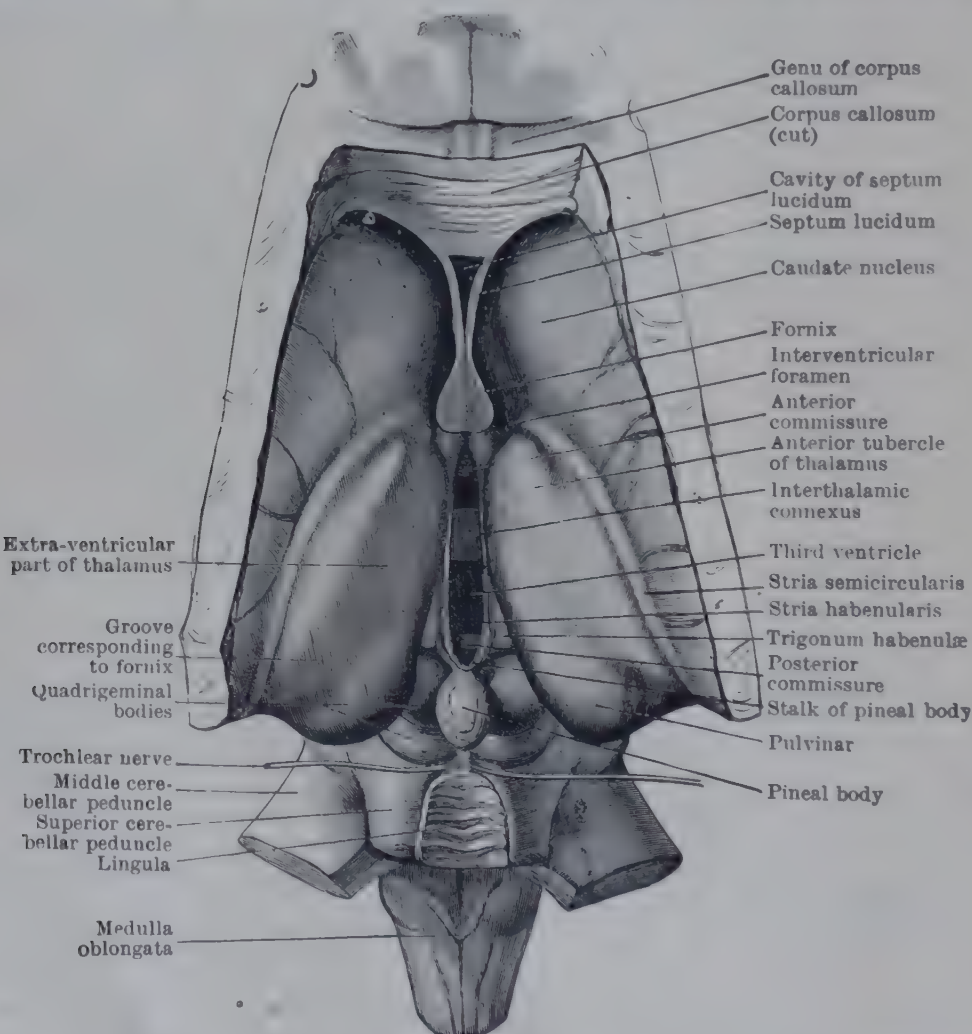

Fig. 824.—Thalami and the Parts of the Brain around them.

(Fig. 824). It is a large, ovoid mass of grey matter which lies obliquely across the path of the cerebral peduncle (Fig. 826). The anterior end of the thalamus lies close to the median plane, and is separated from the corresponding part of the

opposite side by a very narrow interval. The posterior ends of the thalami are larger, and they are farther apart, being separated by a fairly wide interval in which the corpora quadrigemina are seen.

The two thalami, in their anterior two-thirds, lie close together, one on each side of the deep, median cleft called the third ventricle of the brain. The inferior and lateral surfaces are in apposition with, and indeed, directly connected with, adjacent parts of the brain, and on that account it is customary to study them by means of sections through the brain. The superior and medial surfaces face towards ventricular cavities and are mainly free.

The *lateral surface* of the thalamus is applied to a thick layer of white matter, interposed between it and the lentiform nucleus, called the **internal capsule** and composed mainly of fibres passing to and from the cerebral cortex ; a large proportion of these fibres descend to form the basis pedunculi. From the entire extent of the lateral surface of the thalamus large numbers of fibres stream out and enter the internal capsule, to reach the cerebral cortex. They constitute what are termed the **thalamic radiations**. As the fibres leave the thalamus over the whole of its lateral surface they form a very distinct reticulated stratum which is termed the **external medullary lamina.**

The *inferior surface* of the thalamus rests on the hypothalamus. From the latter region many fibres enter the most medial part of the thalamus on its inferior surface, whilst other fibres leave this surface of the thalamus and sweep laterally to take part in the thalamic radiations.

The *superior surface* of the thalamus is free. Laterally it is bounded by a groove which runs antero-posteriorly along the floor of the lateral ventricle of the brain and intervenes between the thalamus and the caudate nucleus. In this groove is placed a slender band of longitudinal fibres termed the **stria semicircularis**, and also the thalamo-striate vein. Medially, the superior surface is separated from the medial surface in its anterior half by a sharp ledge of the ependyma of the third ventricle raised up by a subjacent longitudinal strand of fibres called the **stria habenularis.** When these two structures—the ependymal ridge and the subjacent stria—are traced backwards, they are seen to turn medially and become continuous with the stalk of the pineal body. Behind the portion of the stria which turns medially towards the pineal body a small depressed triangular area situated in front of the superior corpus quadrigeminum—the **trigonum habenulæ**—forms a very definite medial boundary for the posterior part of the superior surface of the thalamus.

The superior surface of the thalamus is slightly convex, and it is of a whitish colour, owing to the presence of a thin superficial covering of nerve-fibres termed the **stratum zonale**. It is divided into two areas by a faint oblique groove which is an impression caused by the edge of the fornix. The two areas which are thus mapped out are very differently related to the ventricles of the brain, and also to the parts which lie above the thalamus. The *lateral area*, which includes the anterior end of the thalamus, forms a part of the floor of the lateral ventricle ; it is covered with ependyma and is overlapped by the choroid plexus of this ventricle. Along the line of the groove the ependymal lining of the lateral ventricle is reflected over the choroid plexus. The *medial area*, which includes the posterior end of the thalamus, intervenes between the lateral and third ventricles of the brain, and takes no part in the formation of the walls of either. It is covered by a fold of pia mater, termed the tela chorioidea of the third ventricle, above which is the fornix, and these two structures intervene between the thalamus and the corpus callosum (Fig. 829, and Fig. 855, p. 971).

The *anterior end* of the thalamus bulges up into the lateral ventricle, forming an elevation which is called the **anterior tubercle of the thalamus**, and it is separated from the anterior column of the fornix by the interventricular foramen. The ependymal roof of the passage between the two interventricular foramina is, on each side, continuous with an ependymal strip that extends along the upper limit of the medial wall of the thalamus behind the foramen. These ependymal strips in the medial wall of the lateral ventricle and in the roof of the third ventricle between them are invaginated by the vascular pia to form a continuous sulcus in

the ependymal area of the brain-wall called the **choroid fissure.** The vascular pia mater covered by the ependymal brain-wall is called the **choroid plexus** (Figs. 829, 837, and 838).

The *posterior end* of the thalamus is very prominent and forms a rather sharp, rounded projection which overhangs the brachia of the corpora quadrigemina. This prominence is called the **pulvinar**. On the lateral part of the lower surface of the pulvinar there is a small bulging called the **lateral geniculate body**; most of the fibres of the optic tract end in it.

The *medial surfaces* of the anterior parts of the two thalami are placed close together, and are covered by the lining ependyma of the third ventricle. A band of grey matter, termed the **interthalamic connexus**, crosses the third ventricle and joins the two thalami together.

Intrinsic Structure and Connexions of Thalamus.—In its early development the thalamus consists of a relatively homogeneous mass of cells in the wall of the third ventricle. It then undergoes a rapid differentiation and becomes divided into a number of separate nuclear elements which are to be distinguished not only by their topographical position but also by their fibre-connexions and the arrangement and appearance of their cells. Some of these thalamic nuclei can be readily defined on macroscopic inspection of unstained sections cut through the thalamus, for they consist of circumscribed areas of grey matter outlined by thin medullary laminæ of white matter (Fig. 826). They are as follows: ventral nucleus, lateral nucleus, the pulvinar, anterior nucleus, medial nucleus, centre-median nucleus, and the lateral and medial geniculate bodies. (Le Gros Clark, 1936; Walker, 1938.)

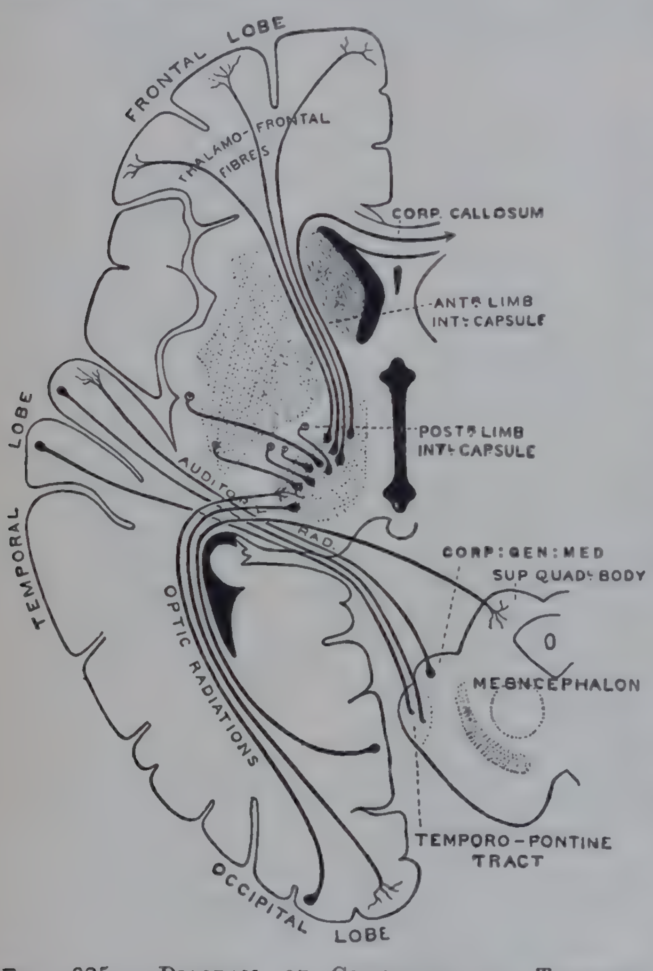

Fig. 825.—Diagram of Connexions of Thalamus with Cerebral Cortex, and of Cortex with Mid-Brain.

The **ventral nucleus** of the thalamus is very indistinctly demarcated from the lateral nucleus. Indeed, the two elements are commonly included under the common term *ventro-lateral nucleus.* The ventral nucleus, however, is distinguished by the fact that it is the terminal station of two systems of fibres which reach it from lower levels of the central nervous system, the lemniscus-system and dentato-thalamic fibres from the cerebellum. The posterior part of the ventral nucleus receives the lemniscus-fibres, and these consist of the medial lemniscus, the spino-thalamic tracts ("spinal lemniscus"), and the secondary trigeminal fibres ("trigeminal lemniscus"). It is therefore a terminal centre for proprioceptive and exteroceptive sensory impulses derived from all parts of the body, and it may appropriately be termed the "lemniscus-nucleus". From its cells a mass of thalamo-cortical fibres takes origin through which these sensory impulses are relayed on to the sensory area of the cerebral cortex, which lies behind the central sulcus. It may be noted that the different regions of the body acquire quite a definite topographical representation within the "lemniscus-nucleus", for sensory impulses from the lower limb terminate in its most lateral part, those from the upper limb in an intermediate position, and those from the head and face region in the most medial portion. Consequently, it is possible for

a small localized pathological lesion in the thalamus to give rise to sensory disturbances in one part of the body only.

The anterior part of the ventral nucleus receives terminal fibres from the dentate nucleus of the cerebellum, and projects on to the motor area of the cerebral cortex in front of the central sulcus. It is therefore a relay centre through which the motor area is brought into functional relation with the opposite half of the cerebellum.

In lower mammals it has been found by experiment that the extreme anterior end of the ventral nucleus appears to receive neither fibres of the lemniscus nor dentato-thalamic fibres, and its connexions remain obscure.

The **lateral nucleus** extends along the upper and lateral part of the thalamus, reaching to the ventricular surface. So far as is known, it receives no fibres from the lower levels of the brain and its afferent connexions are probably derived entirely from other nuclear elements of the thalamus. Its efferent connexions are almost entirely with the parietal lobe of the cerebral hemisphere behind the sensory area of the cortex, but its anterior part probably sends fibres to the cortex of the frontal lobe in front of the motor area. In other words, it is connected with the so-called "association areas" of the cerebral cortex.

The **pulvinar** is really a posterior extension of the lateral nucleus. Superficially it is conspicuous because it forms the prominent posterior pole of the thalamus which projects back in close relation to the superior corpus quadrigeminum of the mid-brain. Its afferent connexions are not known, but it projects on to those areas of the cortex which extend in front of the visual area.

The **anterior nucleus** can be located in the intact thalamus because it is responsible for raising up on the anterior part of its upper surface a small oval eminence—the anterior tubercle—which lies in the floor of the body of the lateral ventricle (Fig. 826). It is a very well-defined element in the human brain. Entering it from below is a sharply circumscribed tract of white fibres——the *mamillo-thalamic tract*—which arises in the mamillary body. Its cells give origin to thalamo-cortical fibres which are distributed to the whole length of the gyrus cinguli of the cerebral hemisphere. The functional significance of the anterior nucleus is still quite obscure, for nothing is yet known of the nature of the impulses conveyed by the mamillo-thalamic tract.

The **medial nucleus**, as seen in transverse section, is a rounded mass of grey matter lying at the upper surface of the thalamus close to the median plane (Fig. 826). Because of its dark colour, which is due to the relative absence of medullated nerve-fibres in its substance, it is a particularly well-defined element. The efferent connexions of the medial nucleus are entirely with the frontal areas of the cerebral cortex, which lie anterior to the motor and premotor areas, and it receives afferent fibres from the hypothalamus which ascend close to the side-wall of the third ventricle. It has been suggested, therefore, that the medial nucleus is essentially a relay mechanism through which the more primitive activities of the hypothalamus are brought into relation with the higher functional levels of the cerebral cortex.

The **centre-median nucleus** is found in the posterior part of the thalamus, lying between the medial nucleus above and the ventral nucleus below. It stands in marked contrast with the other main nuclei of the thalamus in that it has no connexions at all with the cerebral cortex. It is commonly regarded as an integrating mechanism through which other thalamic nuclei are interrelated, but there is no certain knowledge regarding its connexions.

The **geniculate bodies** are developmentally a part of the thalamus, and make their appearance as a differentiated portion of the mass of cells which contribute to the formation of the ventral nucleus. The **lateral geniculate body** is composed in the central region of its posterior two-thirds of a series of six grey laminæ separated by intervening laminæ of white matter. In suitably stained sections the grey laminæ can be seen to be made up of closely packed cells which receive the termination of the optic tract fibres. The latter enter the geniculate body mainly from in front and below, and spread out fanwise to reach the various grey laminæ.

The white laminæ are composed predominantly of axons of the cells of the grey laminæ. These collect together to form the optic radiation through which retinal impulses are ultimately projected on to the visual area of the occipital cortex. The more detailed connexions of the lateral geniculate body will be studied with the optic tract.

The **medial geniculate body** possesses none of the elaborate structure of the lateral geniculate body, for it is composed of an almost homogeneous mass of medium-sized cells. It receives auditory impulses (mainly, but not entirely, from the opposite side) which are conveyed to it by the lateral lemniscus, and its efferent connexions are entirely with the auditory area of the temporal cortex.

It will be observed that, with the exception of the centre-median nucleus, which has no cortical connexions, the greater part of the thalamus can simply be regarded as a nuclear mass interposed between various sensory tracts and the cerebral cortex. In other words, it is a relay station for the projection of these sensory impulses on to the cerebral cortex. It is of some importance to note also that the various cortical areas concerned are also related to the corresponding thalamic nuclei by descending cortico-thalamic fibres. At one time these were believed to provide an inhibitory mechanism whereby the activities of the thalamic centres are "damped down". However, it has been demonstrated by electro-physiological methods that the impulses which they convey actually increase these activities. It is probable that, through the cortico-thalamic fibres, the cerebral cortex is enabled to raise the sensitivity of the thalamic nuclei to afferent impulses reaching it by ascending sensory tracts. Thus the fibres may be regarded as forming part of a mechanism of sensory attention.

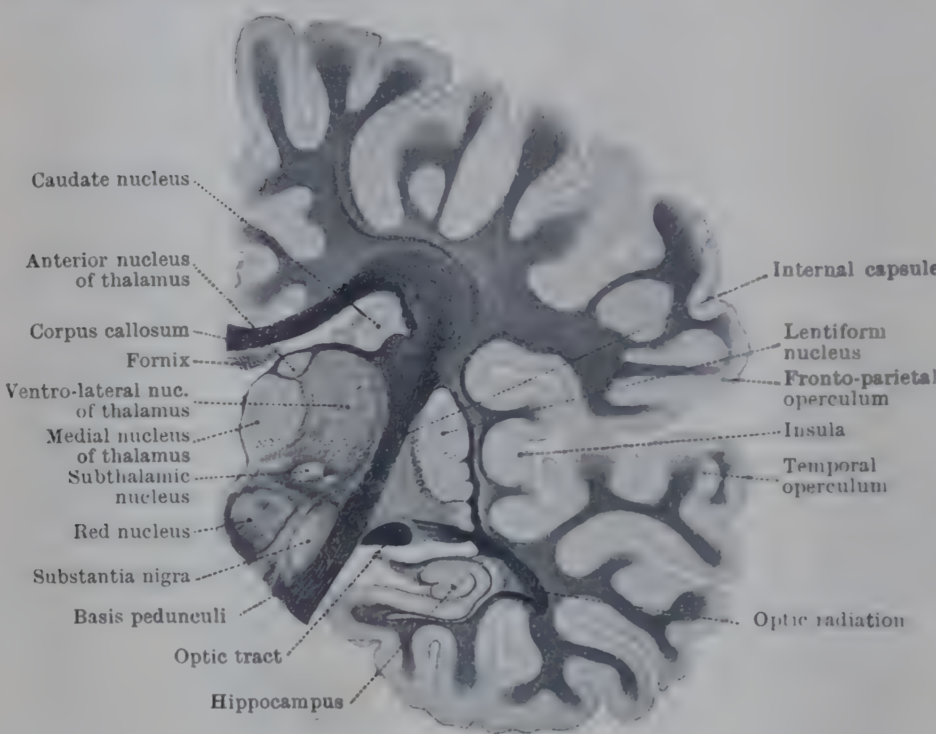

FIG. 826.—FRONTAL SECTION THROUGH CEREBRUM.

Subthalamic Region.—The tegmentum of the mid-brain is prolonged upwards and assumes a position below the posterior part of the thalamus. Here it becomes continuous with a region of the diencephalon which is called the *subthalamus.* This occupies a topographical position between the thalamus above and the cerebral peduncle below, while medially it is bounded by the hypothalamus. Broadly speaking, the subthalamus may be regarded as a structural and functional link between the basal nuclei of the forebrain and the tegmental region of the mid-brain. The **red nucleus** is a conspicuous object in sections through the upper extremity of the tegmentum (Fig. 826) and, gradually diminishing, it disappears before the level of the mamillary body is reached. Carried up around it are the same longitudinal tracts of fibres which have been studied already in relation to it in the mid-brain. Certain of these fibres, placed in immediate relation to the red nucleus, form a *capsule* for it. This capsule is partly derived from those fibres of the superior cerebellar peduncle which pass directly up into the thalamus and also partly from fibres which issue from the nucleus itself. The **medial lemniscus** takes up a position lateral to the red

PLATE LXXIII

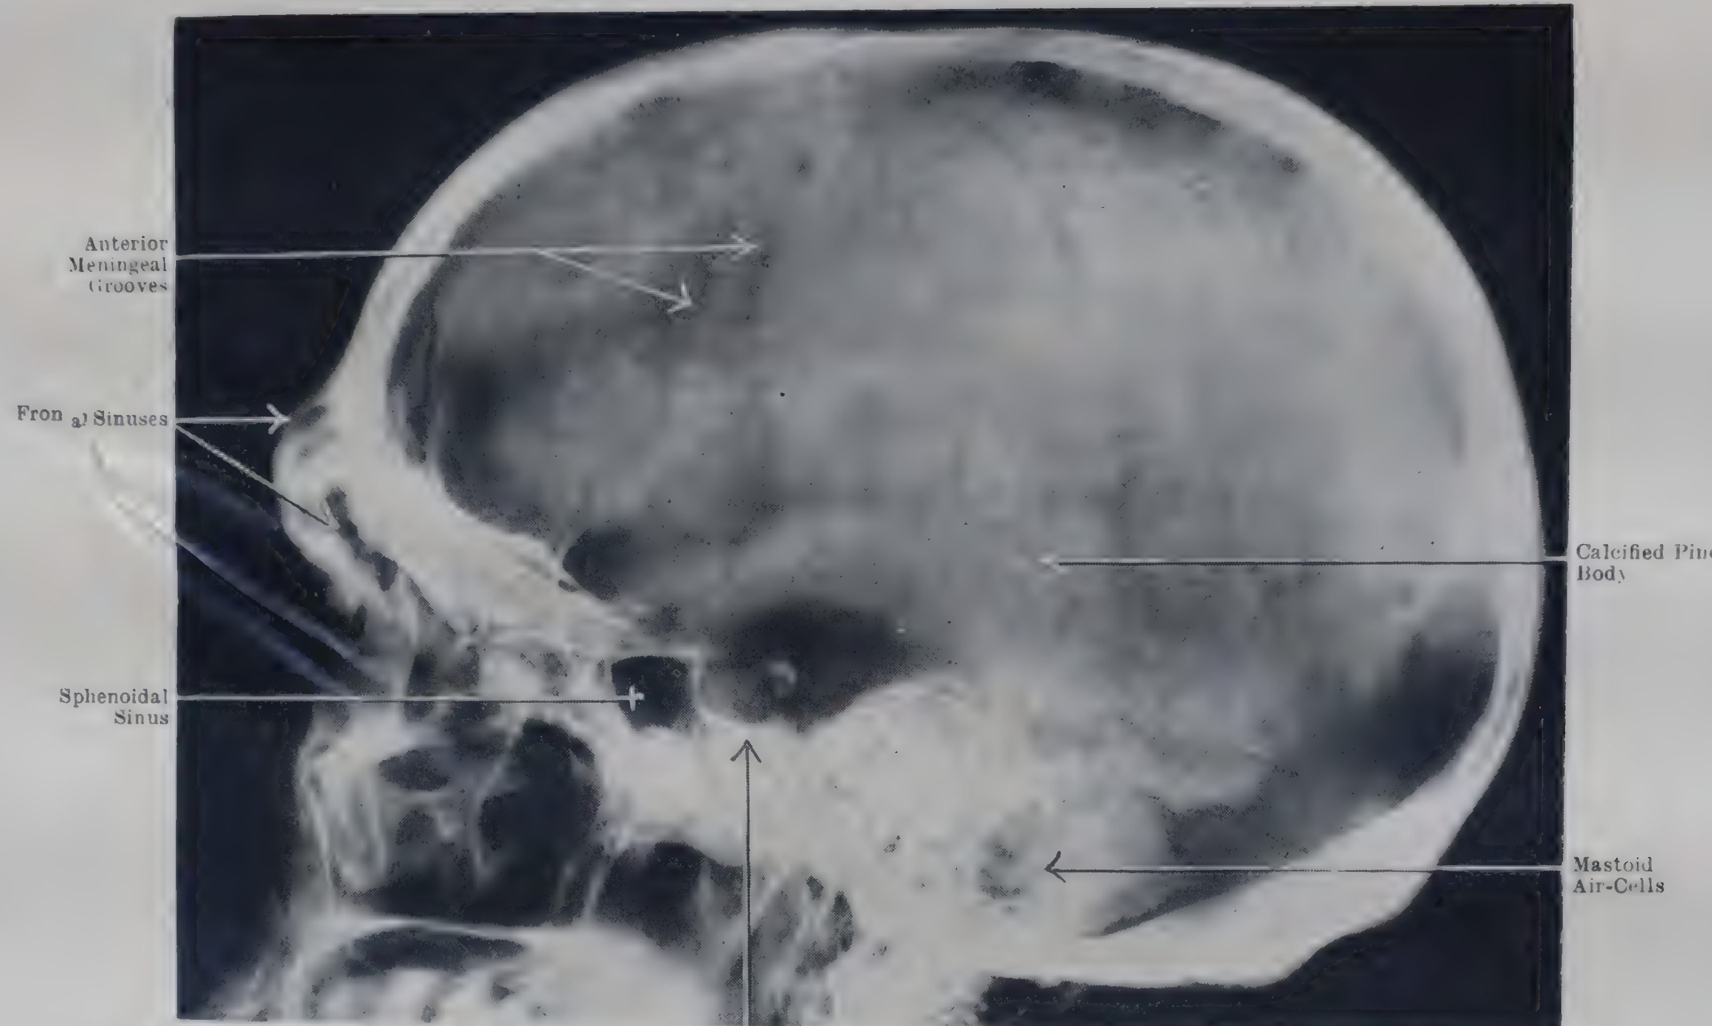

PLATE LXXIII.—LATERAL RADIOGRAPH OF HEAD OF MAN AGED 63, SHOWING HYPOPHYSIAL FOSSA AND CALCIFIED PINEAL BODY.

PLATE LXXIV

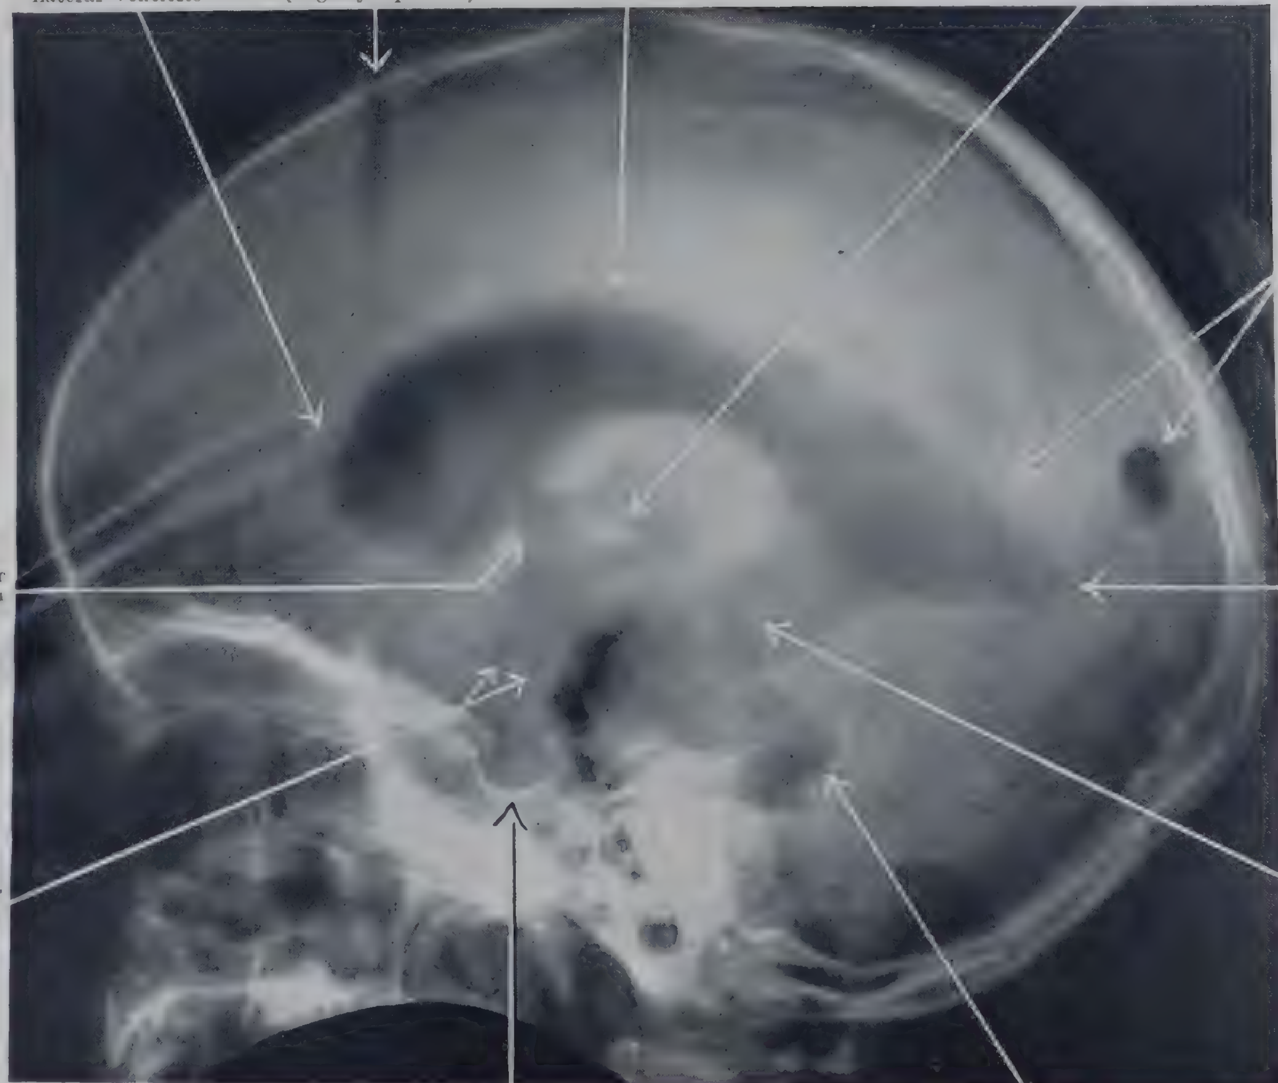

PLATE LXXIV.—LATERAL RADIOGRAPH OF LIVING HEAD OF CHILD AGED 4, AFTER DIRECT INJECTION OF OXYGEN INTO THE LATERAL VENTRICLES (Ventriculograph: Professor Norman M. Dott).

The oxygen-filled Ventricular System appears in the radiograph, like the air-filled sinuses, on account of its relative translucency to the X-Rays. The darker area is due to the overlap of the anterior horns of the two Lateral Ventricles; in this child the whole ventricular system was slightly distended, but the general form is well shown; compare with Plate LXXV, p. 960, for

[Facing p.

nucleus on a posterior plane. When the red nucleus comes to an end, these various fibres are continued onwards and form, in the position previously occupied by the nucleus, a very evident and dense mass of fibres. The fibres of the medial lemniscus and the superior cerebellar peduncle are prolonged upwards into the ventral part of the thalamus, where they end in connexion with the cells of the ventral nucleus.

The **substantia nigra** also is carried into the subthalamic region, where it maintains its original position dorsal to the basis pedunculi. As it is traced upwards, it is seen to diminish gradually in amount. It shrinks from the medial to the lateral side, and finally disappears when the level of the posterior part of the mamillary body is reached.

In coronal sections through the subthalamic region, the most conspicuous

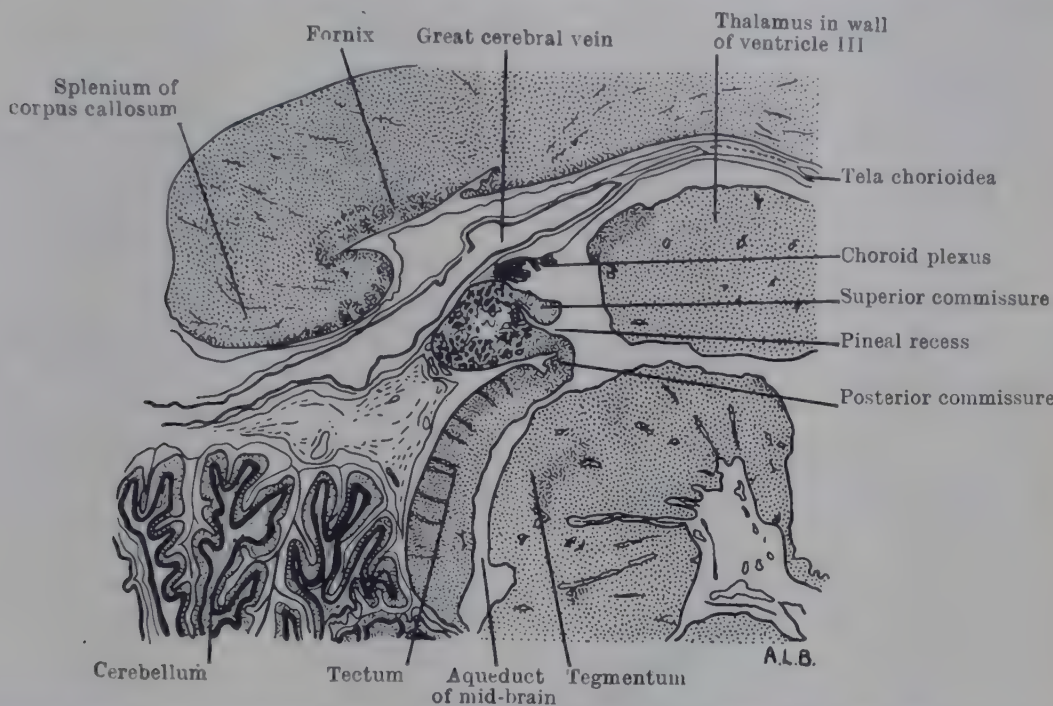

FIG. 827.—MEDIAN SECTION THROUGH THE PINEAL REGION OF A HUMAN BRAIN SHOWING THE RELATIONS OF THE PINEAL BODY. (After Gladstone & Wakeley, 1940.)

object which comes into view is the **subthalamic nucleus** (Fig. 826). It is a small brownish mass of grey matter, shaped like a biconvex lens, which makes its appearance behind the basis pedunculi immediately to the lateral side of the substantia nigra, and, enlarging rapidly in a medial direction, it takes the place of the diminishing substantia nigra. The subthalamic nucleus is made all the more evident by the fact that it is sharply defined by a thin capsule of white fibres. On its medial side these fibres proceed medially and form a very evident decussation across the median plane in the floor of the third ventricle, immediately above the posterior ends of the mamillary bodies. It receives fibres from the globus pallidus of the corpus striatum and emits fibres to the substantia nigra and the tegmentum.

Epithalamic Region.—In the roof of the third ventricle and at its attached margin are certain elements of the diencephalon which collectively form the *epithalamus*. These elements include the pineal body, the habenular commissure, the stria habenularis, and the trigonum habenulæ.

Pineal Body.—This is a small, reddish-brown, conical structure about 7-8 mm. in length with a blunted apex. Its base is attached by a pedicle or stalk to the posterior end of the roof of the third ventricle, and it lies in the groove between the two superior corpora quadrigemina and under cover of the splenium of the corpus callosum (Fig. 827). The stalk of the pineal body is hollowed out by a small recess from the cavity of the third ventricle. Superiorly, the stalk divides and each half curves forwards lateral to the median plane and appears to become continuous with the stria habenularis. Inferiorly, it becomes continuous with the posterior commissure (Fig. 714, p. 828).

The pineal body is composed mainly of a peculiar type of neuroglial tissue, the cells of which have an intimate relation to the capillaries of the vascular plexus which pervades it. These cells are characterized by long processes which extend for some distance in the connective tissue which surrounds the lobules into which the body is subdivided. Their function is not yet determined. It contains also a plexus of nerve-fibres, but it is probable that most of these accompany the blood-vessels which enter the gland. Other nerve-fibres can be seen to extend from the stria habenularis and the habenular nucleus into the pineal body by way of its stalk. There is some evidence that many of these (if not all) are aberrant fibres of the habenular commissure which enter the base of the gland on one side and leave it on the other. Lastly, a fine bundle of nerve-fibres has been described extending from the tip of the pineal body along the great cerebral vein to the floor of the straight sinus in the tentorium cerebelli. The significance of this fasciculus, which has been termed the *nervus conarii*, is not known. The pineal body commonly contains calcareous concretions (" brain sand ") which are sometimes clearly visible in radiographs (Pls. LXXIII, p. 944 and LXXIV, p. 945).

It is frequently stated that the pineal body is a vestigial structure—the remains of the pineal eye of lower vertebrates. This statement, however, is incorrect, for in lower vertebrates the pineal body may be found in association with a pineal eye. Clinical and experimental evidence has from time to time been advanced, which suggests that the pineal body is one of the endocrine glands and that it is related to the growth of the body and particularly the maturation of sexual characters. This evidence, however, is inconclusive, and the functions of the pineal body remain obscure. (See also p. 827, and the monograph by Gladstone & Wakeley, 1940.)

Trigonum Habenulæ.—The small, triangular, depressed area which receives this name lies immediately in front of the superior corpus quadrigeminum in the interval between the stalk of the pineal body and the posterior end of the thalamus (Fig. 824, p. 940). It marks the position of a small mass of nerve-cells which constitute the **habenular nucleus**. The axons of these cells emerge through the lower surface of the ganglion and form a bundle, called the **fasciculus retroflexus**, which takes a curved course downwards and forwards in the tegmentum of the mid-brain, close to the medial side of the red nucleus, and ends in the **interpeduncular nucleus** (p. 923).

The habenular nucleus is intimately connected also with the striæ habenulares and the dorsal part of the stalk of the pineal body.

As previously stated, the **stria habenularis**—a very evident band of white matter—lies on the thalamus at the junction of its medial and superior surfaces, subjacent to an ependymal ridge. When traced backwards, many of the fibres of the stria are observed to end amongst the cells of the habenular nucleus, whilst others are continued past the nucleus to enter the stalk of the pineal body, and, through it, to reach the habenular nucleus of the opposite side, in connexion with the cells of which they terminate. The stria habenularis, therefore, ends partly in the habenular nucleus of its own side and partly in the corresponding nucleus of the opposite side. The decussation of fibres across the median plane forms the dorsal part of the pineal stalk, and is termed the **habenular commissure**.

When the stria habenularis is traced in the opposite direction, it is noticed to split into dorsal and ventral parts near the anterior column of the fornix. The *dorsal part* arises from cells in the hippocampus: these fibres pass into the fornix and when they reach its anterior column they turn abruptly backwards to enter the stria habenularis. The *ventral part* springs from a collection of cells in the grey matter on the base of the brain close to the optic chiasma. The functional significance of the striæ habenulares is unknown.

Hypothalamus.—The part of the brain which forms the floor of the third ventricle, extending from the optic chiasma in front to the upper border of the pons behind, is called the hypothalamus. (Le Gros Clark, Beattie, Riddoch & Dott, 1938; Fulton, 1940.) It contains various elements of grey matter connected by numerous fibre-tracts with each other and with more distant parts of the brain. Viewed from the basal aspect, several features of the hypothalamus can be distinguished macroscopically. These are the *posterior perforated substance*, the *mamillary bodies*, and the *tuber cinereum*.

Posterior Perforated Substance.—This has already been mentioned on p. 878. It is perforated by a number of small vessels—the postero-medial central arteries—

which are derived from the posterior cerebral arteries close to their origin. It is situated at the posterior end of the hypothalamus and should probably be regarded as a part of it.

Mamillary Bodies.—These are a pair of round, white bodies, each about the size of a pea, which lie side by side in the interpeduncular fossa on the base of the brain, immediately in front of the posterior perforated substance.

Each mamillary body is coated on the outside by white matter derived from the anterior column of the fornix, and it contains, in its interior, a composite grey nucleus with numerous nerve-cells. Several important strands of fibres are connected with the mamillary body: (1) The anterior **column of the fornix** curves downwards in the side-wall of the third ventricle to reach the mamillary body in which its fibres end amidst the cells. (2) A bundle of fibres—the **mamillo-thalamic tract**—takes origin in the substance of each mamillary body and extends upwards into the thalamus to end in fine arborizations around the large cells in its anterior nucleus. (3) Another bundle of fibres—the **mamillo-tegmental tract**—takes form within the mamillary body and extends downwards in the grey matter of the floor of the third ventricle, to reach the tegmentum of the mid-brain. This tract is among the most ancient fibre-systems in the brain. Its functional significance, however, is not known.

Tuber Cinereum and Infundibulum.—The tuber cinereum is a small, slightly prominent field of grey matter which occupies the anterior part of the interpeduncular fossa between the mamillary bodies behind and the optic chiasma in front. From its anterior part the **infundibulum**, or stalk of the hypophysis, projects downwards and forwards to connect the base of the brain with the hypophysis. In its upper part the infundibulum is hollow—a small, funnel-shaped diverticulum of the cavity of the third ventricle being prolonged downwards into it.

Hypophysis Cerebri.—This is a small oval structure, flattened from above downwards and with its long axis directed transversely, which occupies the hypophysial fossa in the floor of the cranium. It has two lobes—a large anterior lobe and a smaller posterior lobe—which are closely applied the one to the other. The infundibulum is attached to the posterior lobe (see also p. 822).

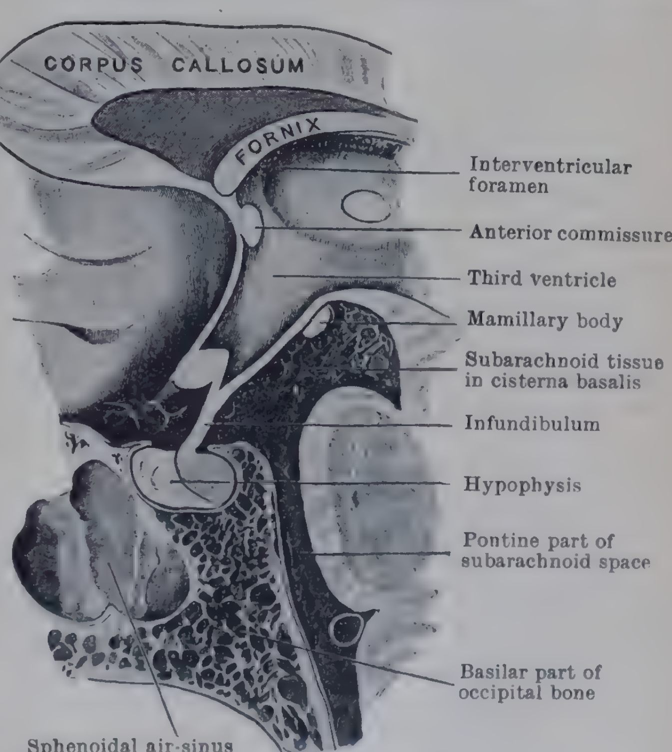

FIG. 828.—MEDIAN SECTION THROUGH THE HYPOPHYSIAL REGION.

The infundibulum and posterior lobe of the hypophysis are developed in the form of a hollow diverticulum which grows downwards from the floor of that part of the embryonic brain which afterwards forms the third ventricle. The original cavity of that diverticulum becomes obliterated, except in the upper part of the infundibulum. In structure, the posterior lobe of the hypophysis is chiefly composed of a peculiar type of neuroglial tissue with characteristic branched cells called "pituicytes". It is vascularized by a fine network of blood-vessels and receives a small but important tract of non-medullated nerve-fibres which has its origin in the hypothalamus. (See the Section on Ductless Glands, p. 824.)

The anterior lobe has quite a different origin—being derived from a tubular diverticulum which grows upwards from the primitive oral cavity. Its connexion with the latter (cranio-pharyngeal canal) is cut off in the course of embryonic development, and the diverticulum becomes encased within the cranial cavity in intimate association with the cerebral portion of the organ. Structurally, it consists of groups and columns of epithelial cells surrounded by capillary vessels.

The hypophysis is intimately connected with the hypothalamus by (1) blood-vessels which extend through the infundibulum and provide a vascular connexion between the sinusoids in the oral portion of the gland and the capillary network in the substance of the hypothalamus (see p. 824), and (2) by nerve-fibres that issue from the hypothalamus and pass into the nervous portion of the hypophysis. In the disease known as acromegaly, the hypophysis is usually greatly enlarged. The proximity of the hypophysis to the optic chiasma accounts for the frequent affection of the visual paths by tumours of the gland.

Intrinsic Structure of Hypothalamus.—Microscopical examination of different parts of the hypothalamus shows that it consists of a complicated series of cell-groups and fibre-tracts. It is not appropriate here to deal with these in detail, but a brief reference to

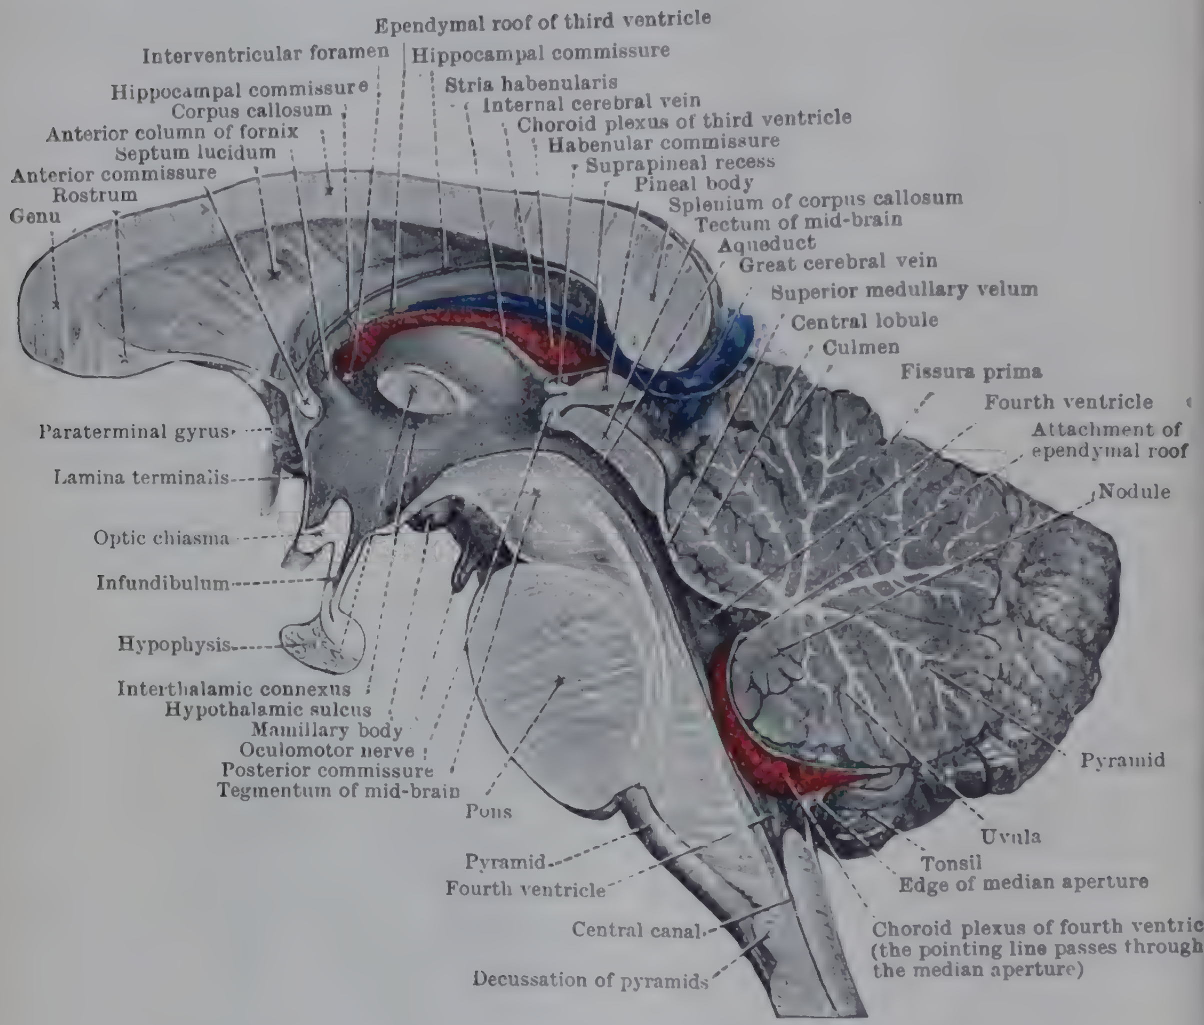

FIG. 829.—THE PARTS OF THE BRAIN CUT THROUGH IN A MEDIAN SECTION. The side-walls of the ventricular cavities also are shown.

them is desirable because of their functional importance. The hypothalamus is one of the most primitive parts of the fore-brain, and experimental and clinical evidence indicates that it is a regulatory centre for the control of the autonomic nervous activities of the body. Lesions of the hypothalamus are therefore often associated with vaso-motor, viscero-motor, and various metabolic disturbances. Anatomically, it is convenient to divide the hypothalamus into three regions antero-posteriorly. In front, in close relation to the optic chiasma, is the **pars optica hypothalami.** This contains two nuclei of closely packed, large nerve-cells—the *paraventricular nucleus* above and the *supra-optic nucleus* below. The latter straddles the optic chiasma on each side of the median plane, and it is this element which mainly gives rise to the tract of fibres which descends to the posterior lobe of the hypophysis—the supra-optico-hypophysial tract. Bilateral lesions of this tract are associated with diabetes insipidus. Behind the pars optica is the **pars tuberalis hypothalami.** This is represented on the base of the brain by the tuber cinereum; it contains several collections of small round cells; and on its surface a series of circumscribed cell-groups—the *nuclei tuberis*—may be responsible for raising up a number of small tubercles which are visible macroscopically. The posterior part of the hypothalamus is the **pars mamillaris hypo-**

thalami. It contains the *nuclei of the mamillary bodies*, together with some more diffuse collections of cells.

From most parts of the hypothalamus, but principally from the posterior region, fine, non-medullated fibres take origin and pass upwards and backwards in the side-wall of the third ventricle to reach a position in the mid-brain immediately in front of the aqueduct. This is the *periventricular system of fibres*, and it is the main efferent path through which the hypothalamus is brought into efferent relation with the splanchnic motor nuclei of the brain-stem, and possibly also with the spinal cord.

Third Ventricle.—The third ventricle is the narrow cleft between the two thalami. Its depth rapidly increases from behind forwards, and it extends from the pineal body behind to the lamina terminalis in front. Its *floor* is formed by the tuber cinereum and the mamillary bodies, and the posterior perforated substance (Figs. 828 and 829). It is interesting to note that the central grey matter which surrounds the aqueduct is directly continuous with the grey matter of the

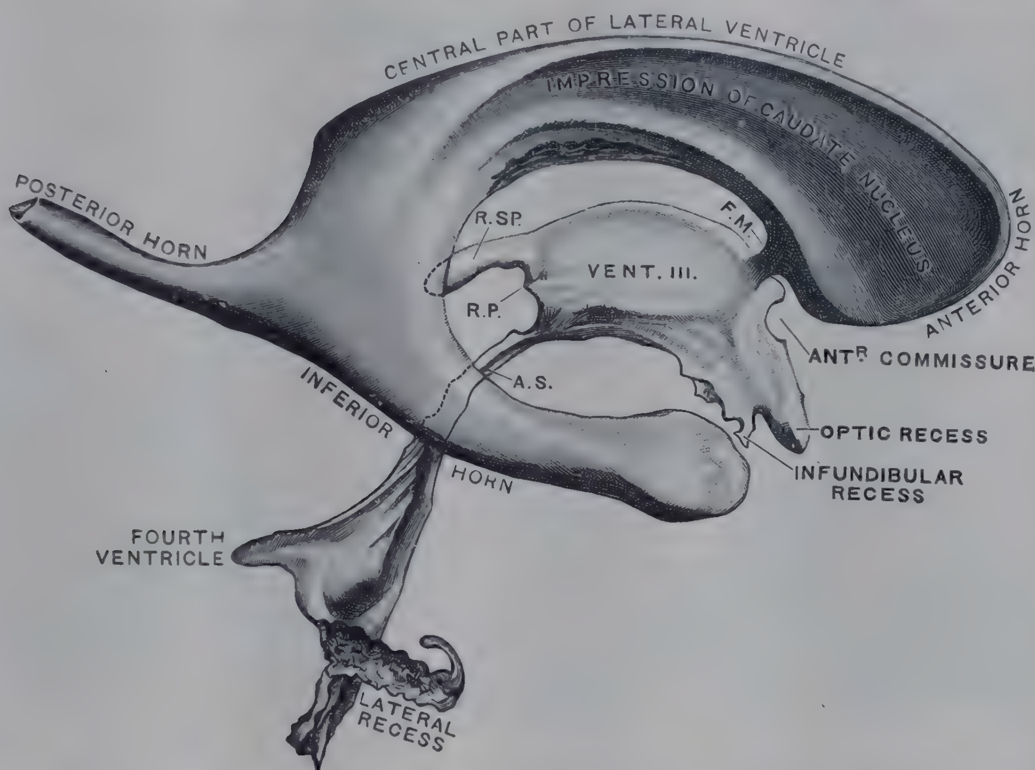

FIG. 830.—PROFILE VIEW OF A CAST OF THE VENTRICLES OF THE BRAIN. (From Retzius, 1900.)

R.SP. Suprapineal recess. A.S. Aqueduct.
R.P. Pineal recess. F.M. Interventricular foramen.

posterior perforated substance and tuber cinereum, and in this way it comes to the surface in the base of the brain. The optic chiasma crosses the floor in front and marks the place where the floor becomes continuous with the anterior wall. The *anterior wall* is formed by the lamina terminalis. This is a thin, delicate lamina which stretches from the optic chiasma in an upward direction to become connected with the rostrum of the corpus callosum. In the anterior part of the cleft between the two thalami, and immediately in front of the anterior columns of the fornix, a round bundle of fibres crosses the median plane in the lamina terminalis. This is the anterior commissure. The anterior commissure bulges into the ventricle from the anterior wall, but, of course, it is excluded from the cavity by the ventricular ependyma. It may be taken as indicating the place where the roof joins the anterior wall. The *roof* is merely the part of the ependymal lining that stretches across the median plane from one stria habenularis to the other. Applied to the upper surface of the ependymal roof is the fold of pia mater termed the tela chorioidea, and the roof is invaginated into the cavity along its whole length by two delicate choroid plexuses which hang down from the under surface of the fold one on each side of the mid-line. When the tela is removed the ependymal roof is torn away with it, leaving only the lines of attachment in the shape of the ridges that cover the striæ habenulares (Fig. 824).

Each *side-wall* of the third ventricle is formed for the greater part of its extent by the medial surface of the thalamus. A little in front of the middle of the ventricle the cavity is usually crossed by the *interthalamic connexus*, which links the thalami one with the other. It apparently has no functional significance, for in the human brain few, if any, fibres cross in it from one side to the other; it is also variable in size and form, and may be altogether absent. In front of the interthalamic connexus the anterior column of the fornix is seen curving downwards and backwards in the side-wall. At first it forms a prominent ridge, but it gradually

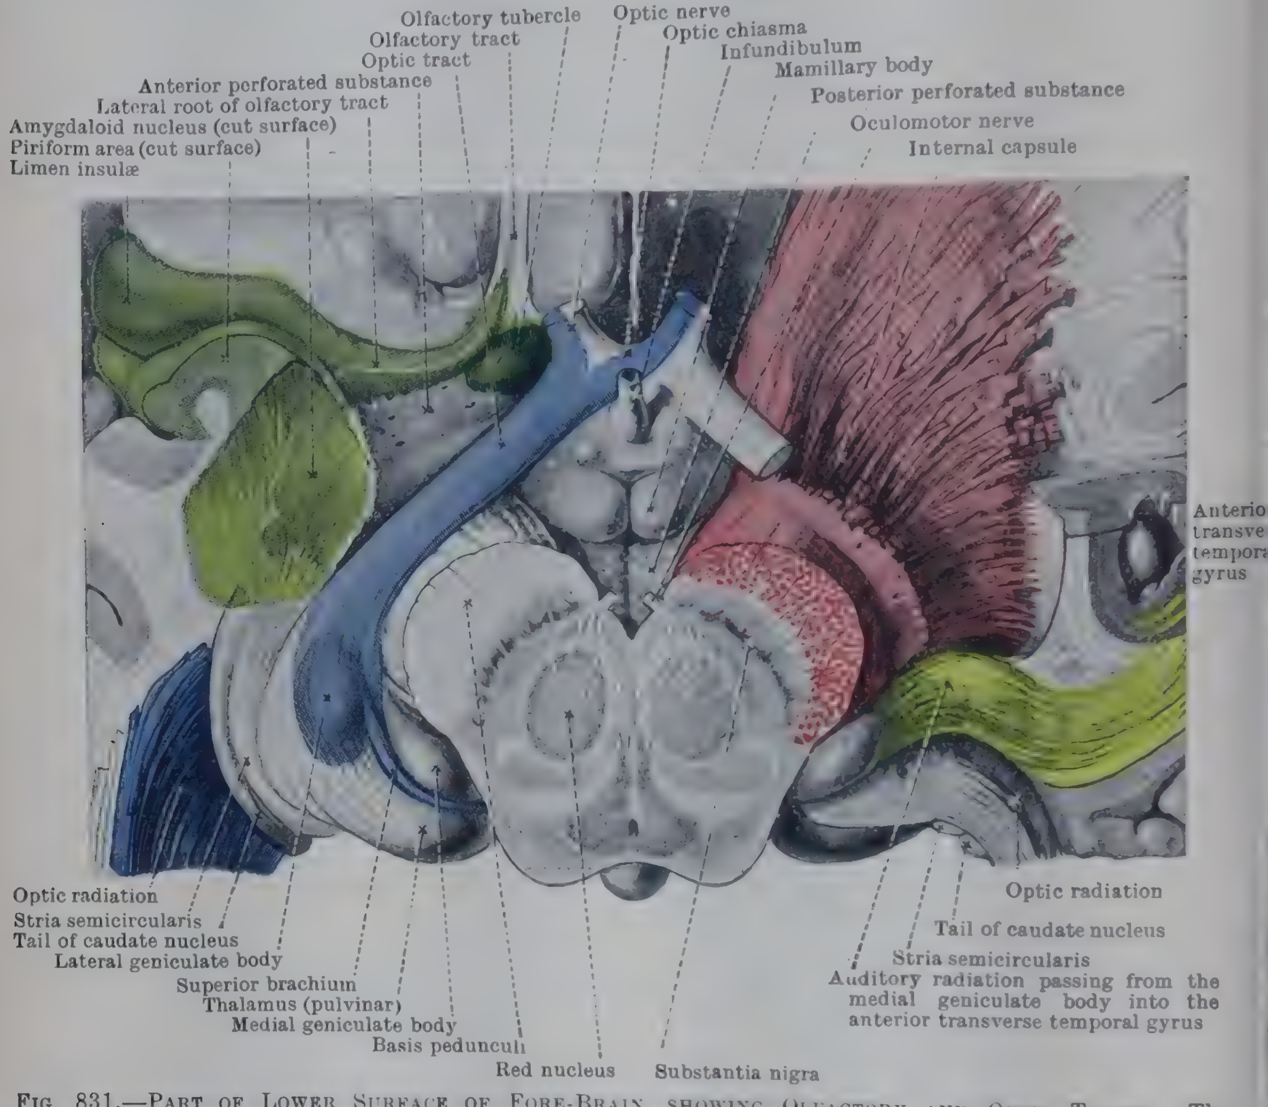

FIG. 831.—PART OF LOWER SURFACE OF FORE-BRAIN, SHOWING OLFACTORY AND OPTIC TRACTS. The mid-brain has been cut across. Olfactory area, *green*; optic fibres, *blue*; pyramidal tract and cortico-pontine fibres, *red*; auditory fibres, *yellow*.

subsides as the strand, on its way to end in the mamillary body, becomes more and more sunk in the grey matter on the side of the ventricle.

The third ventricle communicates with both of the lateral ventricles, and also with the fourth ventricle. The aqueduct of the mid-brain brings it into communication with the fourth ventricle. The opening of this aqueduct is at the posterior part of the floor, immediately below the posterior commissure. The **interventricular foramina**, which bring it into communication with the lateral ventricles, are at the upper and anterior parts of the side-walls; each leads laterally and slightly upwards between the anterior column of the fornix and the anterior end of the thalamus. They are very variable in width but usually are about one-eighth of an inch in diameter; and through them the ependymal lining of the three ventricles becomes continuous. From the foramen a broad shallow groove on the side-wall of the ventricle leads backwards towards the mouth of the aqueduct. It is termed the **hypothalamic sulcus**, and it serves to mark a topographical boundary between the thalamus above and the hypothalamus below.

The outline of the third ventricle, when viewed from the side in a median section through the brain (Fig. 829), or as it is exhibited in a plaster cast of the ventricular system of the brain (Fig. 830), is seen to be very irregular and to have several recesses. Thus, in the anterior part of the floor there is a funnel-shaped recess that leads down through the tuber cinereum into the infundibulum. Immediately in front of this *infundibular recess*, the *optic recess* passes downwards and forwards above the optic chiasma. Posteriorly there are two recesses in the roof of the third ventricle. One—the *pineal recess*—passes backwards for a short distance into the stalk of the pineal body. The second—the *suprapineal recess*—is carried backwards for a greater distance; it is a diverticulum of the ependymal roof, and is therefore difficult to demonstrate by macroscopic dissection.

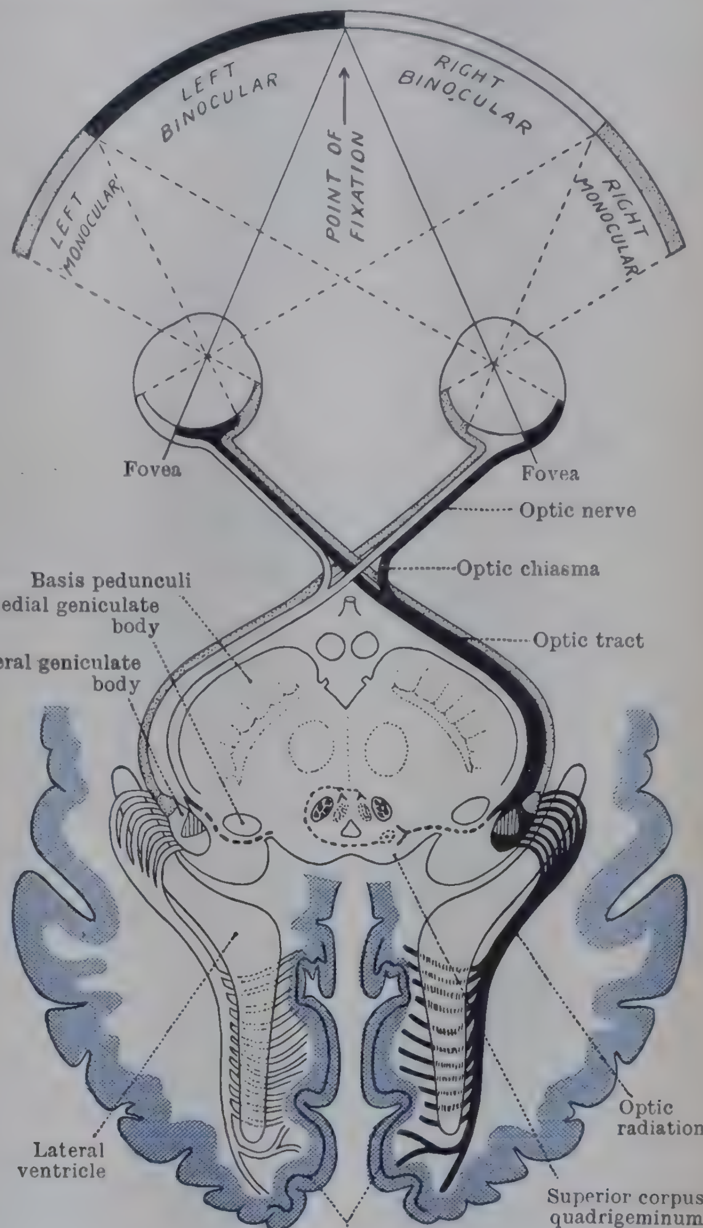

Fig. 833.—Composite Diagram to show the Projection of the Visual Field upon the Retinæ and the Relationship of Retinæ to Lateral Geniculate Bodies and Area Striata of Cerebral Hemispheres. The fibres from the maculæ, some crossed and some uncrossed, are not shown separately in the optic nerves and optic tracts, but their place of delivery in the lateral geniculate body—the intermediate part of its posterior two-thirds—is shown by hatching. The remainder of the posterior two-thirds receives the fibres from nonmacular regions of the binocular retinal field. The monocular retinal field is shown projecting into the anterior third of the lateral geniculate body. No attempt has been made in this figure to localize the delivery within the area striata of fibres from these different regions of the lateral geniculate body. (After Ivy Mackenzie (1934) and Winton & Bayliss (1948).)

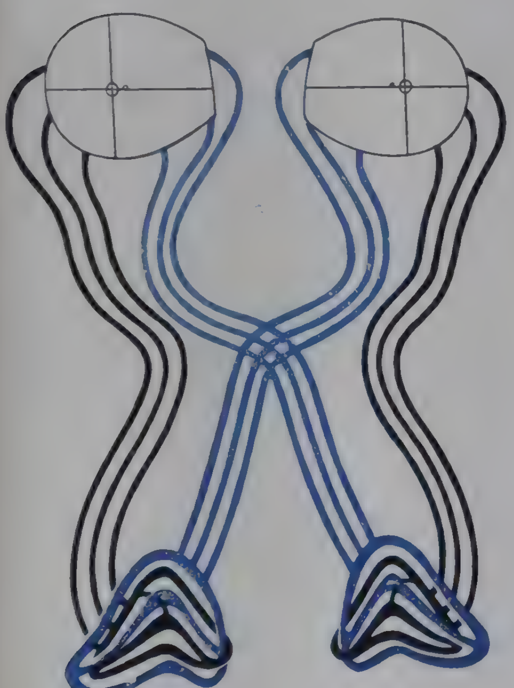

Fig. 832.—Diagram to show Relationship of Crossed and Uncrossed Fibres from Retinæ to Cell-Laminæ of Lateral Geniculate Bodies. The macular fibres, some of which are crossed and some uncrossed, are not shown separately. They are delivered to the cells that lie in the central region of the posterior two-thirds of the body, cf. Fig. 833. (From Ivy Mackenzie (1934), after Le Gros Clark.)

Cerebral Connexions of Optic Tract

At the optic chiasma the optic nerves are joined together and a partial decussation of fibres takes place. The fibres which arise in the medial or nasal half of each retina cross the median plane and join the optic tract of the opposite side. Those from the temporal half of the retina pass into the optic tract of the same side. Approximately two-thirds of the fibres in each optic tract are crossed, and

one-third uncrossed. Each optic tract forms a flattened band which proceeds backwards round the side of the cerebral peduncle, reaching the latter by passing backwards and laterally from the optic chiasma, between the anterior perforated substance and the tuber cinereum. In the neighbourhood of the geniculate bodies the tract appears to divide into two roots, viz., a lateral and a medial (Fig. 831), but only the former is really part of the tract. The so-called medial root can be traced to the medial geniculate body, and it consists of commissural fibres through which the two medial geniculate bodies and probably the inferior corpora quadrigemina are connected across the median plane. This commissure (the commissure of van Gudden) becomes secondarily incorporated in the optic chiasma and has nothing to do with visual functions.

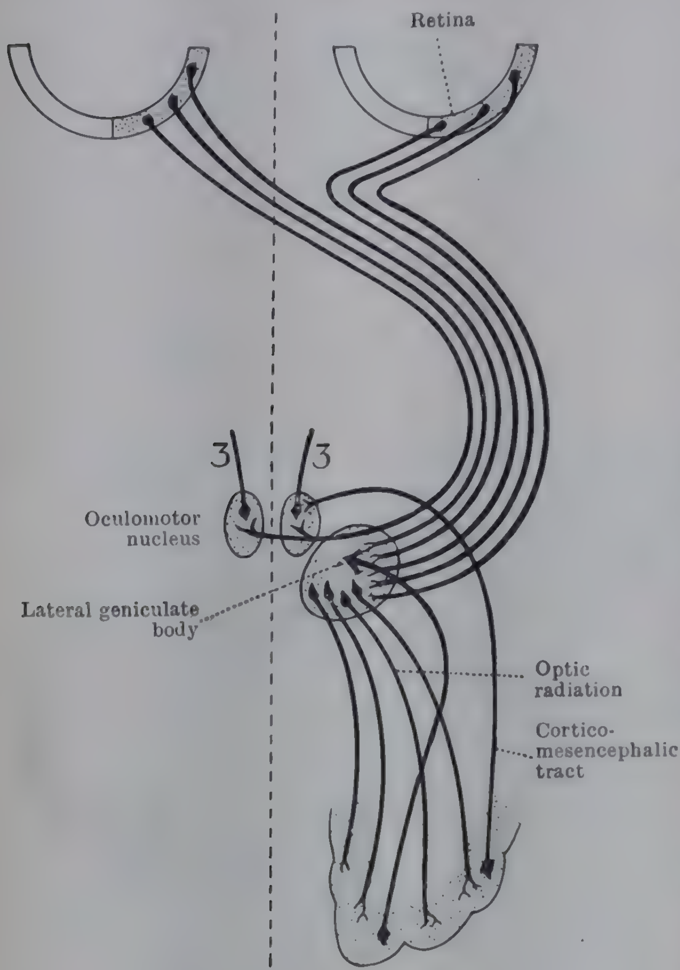

FIG. 834.—DIAGRAM OF CENTRAL CONNEXIONS OF OPTIC NERVE AND OPTIC TRACT.

Optic Tract.—It is important to recognize that each optic tract is composed of fibres from the temporal half of the ipsilateral retina and from the nasal half of the contralateral retina. It follows that section of one optic tract will result in a blindness in the nasal half of the field of vision of the ipsilateral eye and in the temporal half of the contralateral eye. This condition is called "homonymous hemianopia". Further, since the crossed fibres at first lie towards the medial side of the tract, pressure on the tract from the medial aspect (such as may arise from a tumour of the hypophysis) may give rise to a bilateral temporal hemianopia. Lastly, it should be noted that fibres from different areas of the retina retain a corresponding topographical localization in the optic tract, so that small circumscribed lesions in the latter may give rise to a circumscribed defect (*scotoma*) in the field of vision.

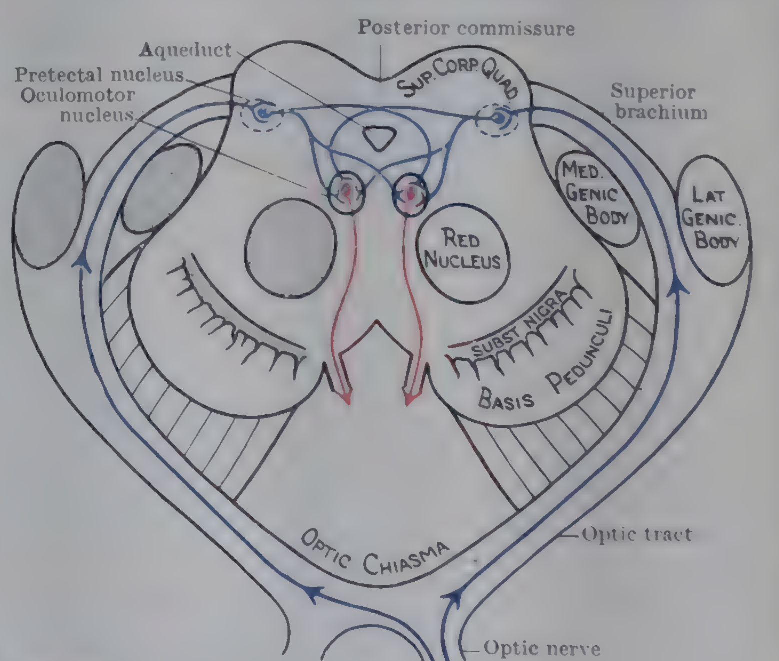

FIG. 835.—DIAGRAM OF SECTION THROUGH MID-BRAIN AND OPTIC CHIASMA SHOWING THE PATH OF PUPILLARY CONSTRICTOR FIBRES. (After Ranson & Magoun, 1933.)

By far the greater number of the fibres of the optic tract end in the lateral geniculate body, but some fibres proceed by way of the superior brachium to the mid-brain and end in the superficial layers of the superior corpus quadrigeminum and in the pretectal nucleus

(Fig. 835). The pretectal nucleus receives the pupillo-constrictor fibres of the optic tract and relays the retinal impulses on to the oculomotor nucleus (p. 919).

The mode of termination of the optic fibres in the lateral geniculate body is very precise. It has been noted that a considerable part of the nucleus consists of six well-defined cell-laminæ. Three of these receive the crossed fibres of the optic tract and three the uncrossed fibres. Moreover, it has been demonstrated that from each spot in the central area of the retina fibres pass to all three corresponding laminæ. It should be noted also that the topographical representation of each part of the retina in the lateral geniculate body is quite sharply defined. Thus, the upper half of the retina projects on to the medial half of the nucleus and the lower half of the retina on to the lateral half. The fibres from the macular area of the retina (related to central vision) are located in the medio-ventral part of the optic tract, and terminate in the central region of the posterior two thirds of the geniculate body.

Cortical Connexions of Optic Path.—The lateral geniculate body, the superior corpus quadrigeminum and the pretectal nucleus are termed the lower visual centres of the brain. The higher visual centre is in the cortex of the occipital lobe of the cerebral hemisphere, and this receives a conspicuous tract of fibres from the lateral geniculate body called the **optic radiation.** In other words, the lateral geniculate body is simply a relay station through which retinal impulses are projected on to the visual cortex. The optic radiation forms a wide, thin sheet of fibres which lies in the white matter of the posterior part of the cerebral hemisphere and passes back to the visual cortex in close relation to the posterior horn of the lateral ventricle. It is of some practical importance to recognize that in its course through the white matter of the cerebral hemisphere the optic radiation is in close topographical relation to the deep aspect of the temporal lobe. Consequently pathological lesions of the temporal lobe may be accompanied by visual defects. Mention should be made of a small fasciculus of fibres which leave the optic tract before it reaches the lateral geniculate body and pass into the subthalamus at the medial margin of the substantia nigra. This so-called "accessory optic tract" has been demonstrated experimentally in lower mammals and probably exists also in the human brain.

The visual cortex emits cortico-tectal fibres which descend to the superior corpus quadrigeminum.

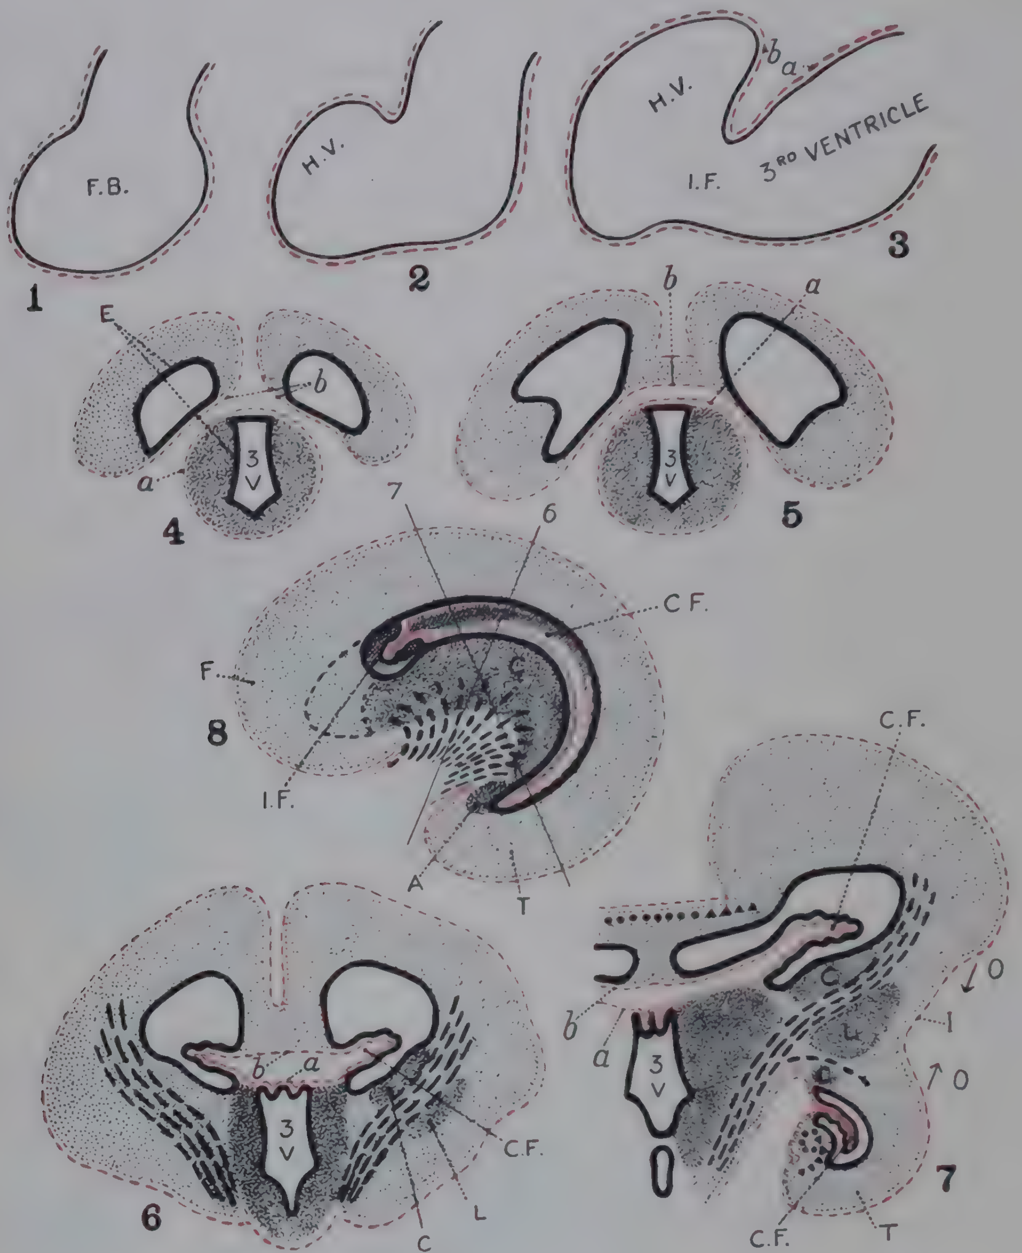

FIG. 837.—DIAGRAMS TO SHOW THE FORMATION OF THE TELA CHORIOIDEA AND ITS RELATION TO THE CHOROID FISSURE AND CHOROID PLEXUSES OF THE LATERAL AND THIRD VENTRICLES.

Adapted from figures in Frazer's *Manual of Embryology*.

In Fig. 1, the vascular tissue forming the primitive pia mater is shown as a broken red line surrounding the front end of the neural tube (F.B.). In Fig. 2, a developing cerebral hemisphere vesicle (H.V.) is seen carrying out over it a covering of pia mater continuous with that surrounding the original forebrain vesicle. Fig. 3 shows that the backward growth of the hemisphere leads to the formation of a double layer of pia mater interposed between it and the roof of the 3rd ventricle. This double layer of vascular pia mater is the tela chorioidea. "The layer '*b*' is derived from the original '*a*', so that any veins in '*b*' must run back to the roof of the interventricular foramen (I.F.) to enter one of the veins of '*a*' and so drain. The tela chorioidea, then, extends to the interventricular foramen because the upper layer was reflected at this point." (Frazer, 1940, p. 202.) But the layer '*b*' is carried out on each hemisphere vesicle (Fig. 4), and the two vesicles become connected by commissures (Fig. 5), and become fused also to the mid-line vesicle containing the 3rd ventricle so that the condition shown in Fig. 6 results. The plane of Fig. 6 is shown on Fig. 8 by a line labelled 6. The ependyma (E) lining the lateral ventricles and the 3rd ventricle is shown by a heavy black line, so that the strip of the medial wall of each hemisphere which consists only of ependyma and likewise the roof of the 3rd ventricle can be easily seen in Figs, 4, 5, 6, 7, 8. The inthrust of the ependymal region of the hemisphere wall is called the choroid fissure (C.F.) (see also description in text, pp. 941, 955). In Fig. 7 the choroid fissure is cut twice. A glance at Fig. 8, upon which the place of Fig. 7 is indicated by a line labelled 7, will show the reason for this.

PARTS DERIVED FROM TELENCEPHALON

Cerebral Hemispheres

The cerebral hemispheres form the largest part of the fully developed brain. When viewed from above they form an ovoid mass, the broader end of which is directed backwards, and the longest transverse diameter of which will be found in the vicinity of the parts which lie subjacent to the parietal eminences of the cranium. The massive, rounded character of the anterior or frontal end of each cerebral hemisphere is a leading human characteristic; but the posterior or occipital end is narrow and pointed, and is directed slightly downwards. The two cerebral hemispheres are separated from each other by a deep median cleft termed the longitudinal fissure.

Each cerebral hemisphere is formed from a small area of the extreme anterior end of the alar lamina, in the angle between the foremost part of the roof and the upper end of the lamina terminalis (Fig. 836 L), which becomes continuous with the roof (at the point marked X).

The rapid expansion of that area leads to the development of a lateral bulging containing a diverticulum of the third ventricle known as the lateral ventricle. This at first communicates with the third ventricle by means of a wide opening (F.M.)—the interventricular foramen—corresponding in size to the extent of the area of the side-wall that was bulged outwards to form the hemisphere vesicle. The thin, ependymal roof of the telencephalon takes no share in the formation of the two cerebral hemispheres, but it serves with the lamina terminalis (L) as a bond of union between them; it forms, also, the upper boundary of the interventricular foramen. At a later stage in development two folds become invaginated from the ependymal roof in the whole extent of the prosencephalon—both its telencephalic and diencephalic parts. In the greater part of their length these folds project into the third ventricle, and form its **choroid plexuses** (Fig. 829); but the anterior parts of the two choroidal folds, namely, those parts formed from the roof of the interventricular foramina (F.M.), become greatly enlarged and project each into the corresponding lateral ventricle. The furrow corresponding to this invagination of the roof is called the **choroid fissure** (p. 941). When the hemisphere vesicle first begins to expand, the thinner part of its wall, which is called the **pallium**, is freely continuous around the vertical caudal margin of the interventricular foramen (Fig. 836 Y) with the wall of the third ventricle.

But, as development proceeds, the wall of the prosencephalon becomes attenuated along the line of the choroid fissure, and eventually the pia mater of the choroid tela of the third ventricle extends laterally into the fissure to produce the **choroid plexus** of the lateral ventricle. It is obvious, therefore, that the choroid plexus of the lateral ventricle will become continuous with that of the third ventricle at the upper margin of the interventricular foramen, and that the choroid plexuses of the third and lateral ventricles all have a common origin from the same tela. Below and lateral to the choroid fissure the wall of the hemisphere remains in close contact with the thalamus. In this way the thalamus comes, in part, to face directly into the lateral ventricle, and the corpus striatum, developing in the floor of the cerebral hemisphere, acquires its close relationship with the thalamus (Fig. 838).

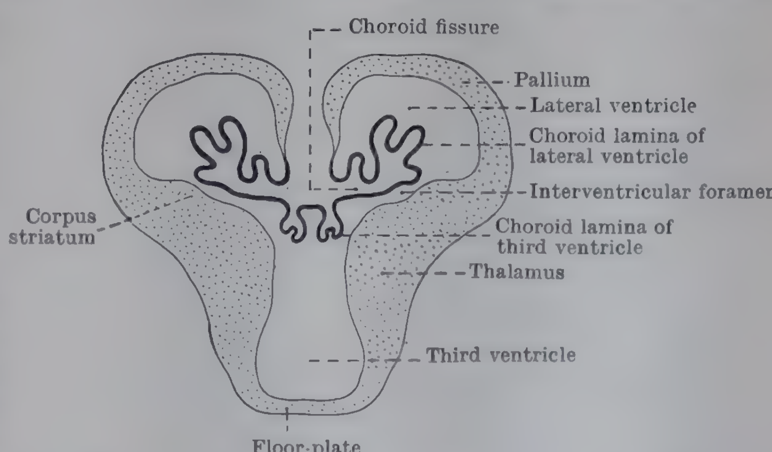

Fig. 838.—Diagram of Transverse Section through Fœtal Brain to show the Invagination of the Roof through each Interventricular Foramen.

At a very early stage in the development of the embryo, long before there is any sign of the hemisphere vesicles, the ectoderm on each side of the anterior neuropore (see p. 838) becomes thickened to form the **area olfactoria** (see Fig. 722 D, p. 838). Certain of the epithelial cells in this area become converted into bipolar sensory cells and these are specialized as receptors for certain kinds of air-borne chemical stimuli that awaken a consciousness of smell. These cells always remain *in situ* in the olfactory epithelium, just as sensory cells do in primitive invertebrates (Fig. 719, p. 835). But other nerve-cells seem to be derived from the area olfactoria which do not remain in the parent epithelium but become attached to the adjoining part of the neural tube. These cells form

the receptive organ for the impressions brought into the brain by the processes of the sensory cells in the olfactory epithelium; and the area of the neural tube to which it becomes attached is destined to become part of the cerebral hemisphere. At the end of the first month this portion of the hemisphere becomes drawn out as a hollow protrusion, the distal end of which is coated with a layer of grey matter and is known as the **olfactory bulb**; the rest forms a peduncle. In the course of its subsequent development in the human brain (though not in those of most mammals) the cavity in the bulb and peduncle becomes completely obliterated. The peduncle becomes so greatly elongated and attenuated that to the unaided eye it appears to be formed wholly of white nerve-fibres passing from the olfactory bulb to the hemisphere; hence it is called the **olfactory tract** (Figs. 831 and 841).

The cerebral hemisphere first appears in the form of a slight bulging on each side of the fore-brain, but it soon assumes large dimensions. At first it grows forwards and upwards (Fig. 839), and a distinct cleft, the floor of which is the roof-plate and lamina terminalis, appears between the two hemispheres: it is known as the **longitudinal fissure**. The separation of the two cerebral vesicles by the longitudinal fissure begins at the end of the first month, and the fissure becomes occupied by the mesodermal tissue which later on forms the **falx cerebri**. The cerebral hemisphere, in its further growth, is carried progressively backwards over the other parts of the developing brain. At the end of the third month it has covered the thalamus. A month later it reaches the corpora quadrigemina, and by the seventh month it has covered not only these, but also the entire upper surface of the cerebellum. From the latter it is separated by a mesodermal sheet which forms the basis of the **tentorium cerebelli**.

In the earlier stages of its development the cerebral hemisphere is a thin-walled vesicle with a relatively large cavity which represents the primitive condition of

the **lateral ventricle**. At first the vesicle is bean-shaped and the cavity is curved. As development proceeds, the posterior portion of the hemisphere grows backwards over the cerebellum in the shape of a hollow protrusion, and a distinct occipital lobe enclosing the posterior horn of the lateral ventricle is the result. This developmental stage begins about the fourth month.

Connexions of Olfactory Nerves

The olfactory nerves are the axons of the spindle-shaped bipolar cells situated in the olfactory mucous membrane (Fig. 840). These axons collect in the submucous layer to form small bundles which enter the cranial cavity through the foramina in the cribriform plate of the ethmoid bone. After forming an intricate plexus on the surface of the olfactory bulb, they enter it over the greater part of its surface, and each fibre breaks up into a tuft of terminal filaments. Towards these tufts dendrites proceed from large **mitral cells** placed in a deeper plane within the bulb, and each dendrite also breaks up into numerous terminal branches intertwined with those of the olfactory nerves. In this way a large number of globular bodies are formed, each consisting of the arborescent terminations of mitral dendrites and a large number of olfactory nerve-fibres. The globular bodies are called the **olfactory glomeruli**. Each mitral cell gives off several dendrites and one axon. It thus happens that a mitral cell, through its dendrite, stands in connexion with many olfactory nerve-fibres. The axon of the mitral cell passes upwards into the bulb, bends backwards, and runs in the olfactory tract towards the cerebral cortex.

The **olfactory bulb** is a small, flattened, elliptical mass of grey matter placed on the cribriform plate of the ethmoid bone. Its posterior end is attached to the rest of the cerebral hemisphere by the olfactory tract (Fig. 763)—a prismatic band of white substance placed in the olfactory sulcus on the orbital surface of the cerebral hemisphere. A short distance in front of the optic chiasma each olfactory tract becomes inserted into the hemisphere (Fig. 831). The swollen pyramidal-shaped attached end of the tract is called the **olfactory pyramid**. Immediately behind the pyramid a small obliquely placed ovoid area of grey matter—the **olfactory tubercle**—can sometimes be detected in the human brain; but in the brains of most mammals with a greater development of the organs of smell this swollen area is much more prominent and constant. In most human brains, however, it is difficult to distinguish it from a much more extensive area, situated behind it and to its lateral side, and named the **anterior perforated substance** (Fig. 831). Along the anterior margin of the perforated substance a very well-defined narrow band of nerve-fibres—the *lateral root of the olfactory tract*—proceeds backwards and laterally from the attached end of the olfactory tract. This is composed of axons of mitral cells proceeding to the hook-shaped part of the temporal lobe called the uncus.

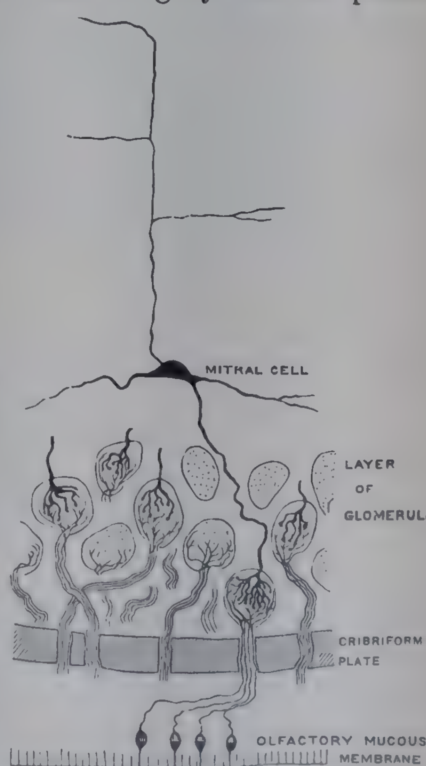

Fig. 840.—Diagram of Minute Structure of Olfactory Bulb.

The *uncus* forms the major part of a cortical layer of grey matter in which the lateral root of the olfactory tract ends. This area of cortex is termed the **piriform area** for the reason that in lower mammals it is distinctly pear-shaped.

The piriform area extends laterally in the deep valley between the orbital and temporal regions of the hemisphere; becoming slightly broader, and reaching what is known as the **insula** (of which it forms the **limen insulæ**), it becomes sharply bent upon itself (Figs. 831 and 841 C). It then passes medially and backwards, and emerges from the valley as a broad area on the under surface of the temporal

region (Fig. 841 C), where it enters into the formation of the uncus of the temporal lobe.

If the brain of almost any other mammal is examined (take the rabbit's as an example), the piriform area will be found to constitute relatively a much larger proportion of the cerebral hemisphere than it does in the human brain; and it is separated from the part of the hemisphere (**neopallium**) that lies above it by a longitudinal furrow called the **rhinal sulcus**. The enormous expansion of the neopallium in the human brain accentuates the flexure of the piriform area at the point x (Fig. 841), and at the point y the exuberant growth of neopallium relegates the swollen, posterior part of the piriform area on to the medial surface (Fig. 842), where the posterior part of the rhinal sulcus persists to

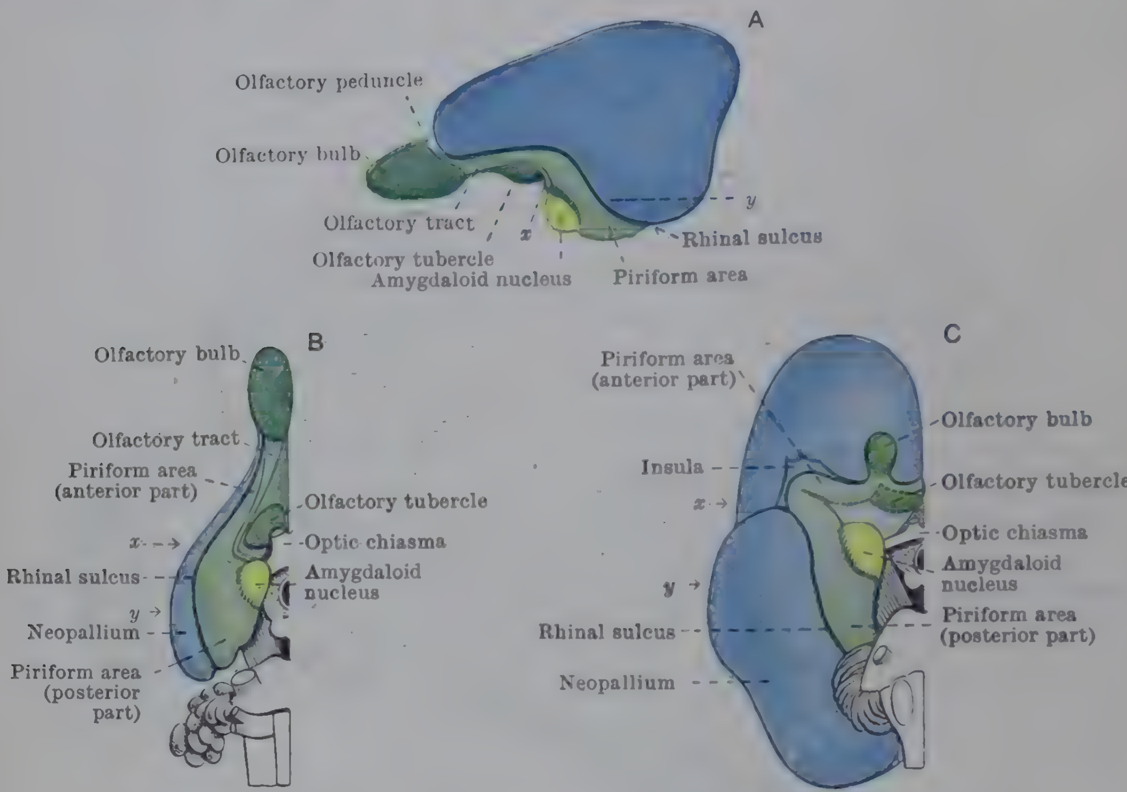

FIG. 841.—RELATION OF OLFACTORY PART OF HEMISPHERE TO NEOPALLIUM.

Olfactory areas, *green*; neopallium, *blue*.

It should be noted that the posterior part of the piriform area is not directly connected with the olfactory tract and is probably concerned with other than purely olfactory functions.

separate it from the neopallium. Strictly speaking, the olfactory tract fibres terminate directly only in the anterior part of the piriform area, and it is probable that the posterior piriform area is concerned with other than purely olfactory functions.

The surface of the piriform area often presents numerous small wart-like excrescences; and it is whitened by a thin layer of fibres prolonged backwards from the lateral root of the olfactory tract. By these fibres olfactory impulses are poured directly from the mitral cells of the bulb into the anterior piriform area. If we call the olfactory nerves the **primary olfactory neurons**, the fibres which pass from the bulb to the anterior piriform area would then be **secondary olfactory neurons**. Some of the olfactory tract fibres terminate in the olfactory tubercle at the anterior part of the anterior perforated substance and in certain elements of the amygdaloid nucleus; others pass up on to the medial surface of the cerebral hemisphere as the *medial root of the olfactory tract*, to terminate in a triangular mass of grey matter situated immediately in front of the lamina terminalis, and called the *paraterminal gyrus* (Fig. 842). There is reason to believe that the fibres of this medial root do not originate in the olfactory bulb, but probably arise from cells in a fine strip of grey matter which accompanies the main olfactory tract.

Hippocampal Formation

Extending back from the region of the uncus, and curving up to reach the under surface of the splenium of the corpus callosum, is a strap-like band of white matter, the *fimbria*. Immediately below this is a thin crinkled strip of cortex called the *dentate gyrus*, sunk deeply in the groove between the fimbria and the neighbouring convolution of the temporal lobe, the hippocampal gyrus (Fig. 842). The dentate gyrus, which is characterized in its structure by a compact layer of small granule cells, is developed along the margin of the pallium bordering the choroidal fissure where, in the fœtus, the choroid plexus becomes invaginated into the cavity of the lateral ventricle. Traced backwards, the gyrus is found to curve round below the splenium of the corpus callosum

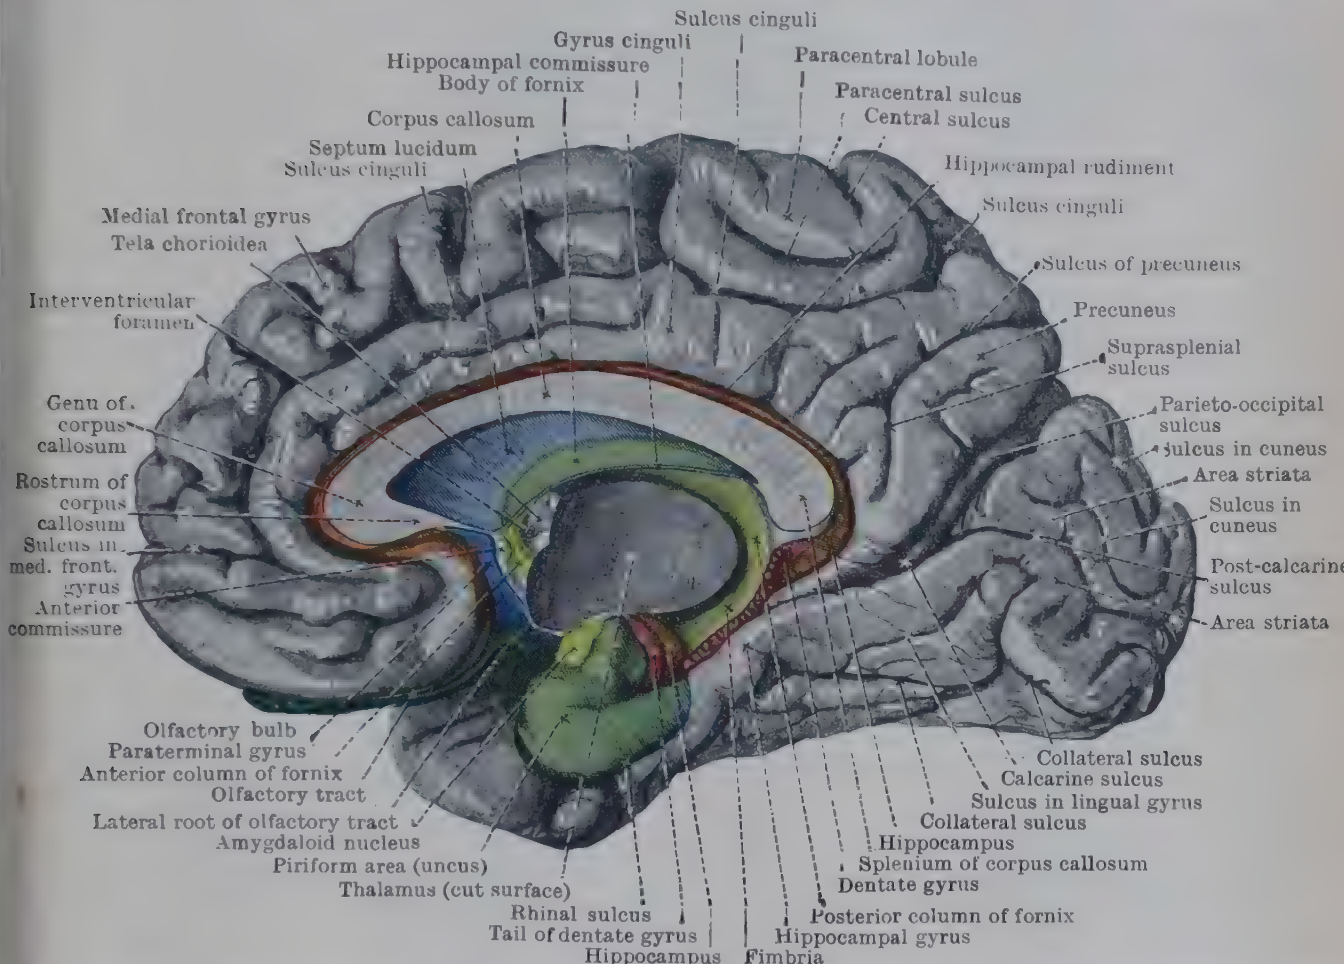

Fig. 842.—Medial Aspect of Right Cerebral Hemisphere, with the Main Olfactory Centres on the Base of the Brain coloured *Green*.

It should be noted that olfactory fibres end directly only in the anterior part of the piriform area.

to disappear from view on to its upper surface. Here it becomes continuous with a thin film of grey matter, the *indusium*, which is too attenuated to be discernible with the naked eye. At its anterior extremity, the dentate gyrus curves up on to the surface of the posterior part of the uncus, where it is called the " tail of the dentate gyrus " (Fig. 842). In lower mammals, in which the olfactory sense is powerfully developed, the dentate gyrus forms a broad and conspicuous convolution. It is a receptive area of the cortex in which terminate fibres (tertiary olfactory neurons) which arise in the anterior piriform area. The olfactory sense in Man is relatively poorly developed and, in association with this, the dentate gyrus has undergone a very considerable reduction. In some cases it is such a slender band of grey matter that it may not readily be distinguished on superficial examination.

The dentate gyrus is separated from the hippocampal gyrus by a shallow groove, the hippocampal fissure. Along the line of this fissure, during the course of embryological development, a broad band of cortex becomes sunk in from the surface and inrolled into the cavity of the descending horn of the lateral ventricle (Fig. 844). In the adult, it can be seen in the floor of the descending horn as a conspicuous elongated eminence (p. 967). This invaginated strip of cortex (which thus lies alongside the dentate

gyrus) is called the *hippocampus*; like the dentate gyrus it is continued anteriorly on to the surface of the uncus and posteriorly fades away into the indusium. The hippocampus and the dentate gyrus together comprise the **hippocampal formation**, and the indusium is to be regarded as an atrophied portion of this formation which has become stretched out into an exceedingly thin layer by the growth of the subjacent corpus callosum.

For many years the hippocampus has been regarded as an important component of the olfactory mechanism of the brain. However, while in lower vertebrates it appears to come under the dominating influence of the olfactory impulses which are conveyed to it by fibres from the dentate gyrus, this is certainly not its only, or even its most important connexion in mammals generally. In lower mammals, the hippocampus receives afferent fibres from two main sources—from the dentate gyrus (which relay olfactory impulses), and more numerous connexions from the neopallial cortex of the temporal lobe (which convey the resultants of neopallial activity as a whole). In the human brain the dentate gyrus, as already noted, has undergone very profound retrogressive changes, and the afferent connexions of the hippocampus are undoubtedly now received almost entirely from the cortex of the temporal lobe. It is not improbable, however, that the anterior extremity of the hippocampus, which is incorporated in the uncus, is still concerned mainly with the reception of olfactory impulses. But this forms a very small proportion of the whole hippocampus.

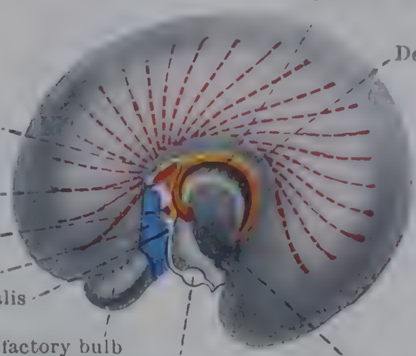

Fig. 843.—Medial Aspect of Right Cerebral Hemisphere of Human Fœtus of Fourth Month.

The broken red lines indicate the paths taken by callosal fibres in the neopallium to reach the upper end of the lamina terminalis.

The **fornix** is the efferent tract from the hippocampus (*a*) to the hippocampus in the other hemisphere, and (*b*) to the hypothalamus.

The axons of the cells of the hippocampus collect on its ventricular surface to form a white layer called the *alveus* (Fig. 844), the fibres of which converge towards the margin of the dentate gyrus, where they bend into a longitudinal direction (*i.e.*, parallel to the edge of the pallium and the choroid fissure) to form a prominent white marginal fringe called the **fimbria** (Fig. 844). The fibres of the fimbria pass first backwards and then upwards and forwards (Fig. 843), and come to lie in the roof of the third ventricle where a certain number of them cross the median plane into the fornix and the fimbria of the other hemisphere, so as to link together in functional association the two hippocampi. The crossing fibres are known as the **hippocampal commissure**.

Most of the fibres that run in the fimbria from the hippocampus to the fornix bend downwards in the anterior lip of the interventricular foramen to enter the thalamic region. They are collected into a vertical rounded column which is called the **anterior column of the fornix**; when it reaches the hypothalamus it bends backward to end in the mamillary body. From the mamillary body (as already noted) the mamillo-thalamic tract relays impulses to the anterior nucleus of the thalamus, and from here again other fibres pass to the gyrus cinguli on the medial aspect of the cerebral hemisphere. The functional significance of this projection-system remains quite obscure, for the nature of the impulses conducted in the first place to the mamillary body by the fornix is unknown.

In primitive vertebrates almost the whole of the cerebral cortex is made up of the piriform area and the hippocampal formation, and in these animals they appear to serve mainly olfactory functions. In the more highly organized brain of mammals, other senses than those of smell acquire a representation in the cortex of the cerebral hemisphere. A definite area of the pallium then becomes set apart to receive impressions of the tactile, visual, auditory, and other senses. This area is the **neopallium**. In the human brain it has grown to such an extent

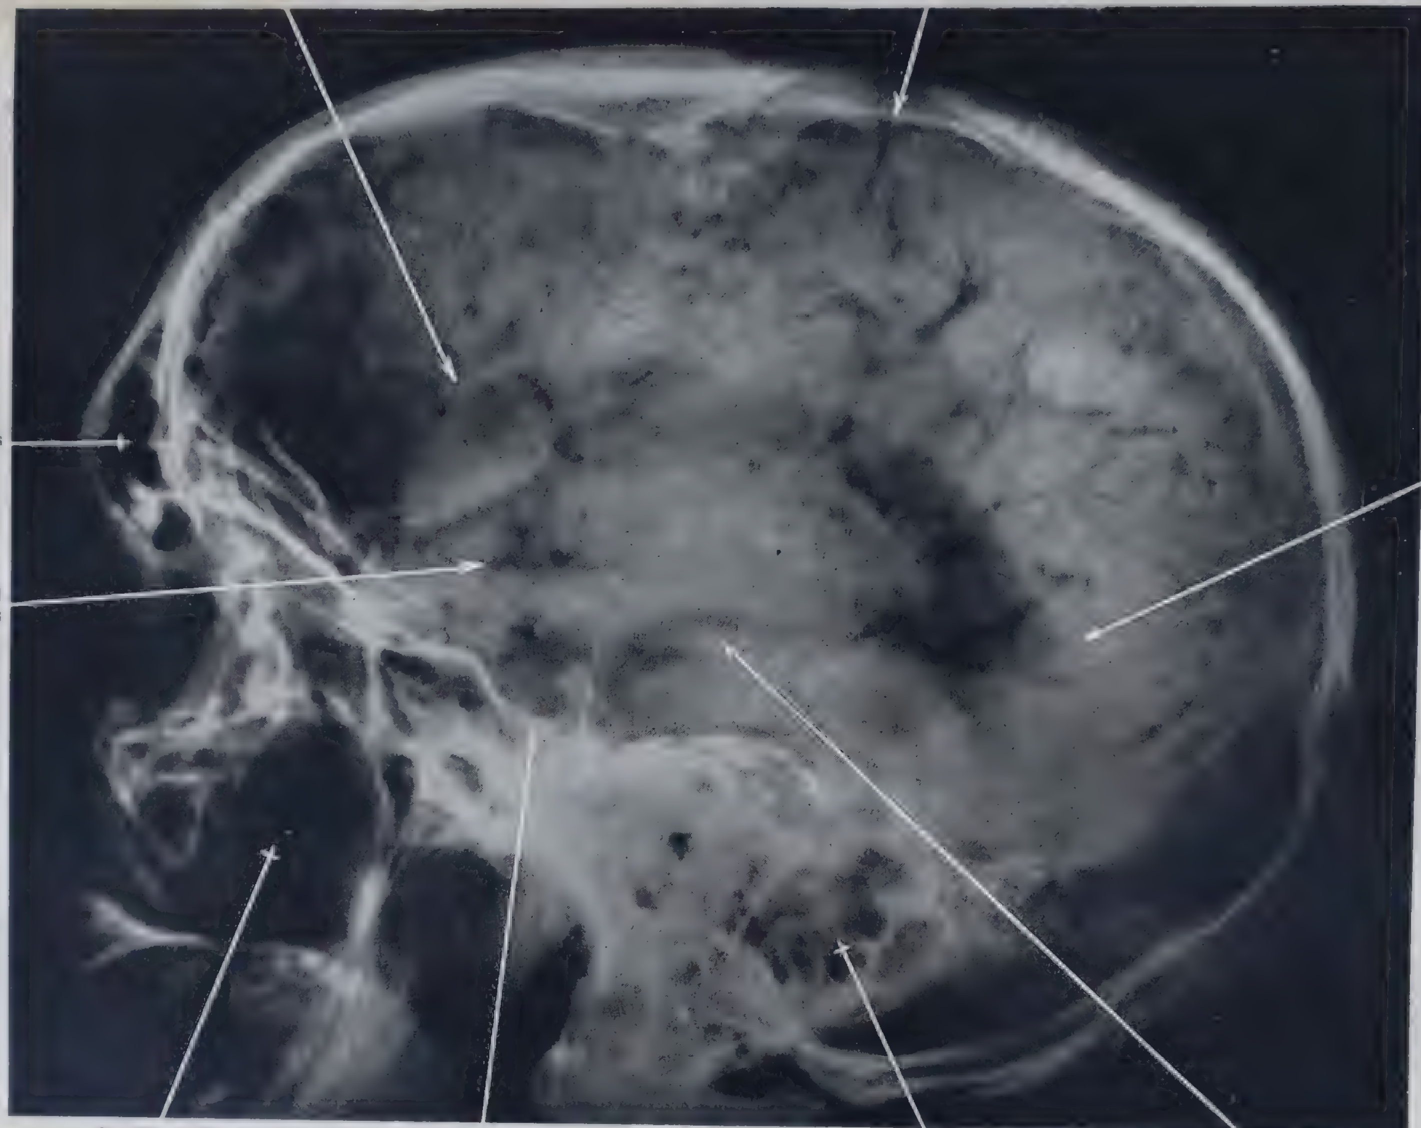

PLATE LXXV.—LATERAL RADIOGRAPH OF LIVING HEAD OF MAN AGED 24, AFTER INJECTION OF OXYGEN INTO THE SPINAL SUBARACHNOID SPACE BY LUMBAR PUNCTURE (Encephalograph : Professor Norman M. Dott).

The Sulci of the Cerebral Hemisphere appear in the radiograph on account of the relative translucency to the X-Rays of the oxygen-filled subarachnoid spaces. The oxygen has entered the Ventricular System also, and the form, size and position of a Lateral Ventricle are well shown. Compare with Plate LXXIV, p. 945, in which the Lateral Ventricles, directly injected, are more obvious but distended.

PLATE LXXVI

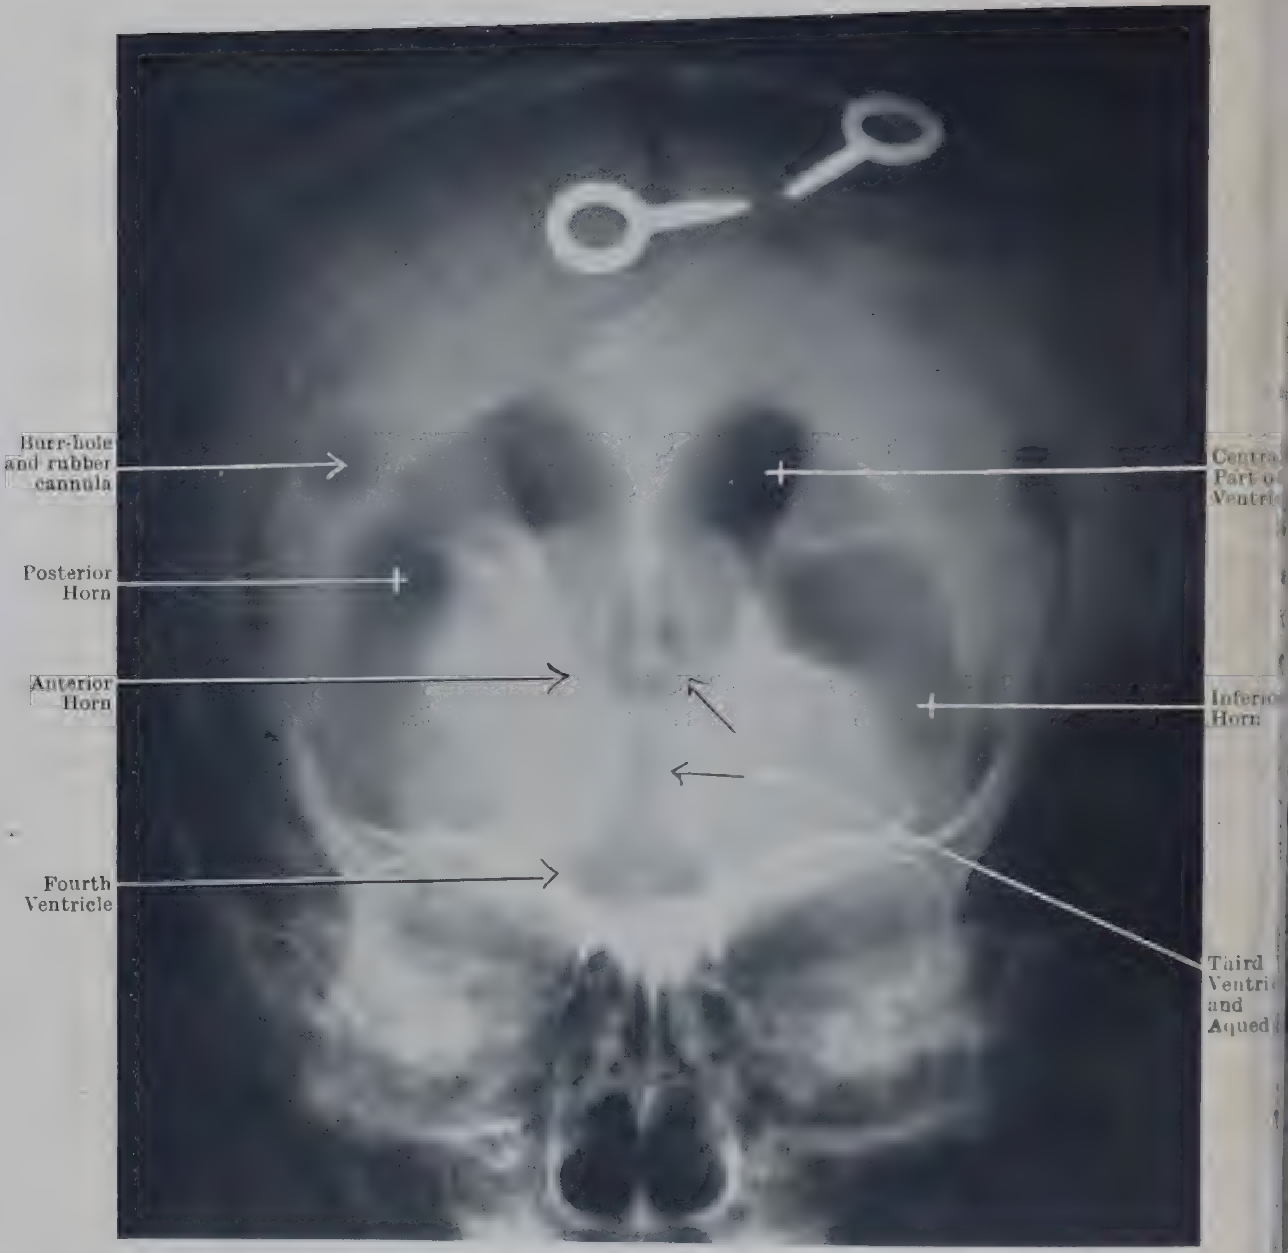

PLATE LXXVI.—ANTERO-POSTERIOR RADIOGRAPH OF LIVING HEAD OF CHILD AGED 4, AFTER DIRECT INJECTION OF OXYGEN INTO THE LATERAL VENTRICLES (Ventriculograph : Professor Norman M. Dott).

The ventricles were slightly distended. For lateral radiograph of the same head, see Plate LXXIV, p. 945.

that it forms almost the whole of the cerebral cortex, and the cerebral hemispheres come to form a mass far greater than the whole of the rest of the brain.

CEREBRAL COMMISSURES AND SEPTUM LUCIDUM

We have seen that certain fibres from the hippocampus cross from one hemisphere to the other, using the upper part of the lamina terminalis as a bridge across the median plane. But at an even earlier stage of development other fibres can

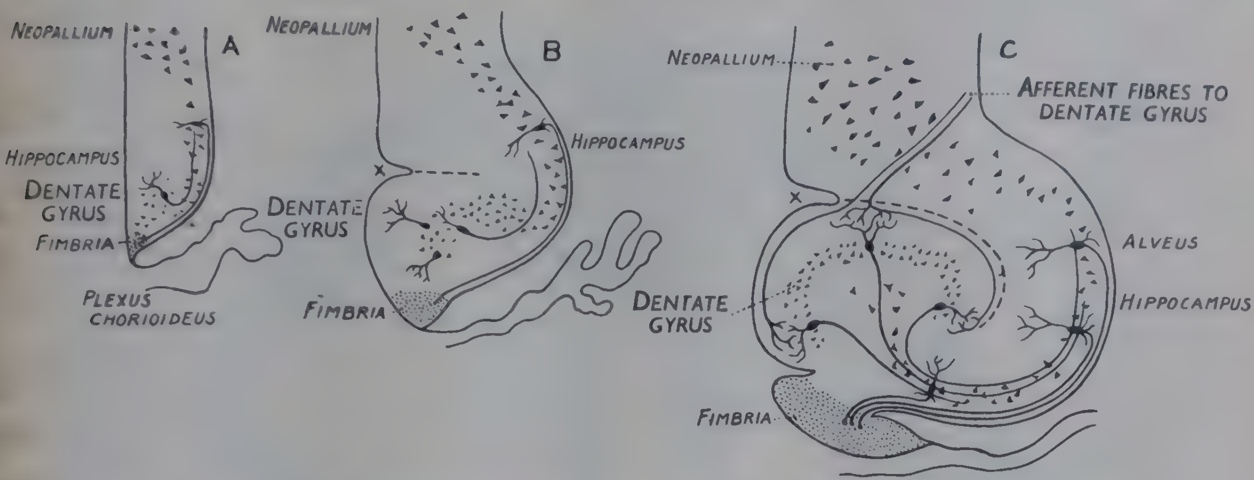

FIG. 844.—THREE STAGES IN THE DEVELOPMENT OF THE HIPPOCAMPAL FORMATION.
The position of the hippocampal fissure is marked X.

be detected at a slightly lower level in the lamina terminalis forming a bundle, of oval outline in sagittal section, called the **anterior commissure.** Its fibres come from the olfactory bulb, area piriformis, olfactory tubercle, and a small temporal area of neopallium. Dorsal to the hippocampal commissure, another commissure is

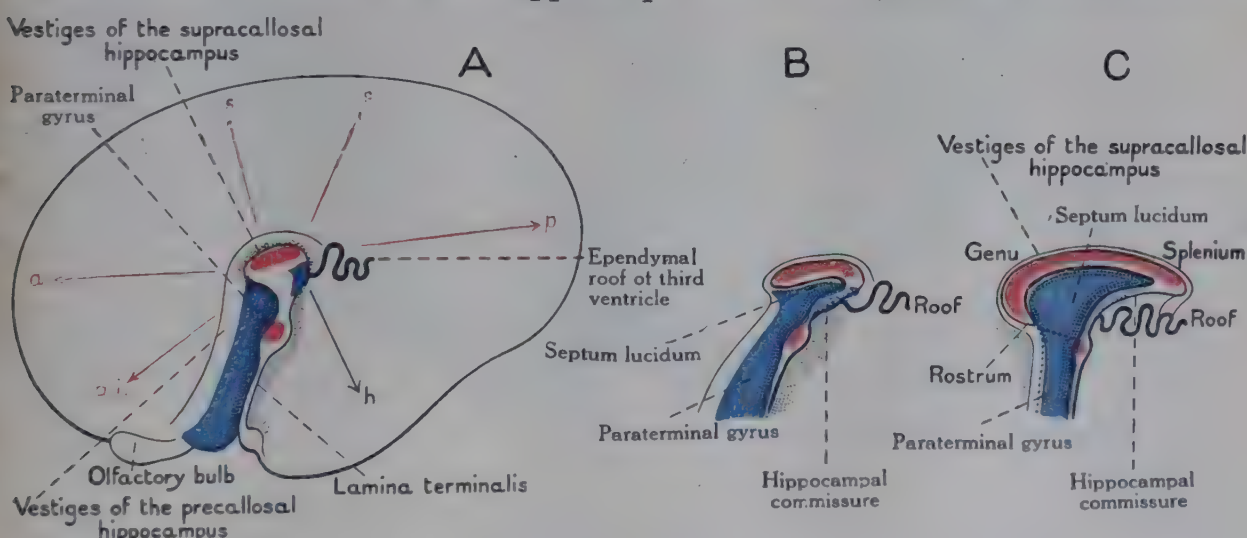

FIG. 845.—THREE STAGES IN THE DEVELOPMENT OF THE CORPUS CALLOSUM.

formed through which the neopallial part of the cortex of one side is connected by a bridge of transverse fibres with that of the other. This is the **corpus callosum.** As the corpus callosum elongates, it pushes its way forwards in the upper part of the paraterminal gyrus of each hemisphere, and as development proceeds a small area of the grey matter related to this gyrus becomes almost completely circumscribed by the corpus callosum and hippocampal commissure. As these commissural bands increase in size this area of grey matter becomes greatly stretched and expanded to form a thin translucent leaf—the **septum lucidum.** A narrow median cleft appears in the septum lucidum dividing it into a pair of laminæ; it is called the *cavity of the septum lucidum.*

As the posterior part of the corpus callosum pushes its way backwards, it

exerts traction on the fibres of the hippocampal commissure and this becomes enormously stretched so as to form a thin lamella (the floor of the cavity of the septum) stretching from a point just above the anterior commissure to the under surface of the swollen posterior end of the corpus callosum, which is called the **splenium** (Fig. 842). The whole of that part of the fornix which lies in the roof of the third ventricle is called the **body of the fornix**, while the part which connects the body with the fimbria of either side is the **posterior column of the fornix.**

The dentate gyrus appears as a notched band behind and below the fimbria;

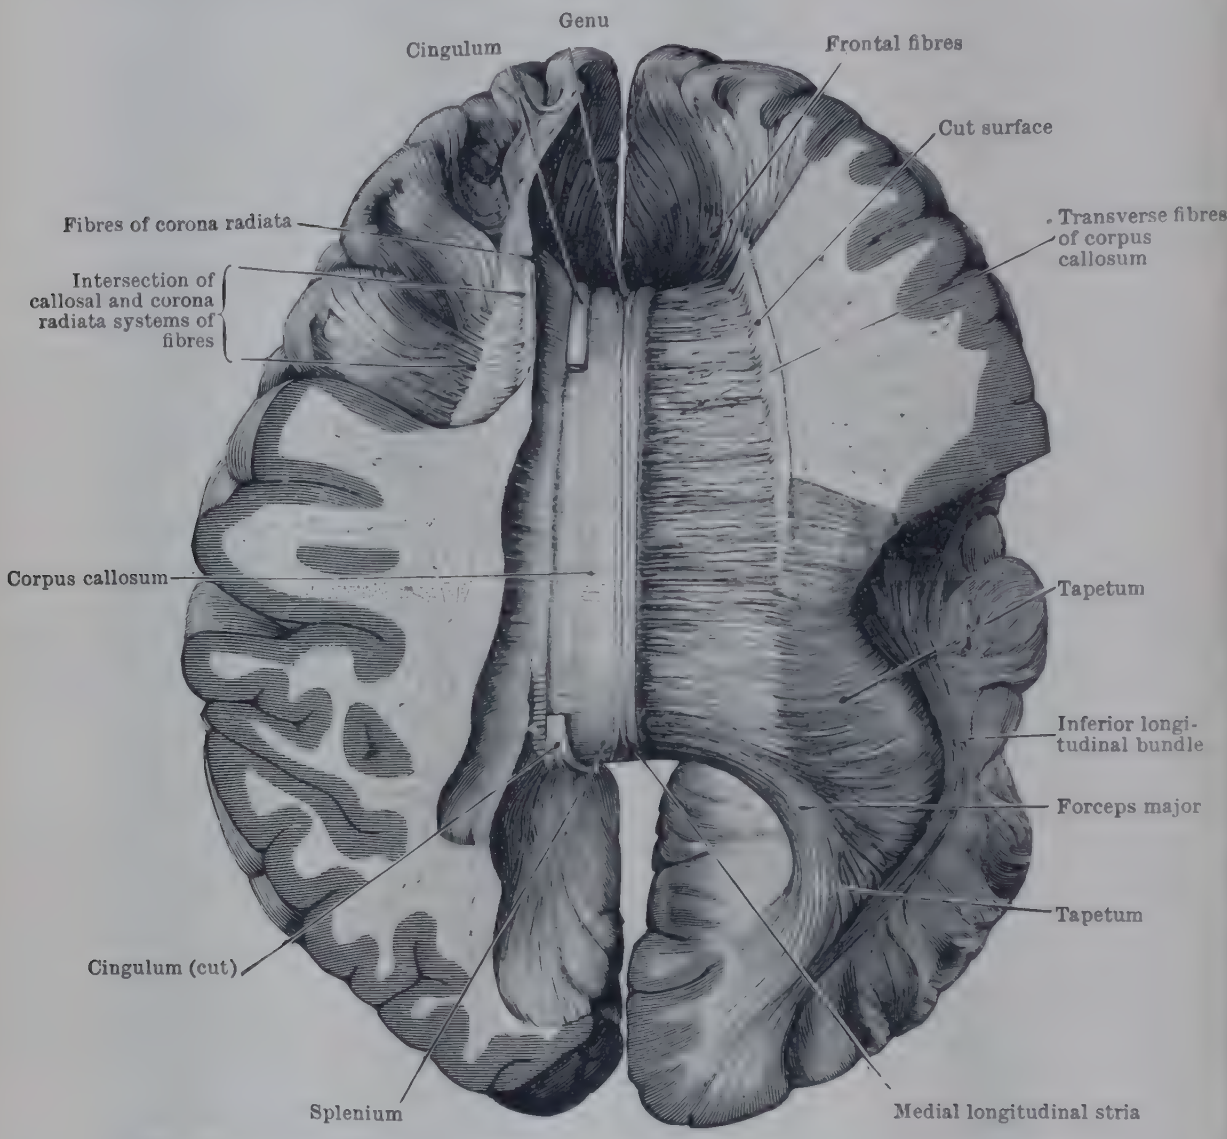

FIG. 846.—CORPUS CALLOSUM, EXPOSED FROM ABOVE AND RIGHT HALF DISSECTED.

its upper end passes on to the under surface of the splenium of the corpus callosum, where it tapers and appears to end; but a close inspection shows that the hippocampal formation is continued as a narrow band round the splenium and passes into a thin film of grey matter—**indusium griseum**—which is prolonged on to the upper surface of the corpus callosum. It proceeds forwards, becoming as a rule still more attenuated, and after surrounding the anterior end (**genu**) of the corpus callosum it passes downwards towards the olfactory pyramid along the line that separates the paraterminal gyrus from the neopallium. The indusium represents the atrophied remains of the anterior part of the hippocampal arc of the fœtal brain (Fig. 843). It is accompanied by longitudinal fibres—the **striæ longitudinales** of the corpus callosum (Figs. 842, 845, 850).

The anterior end of the dentate gyrus dips into a deep furrow in the uncus of the temporal lobe; here it becomes considerably reduced in diameter and then emerges (at right angles to its previous direction) to form the **tail of the dentate gyrus**. Immediately in front of the upper end of the tail of the dentate

gyrus a little knob of solid grey matter appears upon the surface in the middle of the uncus. This is the **amygdaloid nucleus** (Fig. 842).

Corpus Callosum.—The corpus callosum is the great neopallial commissure. It is placed nearer the anterior than the posterior end of the brain; it unites the medial surfaces of the hemispheres throughout very nearly a half of their antero-posterior length, and is highly arched from before backwards (Fig. 829).

The *superior surface* of the corpus callosum forms the bottom of the longitudinal fissure, and on each side of this it is separated from the gyrus cinguli by a slit called the *callosal sulcus*. The surface is covered with the **indusium griseum**, which is continuous at the bottom of the callosal sulcus with the cortex of each hemisphere. Two pairs of delicate longitudinal bands or striæ are embedded in the indusium. The **medial longitudinal stria** is the more strongly marked, and is separated from its fellow of the opposite side by a faint median furrow. The **lateral longitudinal stria** is under cover of the gyrus cinguli. The indusium, with the striæ, represents the vestigial remains of the hippocampus (see above). So thin is the indusium that the transverse direction pursued by the callosal fibres can be easily perceived through it.

The *two ends* of the corpus callosum are much thicker than the main part or **trunk**. The *posterior end*, which is full and rounded, lies over the mid-brain and extends backwards as far as the highest point of the cerebellum. It is called the **splenium**, and its lower part is bent forwards under the upper part, to the inferior surface of which it is closely applied. The *anterior end* is folded downwards and backwards on itself. It is termed the **genu**. The recurved inferior part of the genu rapidly thins as it passes backwards, and receives the name of the **rostrum**. The fine terminal edge of the rostrum becomes connected by means of a band of neuroglial tissue with the lamina terminalis on the front of the anterior commissure (Fig. 829 and dotted line in Fig. 845 C).

The *inferior surface* of the corpus callosum, on each side of the median plane, is coated with ependyma (Fig. 850, p. 967) and forms the roof of the anterior horn and the central part of the lateral ventricle. In the median plane, however, it is attached to subjacent parts, viz., to the septum lucidum in front and directly or indirectly (Fig. 829) to the body of the fornix behind (Fig. 850).

The transverse fibres of the corpus callosum, as they enter the white centre of the cerebral hemisphere, splay out to reach most parts of the cerebral cortex. These diverging fibres intersect those which form the *corona radiata*, that is, the fibres which extend between the internal capsule and the cerebral cortex (Figs. 854 and 855, p. 971). The more anterior of the fibres which compose the genu of the corpus callosum sweep forwards in a series of curves into the anterior region of each hemisphere, and the name **forceps minor** is given to the figure formed by these curving bundles. A large part of the splenium, forming a solid bundle termed the **forceps major**, bends suddenly and abruptly backwards into the occipital lobe (Fig. 846). Fibres from the trunk and upper part of the splenium, curving round the lateral ventricle, form a very definite stratum called the **tapetum**. It is a thin layer in the white centre of the hemisphere which constitutes the immediate roof and lateral wall of the posterior horn and the lateral wall of the inferior horn of the lateral ventricle. In coronal sections through the occipital and posterior temporal regions the tapetum stands out very distinctly (Fig. 846; see also Figs. 851, p. 967, and 853, p. 969).

Septum Lucidum (Fig. 829).—This is a thin vertical partition which intervenes between the two lateral ventricles. It is triangular in shape, and posteriorly it is prolonged backwards for a variable distance between the trunk of the corpus callosum and the fornix, to both of which it is attached. In front it occupies the gap behind the genu of the corpus callosum, whilst below, in the narrow interval between the posterior edge of the rostrum of the corpus callosum and the fornix, it is continuous, in early stages, with the paraterminal gyrus; but the subsequent development of the band of neuroglial tissue (see above) extending from the rostrum to the lamina terminalis breaks this continuity. The septum lucidum is composed of a pair of thin laminæ which are close together but separated (Fig. 848 Fig. 850, p. 967) by a cavity of variable size.

Lateral Ventricle

The cavity in the interior of the cerebral hemisphere is called the **lateral ventricle**. It is lined throughout with ependyma and is filled with cerebro-spinal fluid; it is of varying size, being reduced to a mere chink in places, *e.g.*, the posterior horn; and it communicates with the third ventricle of the brain by means of the **interventricular foramen** (Figs. 829, 849 and Pl. LXXIV, p. 945).

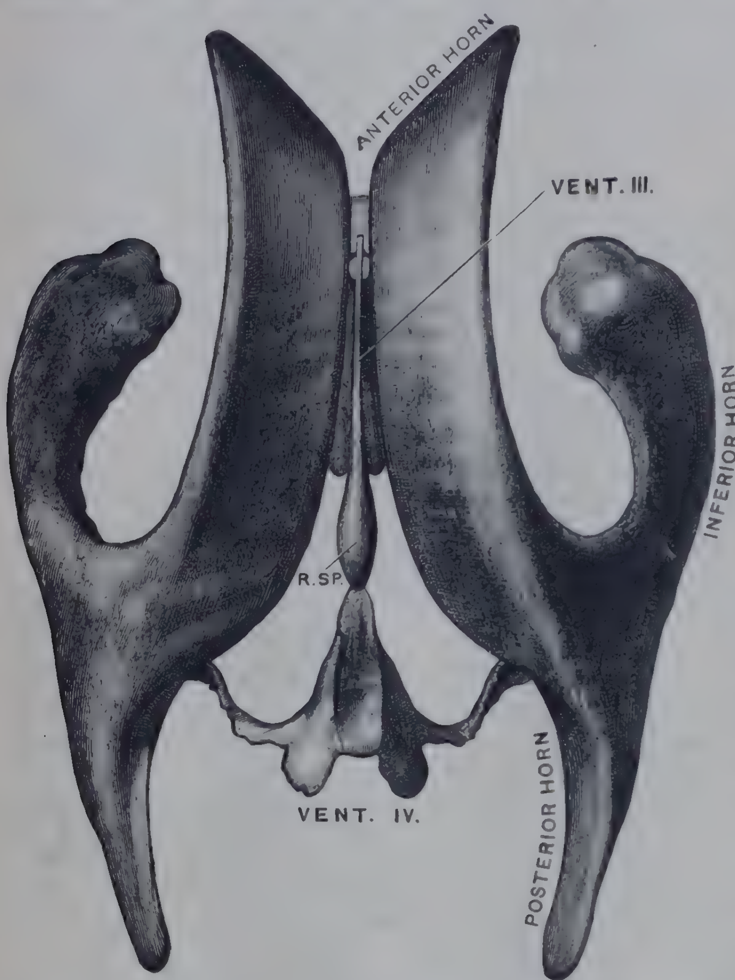

Fig. 847.—Drawing of Cast of Ventricular System of the Brain, seen from above. (After Retzius, 1900.)
Vent. III. Third ventricle. Vent. IV. Fourth ventricle.
R.SP. Suprapineal recess.

The highly irregular shape of the lateral ventricle can be best understood by the study of a cast of its interior (Figs. 830, p. 949, and 847). It is divisible into a central part and three horns,—anterior posterior, and inferior. The **anterior horn** is the part of the cavity in front of the interventricular foramen. The **central part** extends from the interventricular foramen to the splenium of the corpus callosum. At that level it is continuous with the posterior and inferior horns, which diverge from each other. The **posterior horn** curves backwards and medially into the occipital lobe. It is very variable in its length and capacity, for adhesions may occur between its walls. The **inferior horn** proceeds with a bold sweep round the posterior end of the thalamus, tunnels downwards and forwards in the temporal lobe, and then turns medially to end in the region of the uncus (Fig. 852).

The early fœtal lateral ventricle is very capacious and presents an arched form. Its parts correspond to the anterior horn, the central part and the inferior horn, and there is little or no demarcation between them. The posterior horn is a later production which grows backwards into the occipital lobe from the primitive cavity.

The **anterior horn** extends in a forward and lateral direction in the frontal lobe. When seen in coronal section (Fig. 848) it presents a triangular outline. It is bounded *in front* by the fibres of the genu of the corpus callosum; the *roof* is the trunk of the corpus callosum and the floor is the rostrum. The *medial wall*, which is vertical, is the septum lucidum; the *lateral wall* is sloping and presents a marked elevation or bulging, formed by the smooth, rounded head of the caudate nucleus.

The **central part** of the cavity also is *roofed* by the trunk of the corpus callosum. On the *medial side* it is bounded by the posterior part of the septum lucidum and by the line of contact between the corpus callosum and the body of the fornix. On the *lateral side* it is closed by the meeting of the floor and the roof of the cavity. On the *floor* a number of important objects may be recognized. From the lateral to the medial side they are met in the following order: (1) the body of the caudate nucleus; (2) a groove which extends obliquely from before backwards and laterally between the caudate nucleus and the thalamus, and in which are placed the thalamo-striate vein and a white band called the stria semicircularis; (3) a

portion of the upper surface of the thalamus; (4) the choroid plexus; (5) the sharp edge of the body of the fornix (Fig. 849).

The **caudate nucleus** narrows rapidly as it proceeds backwards on the lateral part of the floor of the lateral ventricle. The thalamo-striate vein is covered over with ependyma; it joins the internal cerebral vein close to the interventricular foramen. The connexions of the **stria semicircularis** will be dealt with later. The portion of the upper surface of the **thalamus** which appears in the floor of the ventricle is in great part hidden under the choroid plexus. The ependymal strip of the wall of the hemisphere, as it extends between the edge of the fornix and the upper surface of the thalamus, is invaginated at the choroid fissure into the central part of the lateral ventricle by the richly vascularized edge of the pial fold called the tela chorioidea. This vascular fringe with its ependymal covering is called the **choroid plexus**. In front it is continuous, in the interventricular foramen, with the choroid plexus of the third ventricle (Fig. 829 and Fig. 848), whilst, behind, it is carried into the inferior horn of the ventricle. Although the choroid plexus has all the appearance of lying free within the ventricle, it must be borne in mind that it is invested by the ependyma which represents a portion of the wall of the hemisphere and excludes it from the cavity. As elsewhere, the ependyma which covers the choroid plexus is modified to form a secretory epithelium concerned with the production of cerebro-spinal fluid.

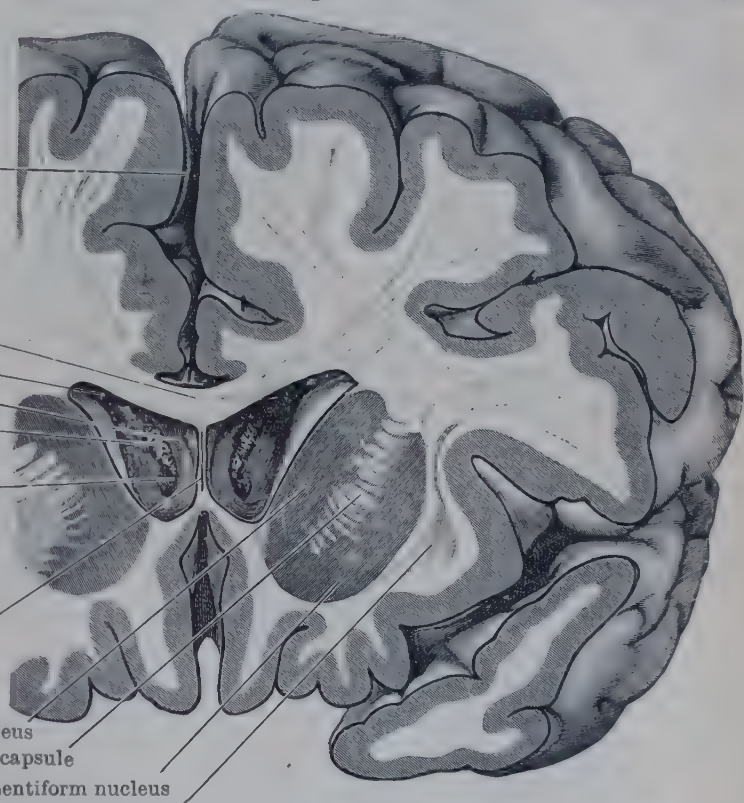

FIG. 848.—CORONAL SECTION THROUGH THE CEREBRAL HEMISPHERES. The section (viewed from the front) cuts the anterior horns of the lateral ventricles, through which the central part of the ventricles, the anterior columns of the fornix, and the interventricular foramina can be seen.

The **posterior horn** is an elongated diverticulum carried backwards into the occipital lobe from the posterior end of the ventricle. It tapers to a point and describes a gentle curve, the convexity of which is directed laterally. Its *roof* and *lateral wall* are formed by the tapetum of the corpus callosum. In coronal sections through the occipital lobe the tapetum is seen as a thin but distinct white layer immediately lateral to the ependyma and to the medial side of a much larger sheet of fibres, viz., the optic radiation.

On the *medial wall* two elongated curved elevations may be observed. The upper of them is termed the **bulb of the posterior horn**, and is produced by the forceps major. Below the bulb is the elevation known as the **calcar avis**. It varies greatly in size in different brains, and is caused by an infolding of the ventricular wall in correspondence with the calcarine sulcus on the exterior of the hemisphere. It may come into contact with and adhere to the lateral wall of the horn in a part or even the whole of its extent.

The calcar avis, which used to be called the "hippocampus minor", has a curious literary association. It is actually mentioned in Charles Kingsley's classical fairy-tale, *The Water-Babies* (chap. 5), where the author amusingly refers to it as the "hippopotamus major". The occasion

for this digression by Kingsley was the famous meeting of the British Association at Oxford in 1860 when a highly animated discussion took place on the subject of Man's descent from lower animals. Sir Richard Owen, the distinguished comparative anatomist, had contended that the hippocampus minor is a feature characteristic of the human brain whereby it is sharply distinguished from the ape's brain. Professor T. H. Huxley, however, had no difficulty in demonstrating the presence of the hippocampus minor in the brain of the chimpanzee, and thus provided a debating point which perhaps received a rather exaggerated emphasis in the ensuing controversy.

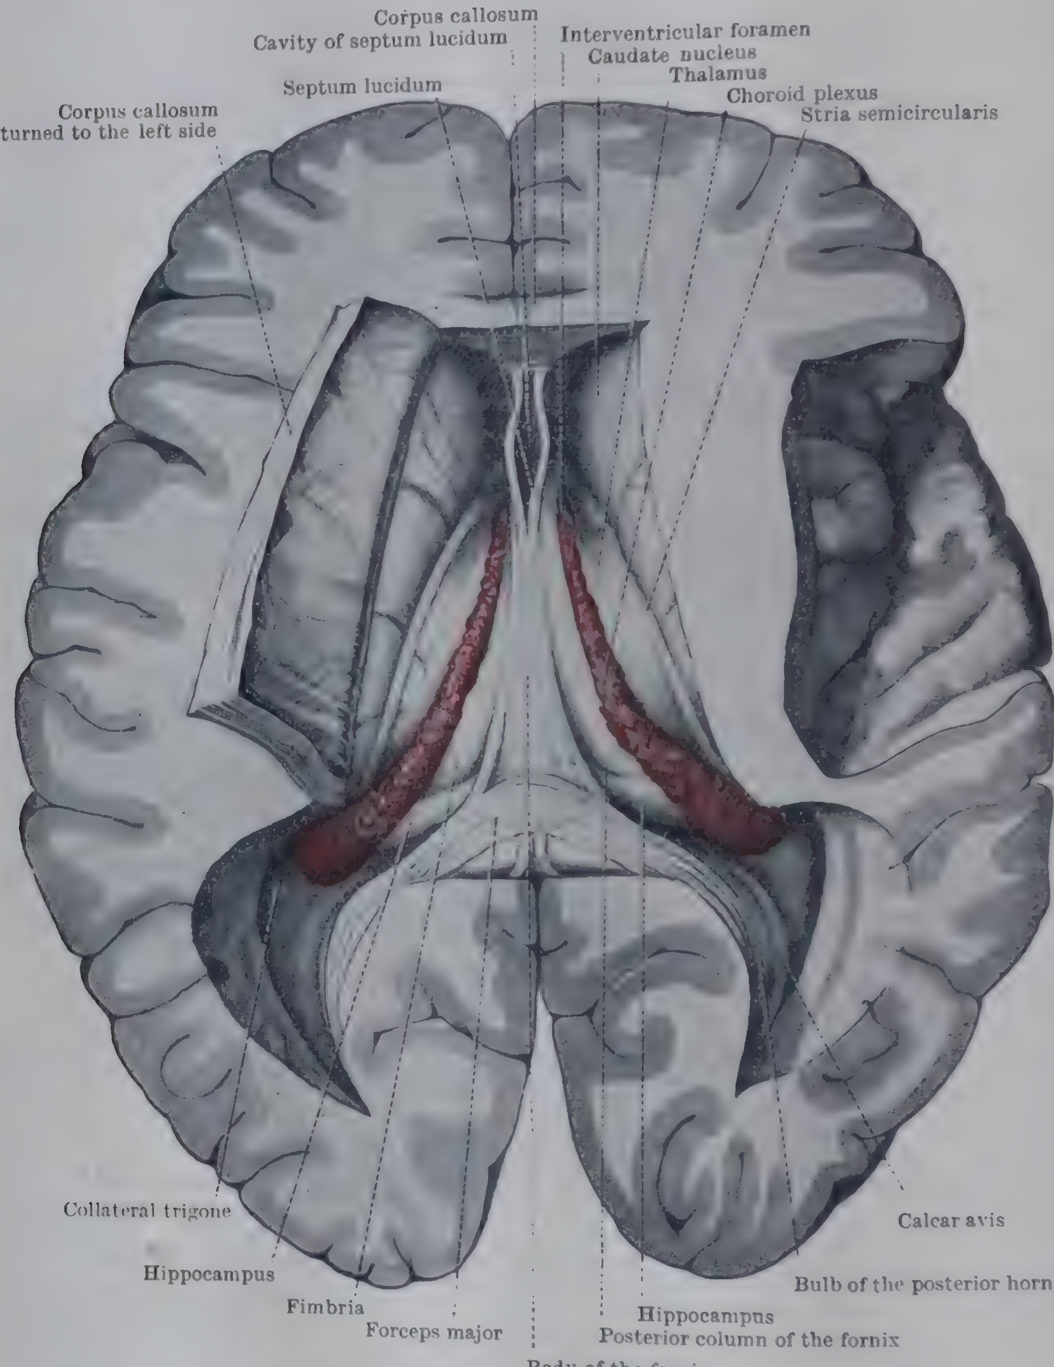

FIG. 849.—DISSECTION TO SHOW THE FORNIX AND LATERAL VENTRICLES.

The **inferior horn** is the continuation of the cavity into the temporal lobe. It is prolonged downwards and forwards behind the thalamus into the temporal lobe, in the centre of which it takes a curved course forwards and medially as far as the uncus.

In the angle between the diverging posterior and descending horns, and therefore between the calcar avis and the hippocampus as they diverge, the cavity presents an expansion of triangular shape, the floor of which is raised and is known as the **collateral trigone**. This eminence is raised up by the collateral sulcus which lies in immediate relation to it.

The *lateral wall* of the inferior horn is formed by the tapetum of the corpus

callosum. At the end of the horn, the *roof* presents a bulging produced by a collection of grey matter termed the **amygdaloid nucleus.** The **stria semicircularis** and the attenuated **tail of the caudate nucleus** are both prolonged into the inferior horn and are carried forwards in its roof to the amygdaloid nucleus. The ependymal *medial wall* of the descending horn is inthrust to form the temporal continua-

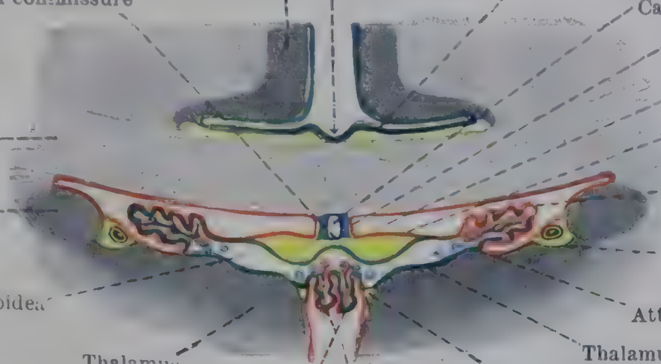

FIG. 850.—DIAGRAM OF CORONAL SECTION THROUGH CENTRAL PARTS OF LATERAL VENTRICLES.

tion of the choroid fissure, in which the choroid plexus is carried downwards and forwards.

On *the floor* of the inferior horn the following structures are seen: (1)

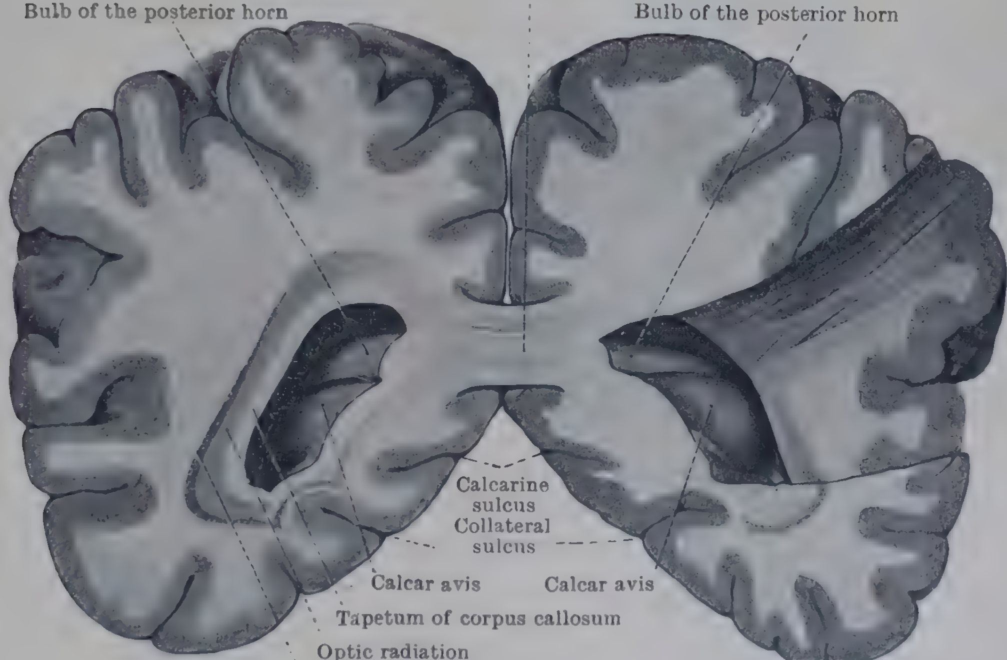

FIG. 851.—CORONAL SECTION THROUGH POSTERIOR HORNS OF LATERAL VENTRICLES, VIEWED FROM THE FRONT.

hippocampus; (2) the choroid plexus; (3) the fimbria; and (4) the collateral eminence.

The **hippocampus** forms an elongated swelling which extends to the tip of the inferior horn and is overlapped by the fimbria. At its anterior extremity it expands into a rounded and slightly lobulated eminence—the *pes hippocampi.* The hippocampus is for the most part covered by the choroid plexus. If this is detached the course of the choroid fissure is seen between the fimbria and the roof of the horn. This fissure appears at a very early date in the development of the cerebral hemisphere, and takes an arcuate course round the posterior end of

the thalamus (Fig. 837). In the region of the central part of the ventricle it extends as far forwards as the interventricular foramen and is formed by the involution of the ependymal part of the wall of the ventricle over the choroid plexus. In the region of the inferior horn, when the choroid plexus, with the involuted ependymal layer which covers it, is withdrawn, the choroid fissure is converted into an artificial gap which leads directly into the horn.

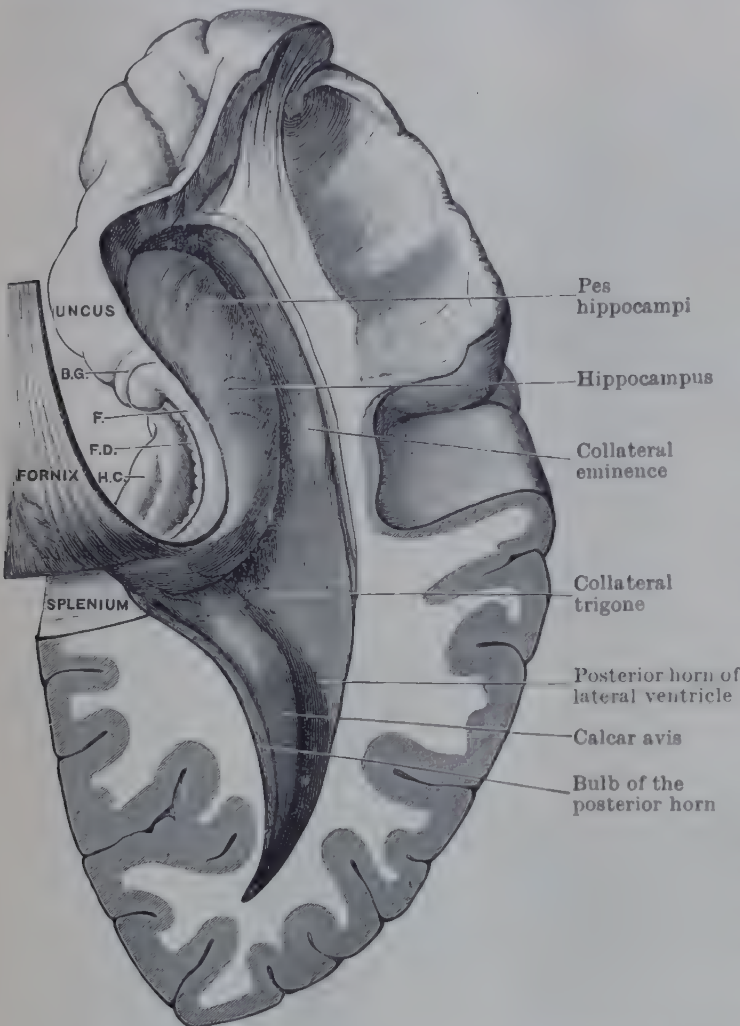

Fig. 852.—Dissection from above to show Posterior and Inferior Horns of Lateral Ventricle.

B.G. Tail of dentate gyrus. F.D. Dentate gyrus.
F. Fimbria hippocampi. H.C. Hippocampal gyrus.

The **choroid plexus** is a convoluted system of blood-vessels embedded in a fold of pia mater which is carried into the central part and the inferior horn of the ventricle. It lies on the surface of the hippocampus and is continuous, behind the posterior part of the thalamus, with the choroid plexus in the central part of the ventricle. But the choroid plexus does not lie free in the ventricular cavity. It is clothed in the most intimate manner by an ependymal layer which represents the medial wall of the inferior horn and central part of the ventricle involuted into the cavity over the plexus. The ventricle, therefore, opens on the surface through the choroid fissure only when that thin epithelial layer is torn away by the withdrawal of the choroid plexus. From the above, it will be understood that the choroid fissure, throughout its whole length (viz., from the interventricular foramen to the end of the inferior horn), is formed by the invagination of a portion of the wall of the hemisphere which remains ependymal. In the central part of the ventricle this layer is attached, on the one hand, to the margin of the fornix, and on the other to the upper surface of the thalamus; in the inferior horn it is attached to the edge of the fimbria, whilst, above, it joins the roof of the horn along the line of the stria semicircularis.

The **collateral eminence** (Fig. 852) varies greatly in its degree of development, which depends upon the depth of the corresponding part of the collateral sulcus in the tentorial surface of the temporal lobe.

Basal Nuclei

Under this heading are included certain masses of grey matter more or less completely embedded in the white substance of the hemisphere. They are the caudate and lentiform nuclei (which together form the corpus striatum) the amygdaloid nucleus, and the claustrum.

The **caudate nucleus** bulges into the lateral ventricle. It is a long curved mass of grey matter divisible into a head, a body and a tail. The head is the smooth bulging seen in the lateral wall of the anterior horn of the ventricle; and

its lower part is continuous with the anterior perforated substance. The body—much narrower—extends backwards in the floor of the central part of the ventricle where it is separated from the thalamus by the stria semicircularis. The tail curves downwards with a bold sweep and enters the inferior horn, in the roof of which it is prolonged forwards to join the amygdaloid nucleus. The caudate nucleus thus presents a free ventricular surface, covered with ependyma, and a deep surface applied to the medial side of the internal capsule and the base of the corona radiata; and, owing to its arched form, it is cut in two places in many of the sections of the hemispheres—both horizontal and coronal.

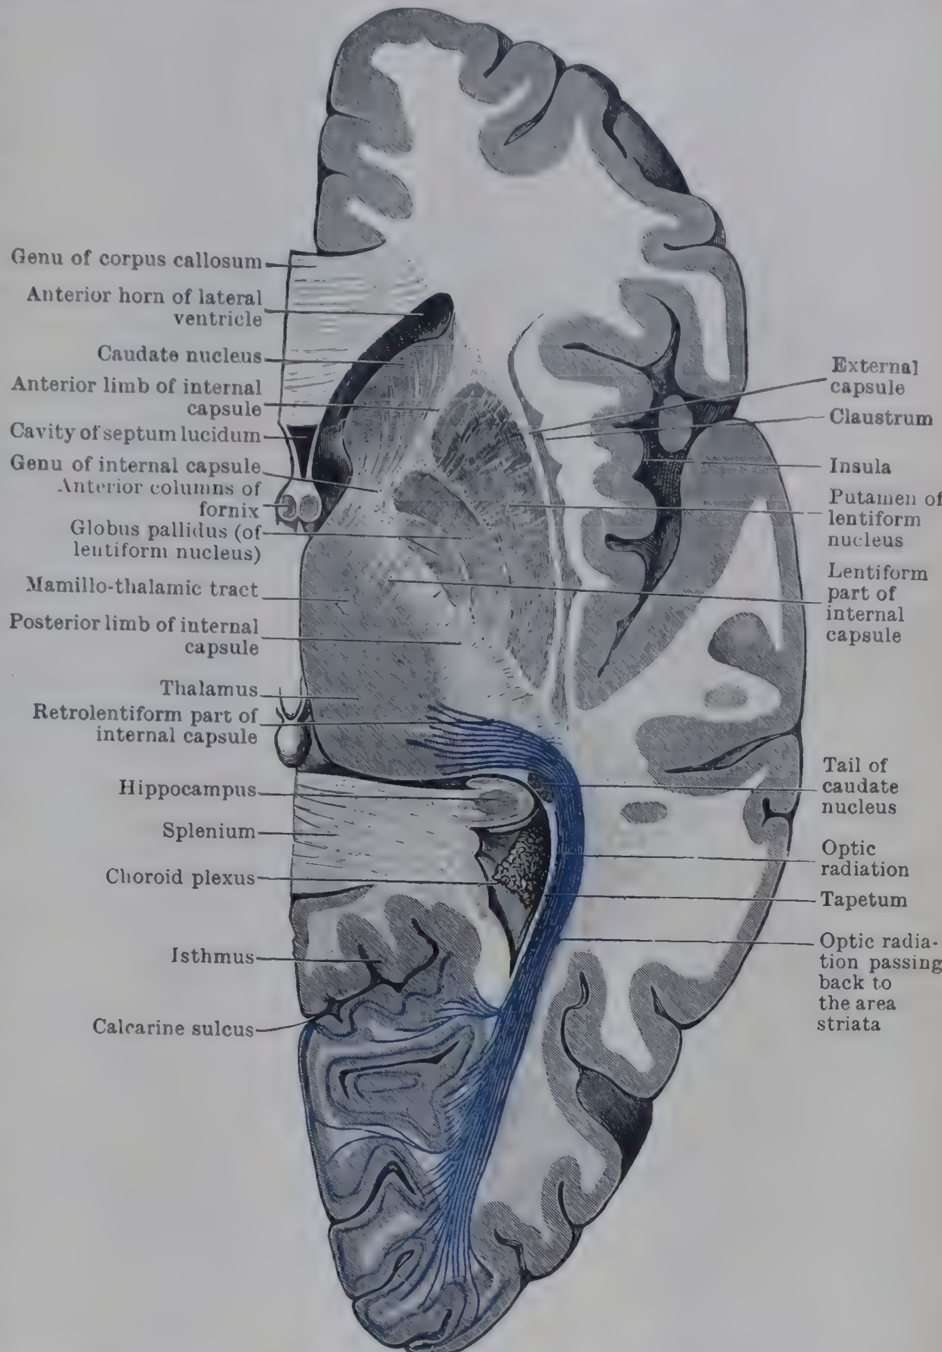

Fig. 853.—Horizontal Section of Right Cerebral Hemisphere at Level of Widest Part of Lentiform Nucleus.

The **lentiform nucleus** is for the most part embedded in the white substance of the cerebral hemisphere lateral to the thalamus and the head of the caudate nucleus. It does not extend either so far forwards or so far backwards as the caudate nucleus; indeed, in extent, it corresponds very closely with the insula. When seen in horizontal section, it presents a shape similar to that of a biconvex lens. Its medial surface bulges more than the lateral surface, and its point of highest convexity is placed opposite the stria semicircularis and the interval between the head of the caudate nucleus and the thalamus. In coronal section the appearance differs very much in different planes of section. Fig. 854 represents a section through its anterior portion. Here it is semilunar in outline; its lower part is directly continuous with the head of the caudate nucleus, and its upper part is intimately connected with the caudate nucleus by bands of grey matter which pass between the two nuclei, breaking up the anterior part of the internal capsule. It is due to the ribbed or barred appearance presented by such a section as this that the term **corpus striatum** is applied to the two nuclei. In the region of the anterior perforated substance both nuclei are fused together where they approach close to the basal surface of the brain.

When a section is made in a plane farther back (*e.g.*, immediately behind the

anterior commissure, as in Fig. 855) the lentiform nucleus has an altogether different shape, and is seen to be completely cut off from the body of the caudate nucleus by the base of the corona radiata (the knife having passed behind the uniting bars of grey matter). It is now wedge-shaped. Its *base* is turned towards the insula and is in direct relation to a thin lamina of white matter termed the external capsule. Its *medial surface* is oblique and is applied to the internal capsule, whilst its *inferior surface* is horizontal and is related to the amygdaloid nucleus and the white matter above the roof of the inferior horn of the ventricle. But, further, two white laminæ are now evident; they traverse its substance in a vertical direction and divide it into three masses; the lateral and larger mass is termed the **putamen**, and the medial two portions together constitute the **globus pallidus**.

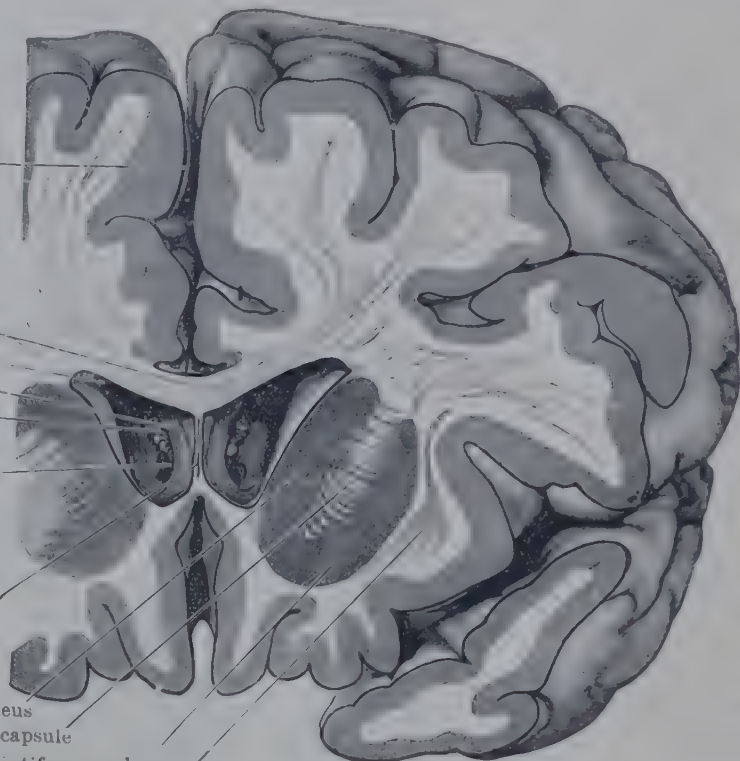

FIG. 854.—CORONAL SECTION THROUGH THE CEREBRAL HEMISPHERES. The section (viewed from the front) cuts the putamen of the lentiform nucleus in front of the globus pallidus.

The **putamen** is much the largest part of the lentiform nucleus. In colour it resembles the caudate nucleus, with which it is closely associated both in structure and in mode of development; and it is the only part of the lentiform nucleus which is connected by bands of grey matter with the caudate nucleus. In antero-posterior length as well as in vertical depth the putamen is larger than the globus pallidus; consequently, in both coronal and horizontal sections through the cerebrum it is encountered before the plane of the globus pallidus is reached.

The external capsule is loosely connected with the lateral surface of the putamen, and it can be readily stripped off. This accounts for the tendency, exhibited in hæmorrhages in this locality, for the effused blood to spread out in the interval between these structures.

The **globus pallidus** is composed of the two smaller and medial masses of the lentiform nucleus. They present a faint yellowish tint, and are paler and more abundantly traversed by medullated fibres than the putamen. The part next the putamen is much larger than the other and extends forwards to a point a little in front of the plane of the anterior commissure.

Structure and Connexions of Corpus Striatum.—It is remarkable, in spite of intensive investigations, that little is yet known of the details of the connexions and functions of this large mass of grey matter which lies embedded in each cerebral hemisphere. It may be said, however, that the corpus striatum represents the "head-nucleus" of a primitive efferent system of the brain—the so-called *extrapyramidal system*. This motor path precedes in evolutionary development the pyramidal tract system (whereby the lower motor levels of the brain-stem and spinal cord are brought under direct cortical control), and it is much more diffusely organized. Interposed in the course of the descending fibres which leave the corpus striatum and enter the brain-stem are a number of nuclear elements which have been described in previous sections, *e.g.*, the subthalamic nucleus, substantia

nigra, the red nucleus, and the olivary nucleus. All these are commonly included as component parts of the extrapyramidal system.

It has already been noted that the caudate nucleus and the putamen have the same macroscopic appearance in section, that they are incompletely separated from each other, and that their partial separation by the internal capsule and the base of the corona radiata is secondarily effected during embryonic development. In their histological structure the two elements are also identical, being composed of densely packed small cells with quite short axons, interspersed with which are scattered larger cells with longer axons. In contrast, the globus pallidus is composed of characteristic large multipolar cells, closely resembling in general appearance typical motor cells of the brain-stem and spinal cord. The structural distinction from the globus pallidus which the caudate nucleus and putamen show has led in recent years to a modification of the usual terminology applied to these elements, for many writers now use the term *striatum* for the caudate nucleus and putamen together, while the globus pallidus is referred to as the *pallidum*. These names have the considerable merit of brevity and convenience.

The afferent connexions of the **striatum** are very uncertain. It has been suggested

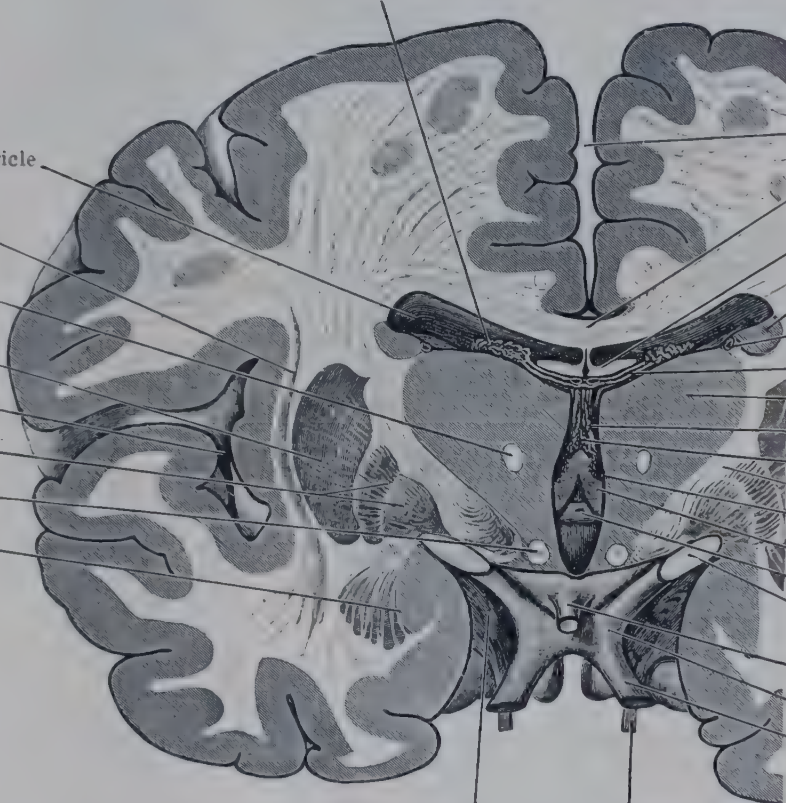

Fig. 855.—Coronal Section through the Cerebrum (viewed from behind) to show the Parts of the Lentiform Nucleus.

that ascending fibres from the subthalamus, conveying a variety of impulses, end in it, but a satisfactory demonstration of some of these presumed connexions has yet to be made. In recent years, however, it has been definitely established that the caudate nucleus receives ascending connexions from the substantia nigra. Descending connexions also exist between certain areas of the cerebral cortex and the caudate nucleus and putamen (see p. 972). Fibres which run in both directions between the striatum and thalamus have also been described, but while strio-thalamic connexions remain doubtful, thalamo-striate fibres almost certainly do not exist except in the case of the centre median nucleus (from which fibres probably pass to the globus pallidus). Numerous short connexions are known to interconnect different parts of the caudate nucleus and putamen with each other, and fibres also run from both these elements to the pallidum. Apart from the latter, no efferent fibres leave the striatum to reach other parts of the brain.

The afferent connexions of the **pallidum** are almost entirely derived from the other striatal elements. There is some evidence that ascending fibres from the hypothalamus and subthalamus reach it, and, in recent years, anatomical and electro-physiological studies have demonstrated that a few fibres of the medial lemniscus (which have their origin in the gracile and cuneate nuclei) terminate in the globus pallidus of the opposite side. Descending fibres from the premotor and general sensory areas of the cortex (and probably from certain other areas) also reach the globus pallidus.

The pallidum is essentially the *efferent* nucleus of the basal nuclei, and from its large motor cells numerous fine medullated fibres take their origin and stream in a downward and medial direction. They describe a characteristic loop over the fibres of the internal capsule where these emerge to form the basis pedunculi, and make their way into the subthalamus and the tegmentum of the mid-brain. This loop is called the **ansa lenticularis** (Fig. 856).

The fibres of the ansa lenticularis end in five main stations: (1) the hypothalamus, (2) the subthalamic nucleus, (3) the substantia nigra, (4) the red nucleus, and (5) the olivary nucleus. Some of these fibres may cross the median plane, but most end on the same side of the brain-stem.

It may be noted that the elucidation of the fibre-connexions of the basal nuclei is made exceptionally difficult by the fact that many fibres which penetrate them are fibres of passage only. For example, large numbers of afferent and efferent cortical fibres run through the caudate nucleus and the putamen on their way up to the cortex or down into the brain-stem.

Whatever the nature of the afferent impulses may be which reach the basal nuclei, it is clear that, by way of the efferent system which leaves the pallidum, they can influence the activities of the hypothalamus, and also those of the red nucleus, subthalamic nuclei and substantia nigra. The last three elements provide intermediate stations through which the basal nuclei are able to modify the activities of lower motor neurons in the brain-stem and spinal cord and thus play a part in the regulation of the tonus of the voluntary musculature of the body. Lastly, the pallido-olivary tract provides a pathway through which the basal nuclei are brought into functional relation with the cerebellar hemisphere of the opposite side.

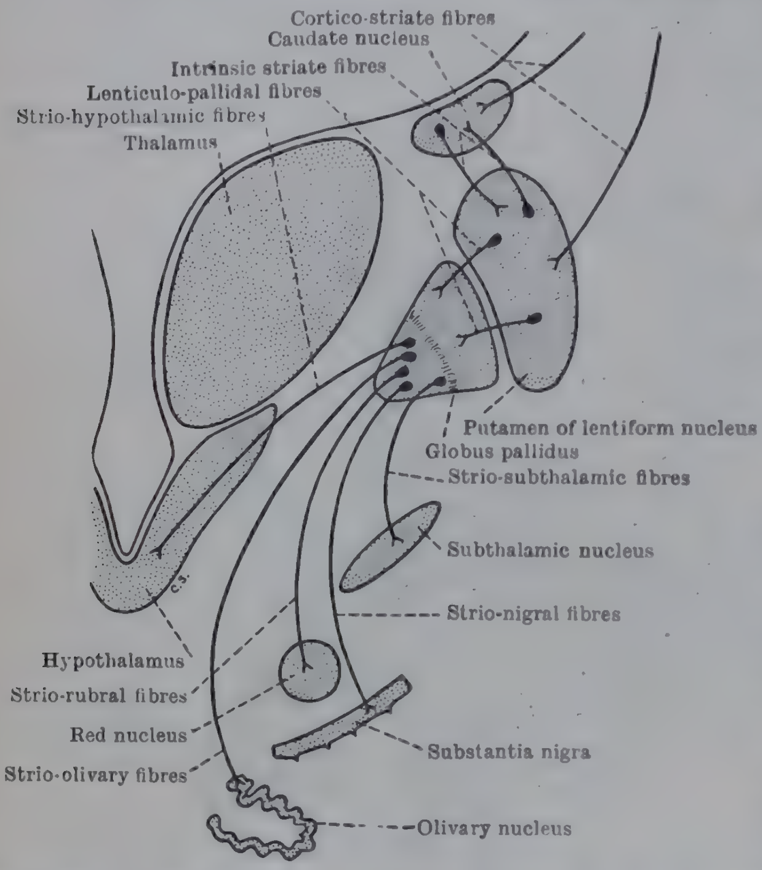

FIG. 856.—DIAGRAM ILLUSTRATING CONNEXIONS OF THE BASAL NUCLEI. The fibres that issue from the globus pallidus constitute the ansa lenticularis.

The relation of the basal nuclei to the control of muscle-tonus is emphasized by clinical observations. For example, lesions affecting the caudate nucleus and putamen are commonly associated with muscular rigidity and a characteristic tremor, while lesions of the globus pallidus are often associated with involuntary spasmodic movements (athetosis and chorea).

For further information on the connexions and functions of the corpus striatum, see *The Diseases of the Basal Ganglia*, edited by T. J. Putnam, 1942.

Claustrum.—This is a thin plate of grey substance embedded in the white matter between the lentiform nucleus and the cortex of the insula. Followed in an upward direction, it becomes gradually thinner and ultimately disappears.

As it is traced downwards, however, it thickens considerably, and at the base of the brain it fuses with the putamen of the lentiform nucleus where this comes to the surface at the anterior perforated substance. Its extent corresponds very closely with the area occupied by the insula, and its lateral surface shows ridges and depressions that correspond to the insular gyri and sulci.

In its histological structure, the claustrum shows resemblances to the underlying putamen, and also to the deeper layers of the superjacent cortex. Embryological evidence also indicates that it is of composite origin, derived from neuroblastic tissue which contributes to the development of the striatum and also from that which gives rise to adjacent parts of the cortex. The functional significance of the claustrum is quite unknown.

Amygdaloid Nucleus.—Near the anterior end of the temporal lobe, a fusiform mass of grey matter appears on the upper surface of the uncus (Fig. 842, p. 959), at the lateral border of the anterior perforated substance (Fig. 831, p. 950). It is part of a rounded mass, called the **amygdaloid nucleus**, which occupies a position in front of and to some extent above the anterior end of the inferior horn of the lateral ventricle. The amygdaloid nucleus is really a composite structure, composed of a number of subsidiary nuclear elements having diverse

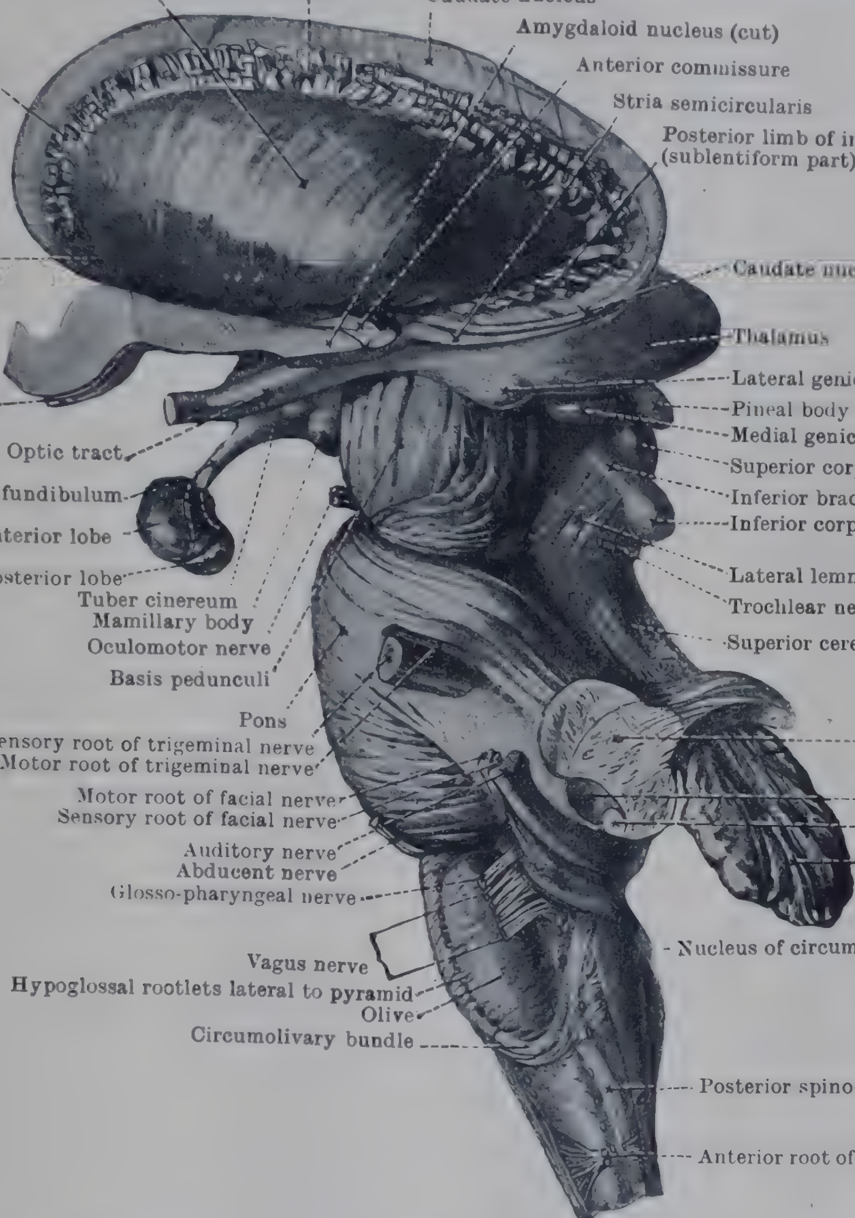

FIG. 857.—DISSECTION EXPOSING THE LENTIFORM NUCLEUS OF THE LEFT HEMISPHERE.

connexions. The tail of the caudate nucleus joins its lower part (Fig. 857), and its upper part is carried up into the putamen. Inferiorly it is continuous with the cortex of the piriform area, to which it is in part functionally related.

Stria Semicircularis.—This is a band of fibres which, for the most part, arises in certain nuclear elements of the amygdaloid nucleus. From this it runs backwards in the roof of the inferior horn of the lateral ventricle (Fig. 831, p. 950, and Fig. 857), and then arches upwards and forwards to gain the floor of the central part of the ventricle. In both situations it lies close to the medial side of the caudate nucleus: at the interventricular foramen it bends downwards towards the anterior commissure. Some of its fibres pass in front of the commissure and others behind it, and ultimately they end in the neighbourhood of the anterior perforated substance. The functional significance of this fibre-bundle is not certainly known, but it is probably related to olfaction.

Internal Capsule.—This term is applied to the broad band of white matter

which separates the lentiform nucleus from the thalamus and the head of the caudate nucleus. It presents different appearances according to the plane in which the brain is cut. A coronal section which passes through the cerebral peduncles shows that, in great part, the internal capsule is directly continuous with the basis pedunculi (Fig. 823, p. 938). Viewed from the lateral aspect after removal of all else of the cerebral hemisphere except the corpus striatum (Fig. 857), the cut ends of the fasciculi of the internal capsule form three-fourths of an ellipse, the other fourth of which is occupied by the bridge of union between the lentiform and caudate nuclei, the anterior perforated substance, the amygdaloid nucleus and the anterior commissure. It may be divided into an **anterior (lenticulo - caudate) part**, a **posterior (lenticulo - thalamic) part**, a **retrolentiform part** (not labelled in the figure), and a **postero-inferior (sublentiform) part**. The last three parts are usually grouped together as the posterior limb. In horizontal section the internal capsule is observed to be bent upon itself at the interval between the thalamus and the head of the caudate nucleus. This bend, which points medially, is called the **genu**. About one-third of the internal capsule lies in front of the genu, and is termed the anterior limb; the remaining two-thirds, which lie behind the genu, constitute the posterior limb (Fig. 853).

The **anterior limb of the internal capsule** intervenes between the lentiform nucleus and the head of the caudate nucleus. In its inferior and anterior part it is much broken up by the connecting bands of grey matter which pass between the anterior part of the putamen and the caudate nucleus.

The anterior limb of the internal capsule is composed largely of *corticipetal fibres* that arise in the anterior part of the ventral nucleus and in the medial nucleus of the thalamus, and go through the anterior limb to reach the cortex of the frontal lobe. It contains *corticifugal fibres* also. These are cortico-thalamic fibres (passing mainly to the medial nucleus of the thalamus), and the frontal components of the cortico-pontine fibres. The **fronto-pontine fibres** arise in the cortex of the frontal region, traverse the anterior limb of the internal capsule, form the medial fifth of the basis pedunculi, and finally end in the nuclei pontis.

The **posterior limb of the internal capsule** is placed between the thalamus and the lentiform nucleus, and it extends backwards for a short distance beyond the posterior end of the putamen on the lateral side of the posterior part of the thalamus. The posterior limb may therefore be described in three parts—lentiform, retrolentiform, and sublentiform.

The **lentiform** (or more properly, **lenticulo-thalamic**) **part** of the posterior limb is composed of both corticipetal and corticifugal fibres. The *corticipetal fibres* enter the internal capsule from the thalamus, where they arise from cells in the ventral and lateral nuclei and proceed upwards to the parietal lobe of the cerebral cortex.

The *corticifugal fibres* are the pyramidal fibres and the cortico-thalamic fibres. The great **motor** or **pyramidal tract** descends from the cerebral cortex through the corona radiata and enters the lentiform part of the internal capsule. The fibres that go to the nuclei of the oculomotor, trigeminal, and facial nerves lie close to the genu, and behind them there are the fibres which go to the hypoglossal nucleus; still farther back are the fibres that end around the motor cells of the anterior grey column of the spinal cord. The fibres of the pyramidal tract, therefore, occupy the genu and the anterior two-thirds of the posterior limb of the internal capsule. The fibres are segregated in the sense that the head-end of the body is represented most anteriorly and the tail-end most posteriorly. The pyramidal fibres have been observed occupying the middle part of the basis pedunculi, into which they pass directly from the internal capsule.

The **retrolentiform** and **sublentiform parts** of the posterior limb contain: (1) the fibres of the optic radiation as they pass from the lateral geniculate body to establish their connexions with the occipital cortex; (2) the fibres of the auditory radiation—*i.e.*, those which connect the medial geniculate body with the auditory cortical field in the temporal lobe (Figs. 825, 862, 864); (3) the *temporo-pontine tract* which is composed of fibres that take origin in the temporal gyri and pass through the sublentiform section of the internal capsule to reach the lateral part of the basis pedunculi. Through this they reach the nuclei pontis, where they end.

If the fibres of the internal capsule are traced upwards they are found to spread out widely from one another in a radiating or fan-shaped manner

to the various gyri of the cerebral hemisphere. This arrangement is termed the **corona radiata.** The fibres of the callosal system, as they proceed into the hemisphere, also radiate, and they intersect the fibres of the corona radiata (Fig. 864, p. 984).

External Capsule.—The thin lamina of white matter between the putamen and the claustrum is called the external capsule. This joins with the internal capsule in front of and behind the putamen, and in this manner the nucleus lentiformis is encapsuled by white matter.

INTRINSIC STRUCTURE OF CEREBRAL HEMISPHERE

The cerebral hemisphere is composed of an external coating of grey matter termed the **cortex**, spread over an internal mass of white matter. The cortex is of peculiar interest, seeing that there is good reason for believing that it is the seat of the higher functions of the brain, or those which may be classed under the general designation of the intellectual functions. It is the same layer of grey matter that provides the means for the conscious recognition of those external impressions which gain access to the cerebro-spinal axis through the sense-organs; and in it are placed also the centres which are concerned with the initiation and control of voluntary movements. The white centre is composed of nerve-fibres which constitute the paths along which nervous impulses are carried to and from the cortex, and from one part of the cortex to another.

CEREBRAL CORTEX

The cortex is spread over the entire surface of the cerebral hemisphere, but it does not form a layer of equal thickness. At the summit of a gyrus it is usually thicker than at the bottom of a furrow. The maximum thickness of cortex (about 4 mm.) is attained in the upper part of the motor area, whilst the minimum (about 1·25 mm.) occurs at the occipital pole. The amount of cortex and the complexity of its gyri differ considerably in different individuals.

In structure also marked differences may be noted in the cortex of different regions, and there is good reason for supposing that these structural peculiarities have a relation to the functional characteristics of particular areas and also play a part in determining the pattern of the furrows that divide the cerebral cortex into a series of ridges or gyri. This structural difference is quite apparent to the naked eye when sections are made through the cortex in a fresh brain, and in some cases sharp transitions in structure occur at the place where one area joins another. It is only to those general structural features which more or less characterize the entire cortical layer that we shall be able to refer.

When sections are made through the fresh brain, and the cut surface is closely inspected, it will usually be apparent that the cortex is distinctly stratified. On the outside there is a thin, whitish layer, and beneath this the grey matter presents two strata of very nearly equal thickness, viz., a middle, grey-coloured stratum and an inner, yellowish-red stratum. Between the two latter layers a narrow white band is visible in many places. This is termed the **outer band of Baillarger**. When the layers indicated above are present, four strata, superimposed one upon the other, are recognized; but in certain regions a second white streak traverses the deep or inner grey layer and divides it further. This is termed the **inner white band of Baillarger**, and, when it is present, the cortex becomes divided obscurely into six alternating white and grey layers.

The outer band of Baillarger is strongly marked in the region of the calcarine and post-calcarine sulci and gives a characteristic appearance to this portion of the cortex. In this locality it receives the name of the **visual stria** (Fig. 853, p. 969).

White Centre of the Cerebral Hemisphere.—The white matter of the hemisphere is composed of medullated nerve-fibres, arranged in a very intricate manner. But the arrangement of these fibres cannot be properly understood until the configuration of the surface of the hemisphere has been considered.

Histological Structure of Cerebral Cortex.—Sections of the cerebral cortex which have been stained with methylene blue show that its cell-content is very rich. Moreover, the cells are arranged in distinct layers, each layer being usually characterized by a predominance of cells of a certain type. The number of layers which can be defined anatomically, their relative thickness and the sharpness of their boundaries, and the types of cells of which they are composed, vary considerably from one part to another, and it is on the basis of these variations that the cortex has been mapped out into a mosaic of different areas, each of which is characterized by its particular histological structure (Figs. 866, 873).

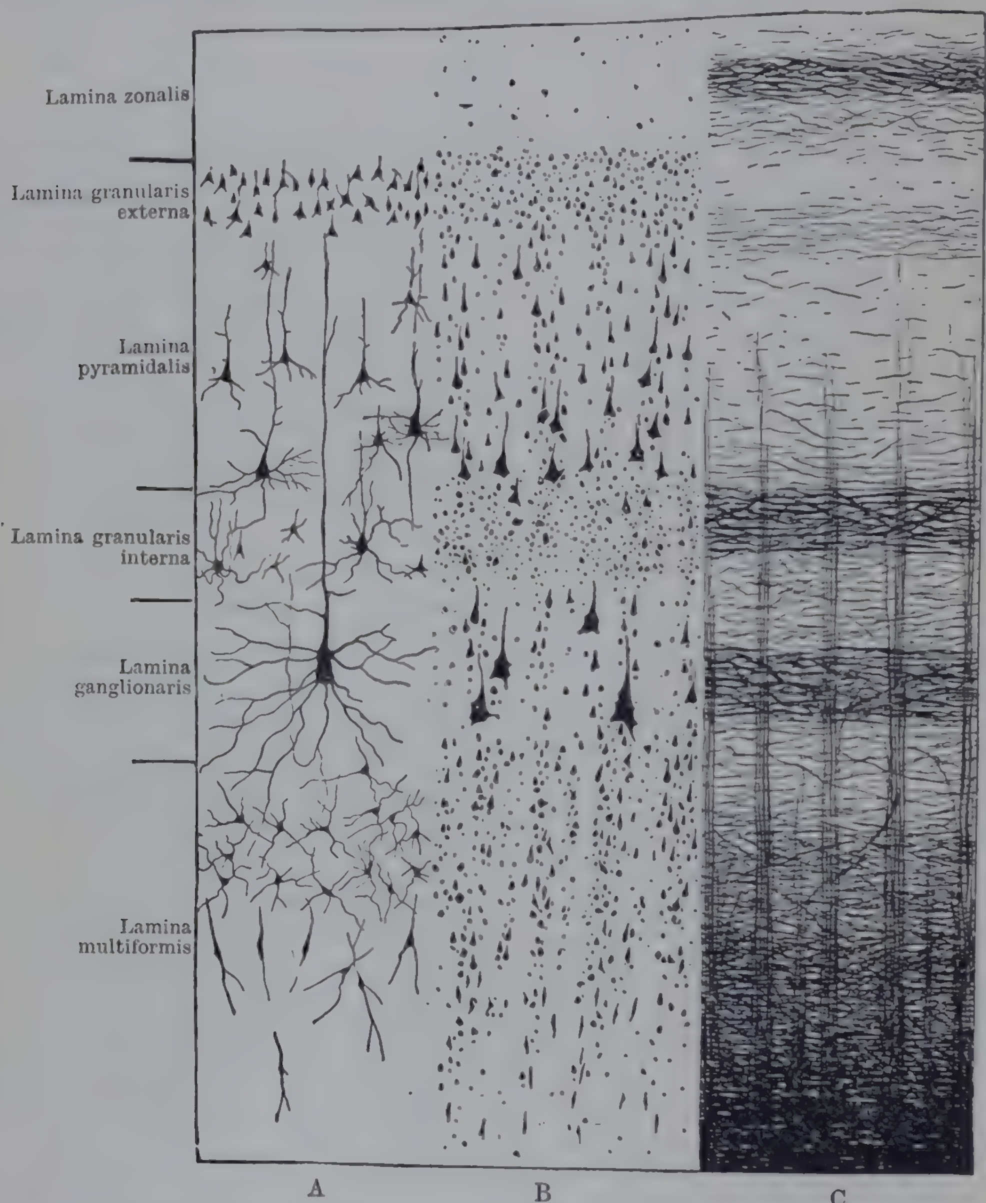

Fig. 858.—Diagram of Arrangement of Cells and of Medullated Nerve-Fibres in the Cerebral Cortex. (Herrick, 1938.)

A. Cells shown by Golgi method ; B. Cells shown by Nissl method ; C. Nerve-fibres shown by Weigert method.

Compare with photomicrograph of peristriate area in Fig. 859.

Some of these cortical areas can be sharply delimited on the surface of cerebral hemisphere, for at their margins the structure changes abruptly. Others pass by a gradual transition into neighbouring areas. Hence the total number of cortical areas which can be defined (and also their relative extent) is partly a question of personal discrimination. There is agreement, however, concerning the position and extent of the main structural areas, and many of these have been shown to correspond with specific functional areas.

In a typical part of the cortex the following laminæ can be defined (Figs. 858, 859) :

(1) **Lamina zonalis.**—This is a thin surface-layer composed of non-medullated and finely medullated fibres which form a closely meshed feltwork ; they are derived partly from ascending axons of subjacent cortical cells, and partly from the terminal branching of the apical dendrites of pyramidal cells. Among these fibres are occasional small spindle-shaped cells. Though relatively insignificant in appearance, the zonal lamina is

probably of considerable importance in the diffusion of nervous impulses in all directions over the surface of the cortex.

(2) **Lamina granularis externa.**—This is a thin and usually ill-defined layer of small cells. It really forms the superficial part of the next lamina, and is composed of the same morphological type of cell.

(3) **Lamina pyramidalis.**—As its name implies, the characteristic feature of this lamina is the pyramidal form of the cells which comprise it. They become progressively larger in the deeper levels of the lamina. From the apex of each pyramid a dendrite proceeds vertically towards the surface, usually reaching the lamina zonalis. Basal dendrites run more or less horizontally from the angles at the base of the cell. From the middle of the base the axon emerges, descends through the subjacent laminæ, and usually reaches the white matter.

(4) **Lamina granularis interna.**—This is composed of small granule-cells with numerous short dendritic processes that branch out in all directions, and many of them also have a very short axon which terminates in the immediate neighbourhood. There are small stellate pyramidal cells in this lamina, somewhat similar (except for their size) to the cells of the pyramidal lamina.

(5) **Lamina ganglionaris.**—The cells found in this lamina are of various types, but in certain areas of the cortex it contains relatively very large cells of the pyramidal type, with coarse dendrites that extend over a considerable area.

(6) **Lamina multiformis.**—This is the deepest of the cortical laminæ, and it is composed of rather closely packed cells of different types, many of them spindle-shaped or pyramidal. It contains also numerous cells with *ascending* axons, sometimes called the *cells of Martinotti*. This type of cell may be found also in the other laminæ, but in fewer numbers.

FIG. 859.—PHOTOMICROGRAPH OF SECTION OF PERISTRIATE AREA OF OCCIPITAL CORTEX SHOWING THE LAMINAR DIFFERENTIATION. The differentiation between the lamina ganglionaris and the lamina multiformis is much less distinct than it is in some other cortical areas. × 45.

Cortical Areas.—The classical works dealing with the histological differentiation of cortical areas are those of Brodmann (1909) and von Economo (1929). It is not appropriate here to consider in detail the range of variation in cortical structure over the cerebral hemisphere. By way of illustration, however, reference may be made to two exceptionally well-defined types of cortex—the motor cortex and the visual cortex.

The **motor cortex,** which is relatively thick, lies immediately in front of the sulcus centralis. It is characterized by the presence in the lamina ganglionaris of very large pyramidal cells—the *giant cells of Betz*—which may reach a size of 120 μ by 25 μ. The axons of these cells form a significant proportion of the fibres of the cortico-nuclear and cerebro-spinal tracts, through which voluntary movements are initiated. The Betz cells are similar to the large pyramidal cells of other regions of the cortex, differing only in the fact that they tend to reach a greater size in the motor cortex (Walshe, 1942). Pyramidal cells, almost as large, are found in a scattered form in the lamina ganglionaris

of the post-central cortex. It is of interest to note their occasional presence in the latter area, for this suggests that the postcentral cortex may also possess motor functions; indeed, there is experimental evidence to show that such functions are of some importance after destruction of the motor cortex proper. Another characteristic of the motor cortex is the absence of the lamina granularis interna, but this *agranular* type of cortex is found also in the premotor area, which lies immediately in front of the true motor cortex. Farther forwards in the frontal lobe, the cortex again shows a lamina granularis interna, forming what is sometimes called the frontal area of the brain.

The **visual cortex** (Fig. 860) is relatively thin, and it has already been noted that it can be distinguished macroscopically by the strong development of the outer band of Baillarger, known here as the *visual stria*. Microscopically it is also characterized by a duplication of the lamina granularis interna (the layer is split in two by the visual stria), and by the presence in the deepest layers of large pyramidal cells with very extensive, horizontally directed, basal dendrites. These cells are sometimes called the solitary cells of Meynert.

It has been suggested that a physiological significance can be attributed to the laminar

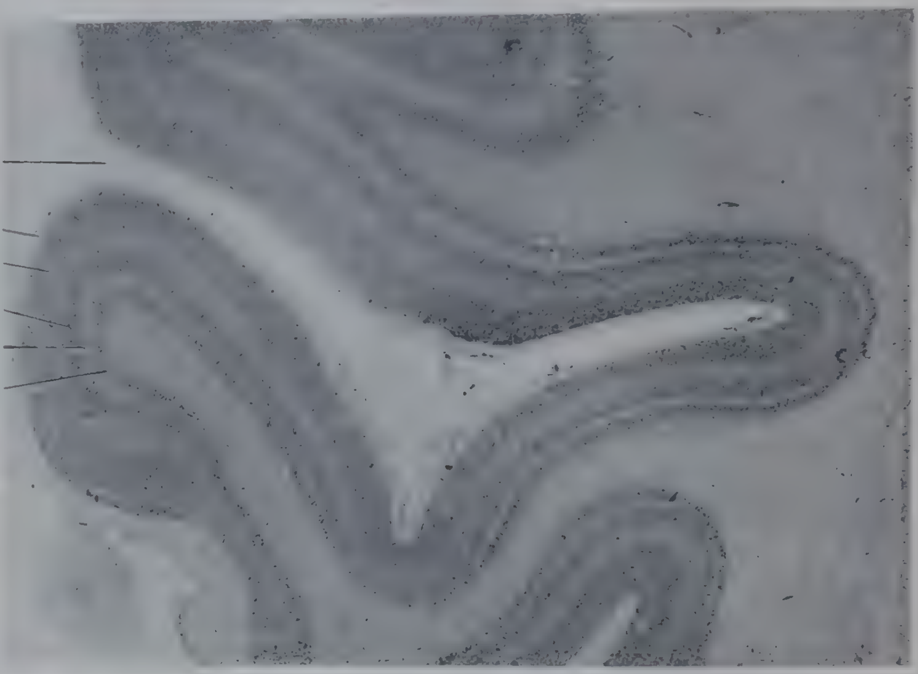

FIG. 860.—LOW-POWER PHOTOMICROGRAPH OF SECTION OF VISUAL (STRIATE) AREA OF OCCIPITAL CORTEX. × 6.

The visual stria is situated in the lamina granularis interna, *i.e.*, superficial to the deep stratum of that lamina indicated in the figure. The junction with the surrounding (peristriate) cortex is clearly seen opposite the X.

formation of the cortex, in the sense that each layer of cells has its specific functions. It is doubtful, however, whether such a conception can be carried very far, for it has been shown that the synaptic connexions between the various layers are of a very intimate nature, so that impulses arriving at one lamina can be immediately transmitted to other laminæ. Nevertheless, it is permissible to state that some of the laminæ have functional implications of a general kind. For example, there is evidence that the lamina granularis interna is predominantly the receptive layer of the cortex. Not only is it particularly well developed in sensory projection-areas and absent in the cortical areas which are mainly motor in function, but afferent fibres have been found by direct histological examination to terminate to a great extent among its cells. In the visual cortex the optic fibres can be seen running obliquely upwards, finally to break up almost entirely in the lamina granularis interna, though this does not preclude the possibility that a minority of the terminals may be related to the deeper levels of the pyramidal layer. The infragranular layers (lamina ganglionaris and lamina multiformis) appear to be concerned partly with the efferent functions of the area concerned. Commissural fibres probably have their origin from the cells of these layers; in the motor cortex they contain the Betz cells; and there is evidence that the large solitary cells of Meynert in the visual cortex give rise to descending fibres that pass down to the mid-brain. Lastly, the lamina pyramidalis seems to be largely concerned with the association functions of the cortex. Running vertically upwards into the cortex are numerous fine fibres (radial fibres) which in some areas are arranged in discrete

fasciculi. Experimental evidence indicates that the radial fibres are partly derived from adjacent areas of the cortex, and they can be seen to terminate mainly in the lamina pyramidalis. It should be emphasized again that these differences in the connexions of the different cortical laminæ are by no means clear-cut.

NEOPALLIUM

The whole of the grey cortex which forms the surface layer of the cerebral hemispheres is sometimes called the *pallium* or mantle. In lower vertebrates the pallium is apparently entirely concerned with olfactory functions, receiving olfactory impulses directly by fibre tracts which relay them from the secondary olfactory centres. In mammals, sensory impressions other than those of smell come to acquire a representation in the pallium, and are relayed to the latter by way of the thalamus. This more recently developed part of the cortex is termed the *neopallium*, and its increasing extent and complexity are the most conspicuous features in the evolution of the brain in the higher mammals.

Fibre-tracts proceed into different districts of the neopallium from the various nuclei of the thalamus to serve as the channels through which tactile, visual, auditory, and other kinds of sensory impulse are poured into it. These districts may be regarded as the **receptive sensory areas** (tactile, visual, auditory, etc.). Another circumscribed area of the cortex, the **motor area**, is characterized by its contribution to the fibres of the pyramidal tract through which voluntary movements are initiated and controlled. Besides the motor area and the various receptive areas, there are large tracts of cortex which cannot be regarded as the territory of any one sense, but as the anatomical substratum of those mental processes which are based on the functional correlation of a variety of sensory impulses. These are the so-called **association areas.** In the human brain the neopallium becomes mapped out into a large series of areas which differ one from the other in structure and in their connexions, and presumably therefore in their functions; and many of these areas may be further subdivided into a series of less obtrusively differentiated territories (Figs. 866 and 873).

As the cortex increases in volume during its development, its depth is increased to a limited extent only. On the other hand, it undergoes a very considerable expansion of its surface area. Thus, it happens that in all larger mammalian brains, as the cerebral hemisphere expands and there is an increasing disproportion between the bulk of the hemisphere and the area of its surface, the cortex must become folded to accommodate itself to the limited area of surface upon which it has to be packed. The situations of the furrows or **sulci** which make their appearance are in part determined by the arrangement and the relative rates of expansion of the various areas into which the neopallium becomes differentiated.

Many furrows belong to a group which we may call (1) **limiting sulci**, *i.e.*, they make their appearance along the boundary lines between areas of different structure; the rhinal and central sulci are examples of this group. Another group, which may be called (2) **axial sulci**, develop by the folding of areas of uniform structure, *i.e.*, along the axis of certain territories; the post-calcarine sulcus and the lateral occipital sulcus belong to this group. There is a third group of (3) **operculated sulci**, where the edge of one area becomes pushed over an adjoining territory, so that a trough is formed (Fig. 861 C), which is neither a limiting nor an axial sulcus; the sulcus lunatus is an example. And finally (4) there is a group in which some more definitely mechanical factor has a predominating influence in the determination of the development of a furrow; the parieto-occipital sulcus and the lateral sulcus are examples of the fourth group.

Longitudinal Fissure.—The longitudinal fissure is not a sulcus of the cortex but is the great cleft between the two cerebral hemispheres. In front and behind it separates the cerebral hemispheres completely. In its middle part, however, the fissure is interrupted and floored by the corpus callosum—a white commissural band which passes between the hemispheres and connects them together. The longitudinal fissure is occupied by a median fold of dura mater, termed the falx

cerebri, which partially divides the part of the cranial cavity allotted to the cerebrum into a right and left chamber.

External Configuration of Cerebral Hemispheres.—Each cerebral hemisphere has three surfaces—supero-lateral, medial, and inferior. The *supero-lateral surface* is convex and is adapted accurately to the internal surface of the cranial vault. The *medial surface* is flat and vertical and bounds the longitudinal fissure; in great part it is separated from the corresponding surface of the opposite hemisphere by the falx cerebri. The *inferior surface* is irregular and is adapted to the floors of the anterior and middle cranial fossæ and, behind them, to the upper surface of the tentorium cerebelli. Traversing this surface in a transverse direction, nearer the anterior end of the hemisphere than the posterior end, is the stem of the lateral sulcus. This deep cleft divides the inferior surface into an anterior or *orbital area*, which rests on the orbital part of the frontal bone and is concave from side to side, and a more extensive posterior or *tentorial area*, which lies on the floor of the lateral part of the middle cranial fossa and on the tentorium cerebelli. This surface is arched from before backwards, and looks medially as well as downwards. In its posterior two-thirds it is separated from the cerebellum by the tentorium cerebelli.

The borders between the surfaces are the supero-medial, the superciliary, the

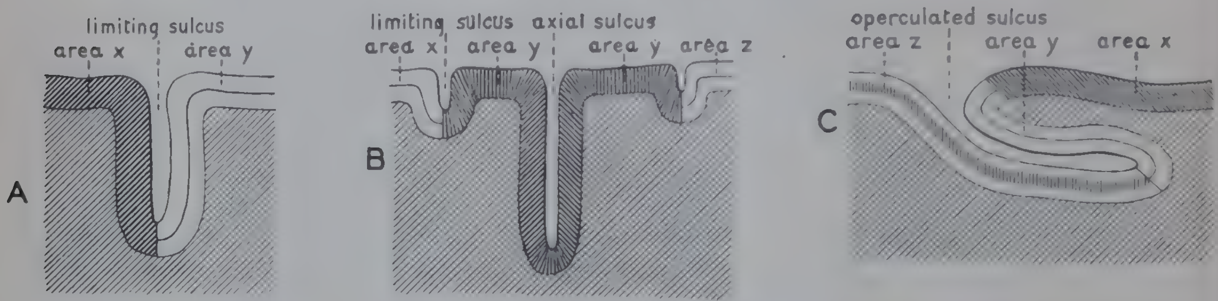

Fig. 861.—Diagrams to explain Three Types of Cerebral Furrows.

infero-lateral, the medial occipital, and medial orbital. The *supero-medial border*, convex from before backwards, intervenes between the supero-lateral surface and the medial surface of the hemisphere. The *superciliary border* is highly arched and separates the orbital surface from the supero-lateral surface. The *infero-lateral border* marks off the tentorial surface from the supero-lateral surface. The *medial occipital border* can be seen only when the brain has been hardened *in situ*. It extends from the occipital pole towards the splenium of the corpus callosum and intervenes between the medial and tentorial surfaces. It lies along the straight blood-sinus and occupies the angle between the falx cerebri and the tentorium cerebelli. The *medial orbital border* separates the orbital surface from the medial surface.

The anterior end of the cerebral hemisphere is called the **frontal pole**, and the posterior end is termed the **occipital pole**. On the inferior surface of the hemisphere the prominent point of cerebral substance which extends forwards below the lateral sulcus receives the name of the **temporal pole**. In a well-hardened brain a broad groove is usually present on the medial and inferior aspect of the occipital pole of the right hemisphere; it corresponds to the commencement of the right transverse venous sinus; the left transverse sinus may make a less distinct groove on the occipital pole of the left hemisphere. On the tentorial surface, a short distance behind the temporal pole, a well-marked depression, called the **petrous impression,** is always visible; it corresponds to the elevation on the anterior surface of the petrous portion of the temporal bone over the superior semicircular canal.

White Matter of Cerebral Hemispheres

According to the connexions which they establish, the nerve-fibres in the white matter of the hemispheres may be classified into three groups, viz., (1) commissural fibres; (2) association fibres; and (3) itinerant (projection) fibres.

Commissural Fibres.—These are fibres which link together corresponding

parts of the cortex of opposite cerebral hemispheres. They are arranged in three groups forming three definite structures, viz., the corpus callosum, the anterior commissure, and the hippocampal commissure.

The **corpus callosum** has in a great measure been already described (p. 963). As it enters each hemisphere, its fibres spread out in an extensive radiation. It thus comes about that most parts of the cerebral cortex, with the exception of the olfactory bulb, the olfactory parts of the hemisphere, and the inferior and anterior part of the temporal lobe, are reached by the callosal fibres. But it should be noted that all the regions of the cortex do not receive an equal proportion of fibres.

The **anterior commissure** is small, and quite subsidiary to the corpus callosum, although originally it was the principal cerebral commissure long before the corpus callosum was evolved. It connects together the two olfactory bulbs, and also portions of the opposite temporal lobes. It has a cord-like appearance and in median section appears as a small oval bundle in the lamina terminalis (Fig. 842, p. 959). The median free portion is placed immediately in front of the anterior columns of the fornix as they curve downwards, and also in intimate relation to the anterior end of the third ventricle. Posteriorly the small portion of the anterior commissure which appears in the ventricle between the two columns of the fornix is clothed with ependyma.

The lateral part of the anterior commissure penetrates the cerebral hemisphere, and, gaining the inferior part of the anterior end of the internal capsule, divides into two portions, viz., a small olfactory part and a much larger temporal part.

The **olfactory portion** of the anterior commissure is an exceedingly small fasciculus. It passes downwards and forwards, and it finally enters the olfactory tract. It is composed of decussating fibres of the olfactory tract and of commissural fibres which bind one olfactory bulb to the other.

The **temporal portion** is formed of almost the whole of the fibres of the commissure. It is carried laterally under the lentiform nucleus, until it gains the interval between the globus pallidus and the putamen. At this point it changes its direction and sweeps backwards. In coronal sections through the brain, behind this bend, the temporal portion of the anterior commissure appears as an oval bundle of fibres cut transversely and placed in close contact with the inferior surface of the lentiform nucleus. Finally it turns sharply downwards on the lateral aspect of the amygdaloid nucleus, and its fibres are lost in the white centre of the temporal lobe. When the lateral part of the anterior commissure is displayed by dissection, it is seen to be twisted like a rope.

The **hippocampal commissure** is composed of fibres that connect the two hippocampi. It is described on p. 960.

Association Fibres.—The association fibres bind together different portions of the cortex of the same hemisphere. They are grouped into long and short association bundles (Fig. 862).

The greater number of the **short association fibres** pass between adjacent gyri. They curve round the bottoms of the sulci in U-shaped loops (Fig. 862). Some of them occupy the deepest part of the cortex itself, and are termed *intracortical association fibres*; others lie immediately subjacent to the grey matter and receive the name of *subcortical fibres.* Many groups of short association fibres, instead of linking together contiguous gyri, pass between gyri more or less remote. It is only after birth that these association fibres assume their sheaths of myelin and acquire their full functions.

The **long association bundles** lie more deeply and can be traced by dissection for considerable distances in the white matter. They contain fibres that unite districts of the cortex far removed from each other, but experiments on lower mammals, as well as ordinary dissection, suggest that they include also groups of fibres that run in them for relatively short distances. The best defined of these long fasciculi are the following: (1) the uncinate; (2) the cingulum; (3) the superior longitudinal; and (4) the inferior longitudinal.

The **fasciculus uncinatus** is composed of fibres which arch over the stem of the lateral sulcus and connect the frontal pole and the orbital gyri with the anterior

portion of the temporal lobe; its middle and most definite part is easily found if the grey matter of the limen insulæ is scraped away.

The **cingulum** is a very well-marked and distinct band which is closely associated with the medial edge of the neopallium. Beginning in front, in the region of the anterior perforated substance, it arches round the genu of the corpus callosum and is carried backwards on its upper surface under cover of the gyrus cinguli, and it stands in intimate relation to the white centre of this gyrus (Fig. 846, p. 962). At the posterior end of the corpus callosum the cingulum turns round the splenium and is carried forwards, in relation to the hippocampal gyrus, to the uncus and the temporal pole.

The **superior longitudinal bundle** is an arcuate bundle placed on the lateral side of the base of the corona radiata; it connects the frontal, occipital, and temporal regions of the hemisphere. It lies in the root of the fronto-parietal operculum

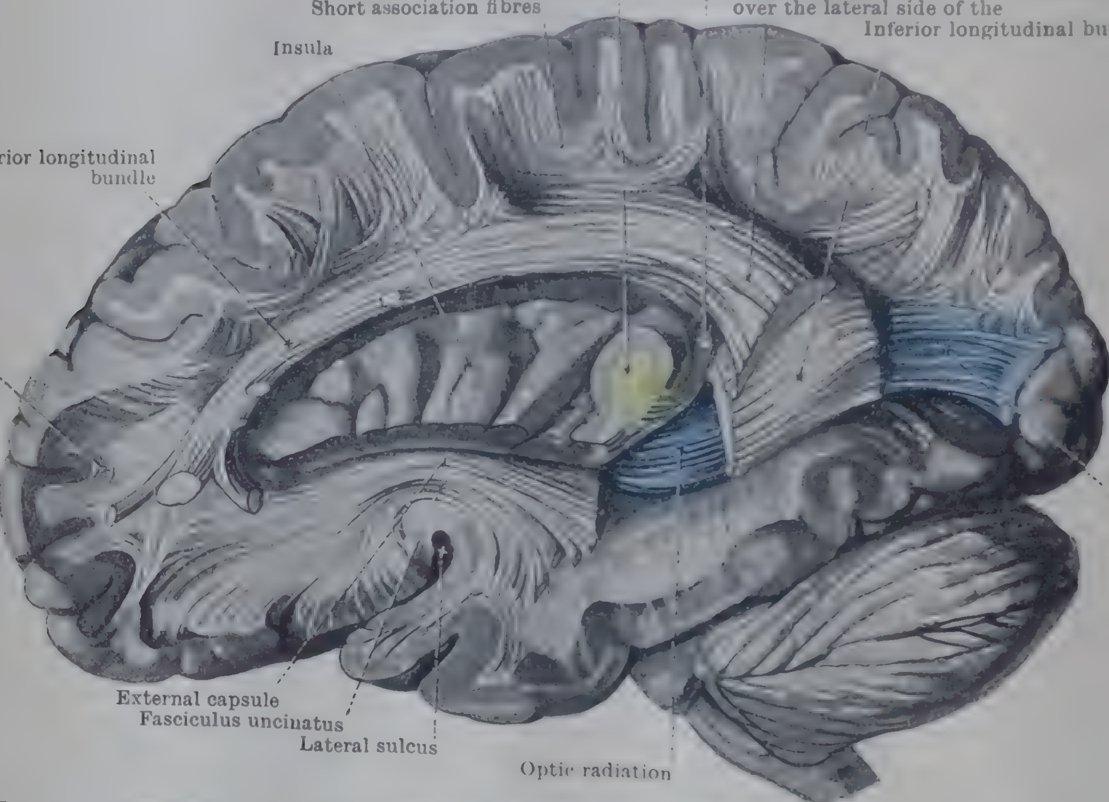

FIG. 862.—DISSECTION OF LEFT CEREBRAL HEMISPHERE TO DISPLAY THE OPTIC AND AUDITORY RADIATIONS AND THE GENERAL DIRECTION OF THE PRINCIPAL ASSOCIATION BUNDLES.

and sweeps backwards over the insular region to the posterior end of the lateral sulcus. There it bends downwards round the posterior end of the putamen and proceeds forwards in the temporal lobe to reach its anterior extremity. As it turns downwards to reach the temporal lobe numerous fibres radiate from it into the occipital lobe.

The **inferior longitudinal bundle** is a very conspicuous one which extends along the whole length of the occipital and temporal regions. In the occipital lobe the inferior longitudinal bundle is immediately lateral to the optic radiation, which takes a similar direction and from which it is distinguished by the greater coarseness of its fibres (Figs. 851, p. 967; 862).

Other long association bundles have been described (*e.g.*, the fronto-occipital); but they are small, and it is difficult to define them by dissection.

Projection Fibres.—We have already seen that many parts of the cerebral cortex are linked to other cortical areas, not only in their own neighbourhood (short association fibres) (Fig. 862), but also in some cases in more distant parts of the hemisphere (long association fibres), as well as to the cortex of the other hemisphere (commissural fibres). In addition there are two large series of fibres: (i) an ascending group which conveys to the cerebral cortex impulses coming from the thalamus and, through it, from the various other sensory nuclei scattered throughout the

brain-stem and spinal cord; and (ii) a descending group connecting the cerebral hemisphere with various parts of the diencephalon, mesencephalon and hind-brain as well as with all the motor nuclei scattered throughout the central nervous system. These two groups of tracts, respectively passing to and from the cerebral cortex, are known collectively as its **projection** or **itinerant fibres**.

While the general arrangement of the projection fibres of the cerebral hemisphere is being examined, it is convenient to refer incidentally to certain other fibre-tracts which do not fall strictly within this group.

Sensory Tracts.—A certain proportion of the fibres that enter the spinal cord by its posterior root, mediating proprioceptive impulses from muscles, tendons, and joints, pass upwards without interruption in the posterior white columns throughout the whole length of the spinal cord until they reach the medulla oblongata, where they end in the nucleus gracilis and nucleus cuneatus. From those nuclei, arcuate fibres arise, and, after crossing the median plane, proceed upwards in the **medial lemniscus** of the other side to end in the ventral nucleus of the thalamus. There a third group of fibres arises and proceeds upwards through the internal capsule to the cerebral cortex, where the impulses conveyed by it excite a consciousness of position and movement. But the sensory fibres that transmit impulses subserving touch, pain and temperature end in the spinal cord near their place of entry into it, and from the cells related to the endings of those fibres new tracts (**spino-thalamic**) arise, cross the median plane to reach the anterior and lateral white columns of the opposite side. They then proceed upwards throughout the whole length of the spinal cord and brain-stem to the thalamus, where they end in relationship with cells of the ventral nucleus. The fibres that arise from this nucleus proceed to the postcentral gyrus and convey impulses to it which may excite a consciousness of touch, pressure, pain, heat, or cold. Some of these spino-thalamic fibres join the medial lemniscus in the medulla oblongata, but others remain separate from it until they reach the level of the pons, where they become added to its lateral margin (Fig. 863).

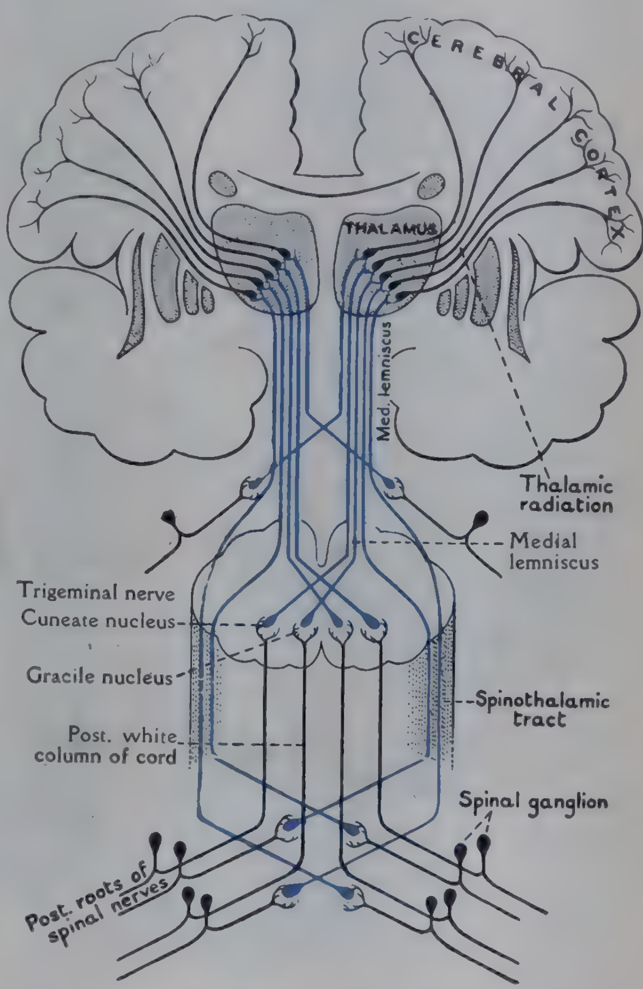

FIG. 863.—DIAGRAM OF THE SENSORY TRACTS TO THALAMUS AND CEREBRAL CORTEX.

Other groups of fibres, serially homologous with both medial lemniscus and the spino-thalamic tracts, come from the nuclei of the trigeminal nerve and become added to the great strands that are proceeding upwards towards the thalamus (Fig. 863).

Of the other great ascending tracts in the spinal cord, such as the two pairs of spino-cerebellar tracts, nothing further need be said; nor is it necessary to do more than remind the reader that from the dentate nucleus of the cerebellum a great tract (superior cerebellar peduncle) ascends to the opposite red nucleus and thalamus, and through the thalamus establishes an indirect connexion with the cerebral cortex in the precentral region.

The other sensory pathways to the cerebrum auditory, vestibular, visual, gustatory, and olfactory—are described elsewhere.

Corticifugal Strands.—The **pyramidal tract**—the great motor tract—is composed of fibres many of which arise from the giant pyramidal cells of Betz in the district immediately in front of the central sulcus (p. 994). The fibres descend through the corona radiata into the genu and posterior limb of the internal capsule. From this point the further course of the pyramidal fibres has been traced, viz., through the basis pedunculi and pons, and the pyramid of the medulla oblongata. At the level of the foramen magnum the pyramid partially decussates in the manner already described; and it enters the spinal cord as the lateral cerebro-spinal and

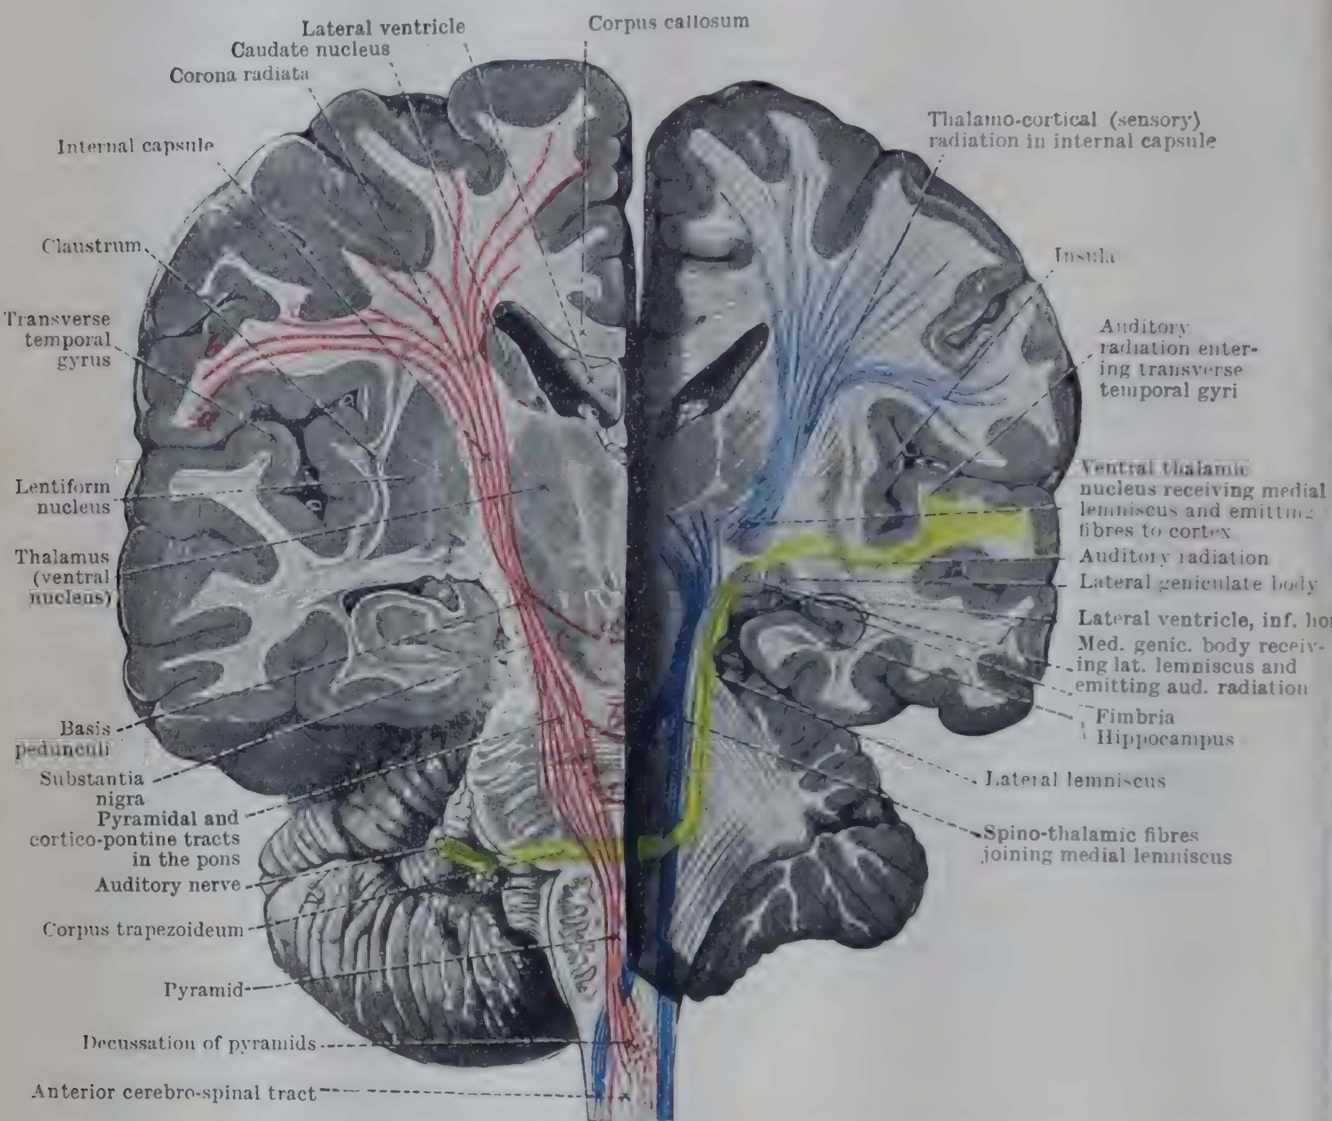

FIG. 864.—CORONAL SECTIONS OF BRAIN, PASSING IN THE RIGHT HALF (left side of Fig.) IN THE LINE OF THE PYRAMIDAL TRACT (*marked in red*). Sensory fibres (*blue*) and auditory fibres (*yellow*) have been represented in the left half, which is cut on a more posterior plane.
a, *b*, *c*, Cortico-nuclear fibres.

anterior cerebro-spinal tracts. The fibres that compose these tracts end in connexion with the motor column of cells from which the fibres of the anterior roots of the spinal nerves arise.

Similar fibres arise from the lower part of the precentral area and proceed through the internal capsule and cerebral peduncle to all the somatic motor nuclei of the opposite half of the brain-stem. Hence the cerebral cortex of one hemisphere can control all the voluntary muscles of the opposite half of the body.

It is of some practical importance to recognize that the large Betz cells which give rise to fibres of the pyramidal tract are not confined to the precentral gyrus (though they are characteristic of this region). Scattered Betz cells are also to be found in the cortex of the postcentral gyrus (see p. 977).

The **fronto-parieto-pontine tract** is composed of fibres which arise as the axons of the cells in the frontal and parietal cortex. It descends in the internal capsule and enters the medial part of the basis pedunculi, through which it gains the basilar

part of the pons. In the pons its fibres end amongst the cells of the nuclei pontis, from which axons arise and establish relations with the cortex of the opposite cerebellar hemisphere.

The **temporo-occipito-pontine tract** consists of fibres which spring from the cells of the temporal and occipital cortex. It passes medially under the lentiform nucleus, enters the sublentiform part of the posterior limb of the internal capsule, and thus gains the lateral part of the basis pedunculi. From there it descends into the basilar part of the pons, in which it ends in the nuclei pontis.

Other Descending Fibres from Cerebral Cortex.—The cortex is connected also with the elements of the basal nuclei, particularly the caudate nucleus and the putamen, and with the thalamus.

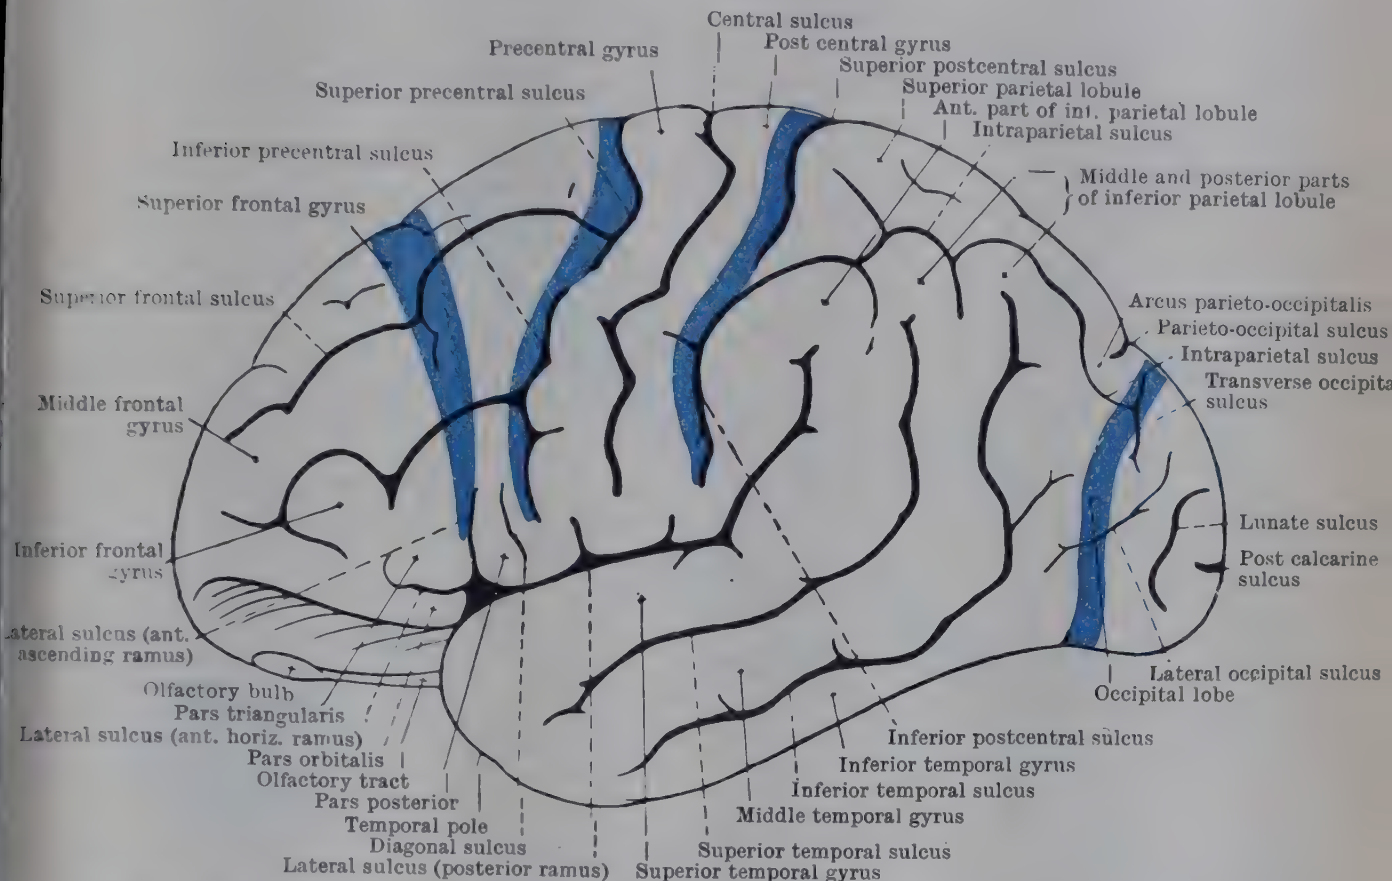

FIG. 865.—DIAGRAM OF SULCI AND GYRI ON SUPERO-LATERAL SURFACE OF HEMISPHERE WITH THE "SUPPRESSOR AREAS" COLOURED.

The middle frontal sulcus, sometimes found between the superior and inferior frontal sulci, is not shown.

Cortico-Striate Fibres.—In recent years, the existence of important descending connexions between certain areas of the cortex and the basal nuclei have been demonstrated by anatomical and electro-physiological studies. In the first place, certain narrow bands of cerebral cortex were shown on stimulation to have an inhibitory effect on cortical functions as a whole, manifested in the suppression of the normal electrical activity of the cortex and of the motor responses which normally follow stimulation of the motor cortex. These bands of cortex have been called "**suppressor areas**". The approximate extent and position of suppressor areas in the human brain (as inferred indirectly from experimental observations on the brain of the chimpanzee) are shown in Fig. 865. As will be seen by comparing this diagram with Fig. 866, the areas are represented by strips of cortex which lie *approximately* (1) along the posterior margin of the main frontal area, (2) along the boundary between the motor and premotor areas, (3) along the posterior boundary of the general sensory area, and (4) along the margin of the visuo-sensory area. On the medial surface of the brain another suppressor area is accommodated in the gyrus cinguli.

From all these suppressor areas, cortico-striate fibres descend to the caudate nucleus where they terminate. These connexions have been shown experimentally to mediate impulses which ultimately lead to the inhibitory effects noted above.

Other cortico-striate connexions have been shown to descend from the premotor and general sensory areas to the globus pallidus, and from the motor area to the putamen. (Dusser de Barenne *et al.*, 1941; 1942.)

Cortico-Thalamic Fibres.—These fibres descend from all those areas of the cortex which receive ascending fibres from the thalamus, and they terminate in the corresponding thalamic nuclei. They have already been mentioned in the account of the connexions of the thalamus. It has also been noted that *cortico-tectal fibres* descend from the occipital cortex to end in the superior corpus quadrigeminum.

SULCI AND GYRI OF CEREBRAL HEMISPHERES

Lateral Sulcus of Cerebrum.—This is the most conspicuous furrow on the surface of the cerebral hemisphere. In reality it is formed not as a furrow on the surface of the hemisphere but as a great fossa, the margins of which develop

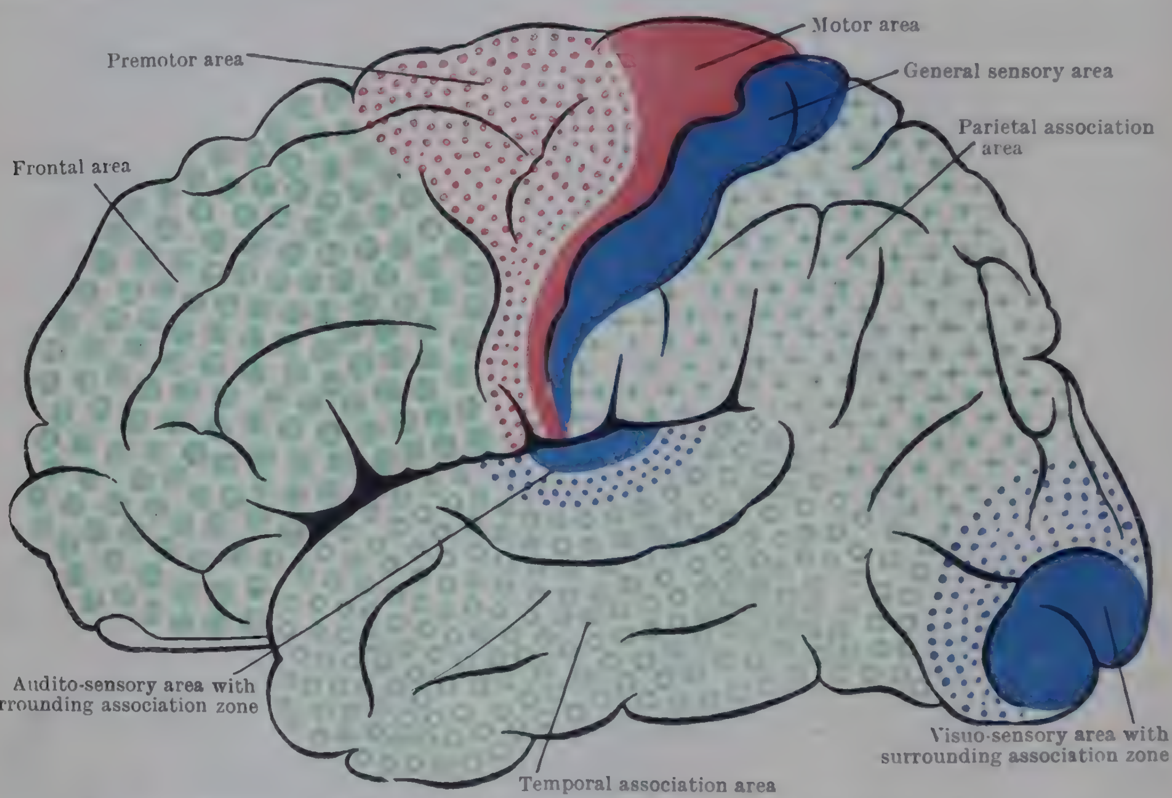

Fig. 866.—Principal Cortical Areas on Lateral Surface of Cerebral Hemisphere. Motor areas, *red*; sensory areas, *blue*; general association areas, *green*.

into large lip-like folds that bulge over the fossa and meet to form the superficial pattern of the lateral sulcus. It has a main stem and three rami. The **stem** is on the inferior surface of the hemisphere. It begins at the vallecula cerebri and passes laterally, forming a deep cleft between the temporal pole and the orbital surface of the frontal region. Appearing on the lateral surface of the hemisphere, the sulcus divides into three radiating rami. These are: (1) the posterior ramus, (2) the anterior horizontal ramus, (3) the anterior ascending ramus—the last of which is inconstant.

The **posterior ramus** is the longest and most constant of the three branches. It extends backwards, with a slight inclination upwards, on the lateral surface of the hemisphere for a distance of about 3 inches. It separates the frontal and parietal regions, which lie above it, from the temporal region, which lies below it; and it finally ends by turning upwards into the part of the parietal region that is subjacent to the parietal eminence of the cranium.

The **anterior horizontal ramus** extends forwards in the frontal region for a distance of about ¾ of an inch immediately above and parallel to the posterior part of the superciliary margin of the hemisphere.

The **anterior ascending ramus** proceeds upwards and slightly forwards, into the lower part of the lateral surface of the frontal region for a variable distance

(1 inch or less). In many cases the two anterior limbs spring from a short common stem, and not infrequently there is only a single anterior limb.

Circular Sulcus.—If the lips of the posterior ramus are pulled widely apart, the **insula** will be seen at the bottom. When the lateral sulcus is closed, the insula is completely hidden from view by overlapping portions of the cerebral hemisphere, and, when brought into view in the manner indicated, it is observed to present a triangular outline and to be surrounded by a limiting groove named **the circular sulcus**.

The insula consists of three areas of different structure. At the antero-inferior corner (where the circular sulcus is deficient) the knee-like bend of the area piriformis (see Figs. 867 and 868) appears at the **limen insulæ**. The rest is divided by an oblique furrow into a posterior part divided into two *long gyri* and an anterior part divided into several *short gyri*.

Opercula Insulæ.—The overlapping portions of the cerebral substance which cover over the insula are termed the insular opercula, and they form, by the apposition of their margins, the boundaries of the three rami of the lateral sulcus.

The **temporal operculum** extends upwards over the insula from the temporal region, and its upper margin forms the lower lip of the posterior ramus.

The **fronto-parietal operculum** is carried downwards from the frontal and parietal regions over the insula, and its lower margin, meeting the temporal operculum, forms the upper lip of the posterior ramus.

The small triangular piece between the ascending and horizontal anterior rami is called the **frontal operculum.** It covers over a small part of the anterior portion of the insula, and is sometimes termed the **pars triangularis**.

The **orbital operculum** is, for the most part, on the inferior surface of the hemisphere. It lies below and to the medial side of the horizontal anterior ramus of the lateral sulcus, and proceeds backwards from the orbital surface of the frontal lobe over the anterior part of the insula.

Development of Lateral Sulcus and of Insular District of Cerebral Hemisphere.—It is only during the latter half of intra-uterine life that the opercula take shape and grow over the insula to shut it out from the surface. In its early condition the insula presents the form of a depressed area on the side of the cerebral hemisphere, surrounded by a distinct boundary wall (Fig. 867 A). After a time the depressed area assumes a triangular outline, and then the bounding wall is observed to be composed of three distinct parts, viz., a superior or fronto-parietal, an inferior or temporal, and an anterior or orbital part (Fig. 867 B). The angle formed by the meeting of the superior and anterior portions of the boundary may become flattened, and a short oblique part of the limiting wall develop into a small triangular frontal operculum (Fig. 867 F.). Each of these portions of the bounding wall of the depression becomes a line of growth from which an operculum takes origin, and by the approximation of these opercula the insula becomes closed in and the rami of the lateral sulcus are formed (Fig. 867 C).

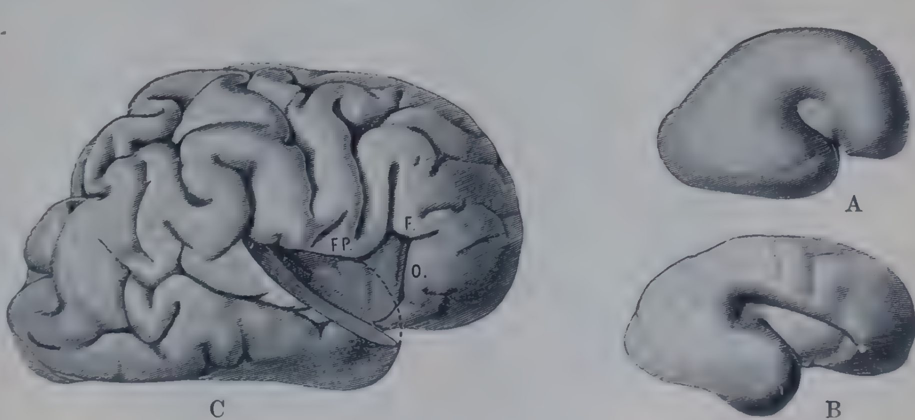

FIG. 867.—RIGHT HEMISPHERES OF HUMAN FŒTUSES SHOWING THREE STAGES IN DEVELOPMENT OF INSULA AND INSULAR OPERCULA.

A, Right cerebral hemisphere from a fœtus in latter part of fourth month; B, Right hemisphere in fifth month; C, Right hemisphere in latter part of eighth month.

In C the temporal operculum has been removed, and a large part of the insula is thus exposed. The outline of the temporal operculum is indicated by a dotted line.

F.P., Fronto-parietal operculum. F., Frontal operculum. O., Orbital operculum.

The lateral sulcus is an example of the fourth category of furrows enumerated on p. 979. It is largely the result of the operation of the mechanical factors incidental to the bending downwards of the pallium in front of and behind the place where

the wall of the hemisphere is supported and held in position by the corpus striatum. The cortical area roughly corresponding to the surface of the corpus striatum is the insula; the temporal region extends downwards behind it, and the frontal region to a less extent in front of it (Fig. 867 A). Then, towards the end of the fifth month of intra-uterine life the exuberant growth of the free fronto-parietal pallium above the insula (Fig. 867 B) and the temporal pallium below and behind it leads to the development of lip-like folds of neopallium—the opercula—which gradually approach one another (Fig. 867 C) and eventually cover up the insula. Other factors come into play in determining the form and topographical relations of the lateral sulcus. For example, the posterior part of the sulcus is the morphological boundary between the auditory and tactile territories of the neopallium.

TEMPORAL LOBE

The part of the cerebral hemisphere which lies below the level of the lateral sulcus is the **temporal lobe**. Anteriorly it ends in a free, rounded extremity—the temporal pole—which, in the skull, fits into the middle cranial fossa beneath the edge of the lesser wing of the sphenoid. Posteriorly its boundary with the occipital lobe is usually taken to be a notch on the lower border of the hemisphere (*preoccipital notch*), about an inch and a half in front of the occipital pole.

Viewed from the surface it is possible to distinguish two main temporal sulci which are more or less horizontally disposed. The *superior temporal sulcus* runs nearly parallel to the lateral sulcus. Anteriorly it turns downwards on the surface of the temporal pole, while posteriorly it inclines upwards and ends in the inferior

Auditory area, *uniform blue*; surrounding association areas, *blue spots*; olfactory parts, *green*.

parietal lobule. Between the lateral sulcus and the superior temporal sulcus is the **superior temporal gyrus**.

The *inferior temporal sulcus* is usually difficult to define, for it is commonly composed of a series of separate sulci which may show an irregular arrangement. Its posterior extremity may be seen to turn up into the inferior parietal lobule. Between the superior and inferior temporal sulci is the **middle temporal gyrus**, while below the inferior temporal sulcus is the **inferior temporal gyrus**.

On the infero-medial aspect of the temporal lobe two other longitudinal sulci

are to be distinguished. One of these is the *occipito-temporal sulcus*, which extends back into the occipital lobe and forms the medial boundary of the **lateral occipito-temporal gyrus**. The other is the *collateral sulcus*. This marks the lateral boundary of the **hippocampal gyrus**, a strip of cortex which lies between it and the *hippocampal sulcus*, and is not to be confused with the hippocampus, which, as already noted, is invaginated into the floor of the descending horn of the lateral

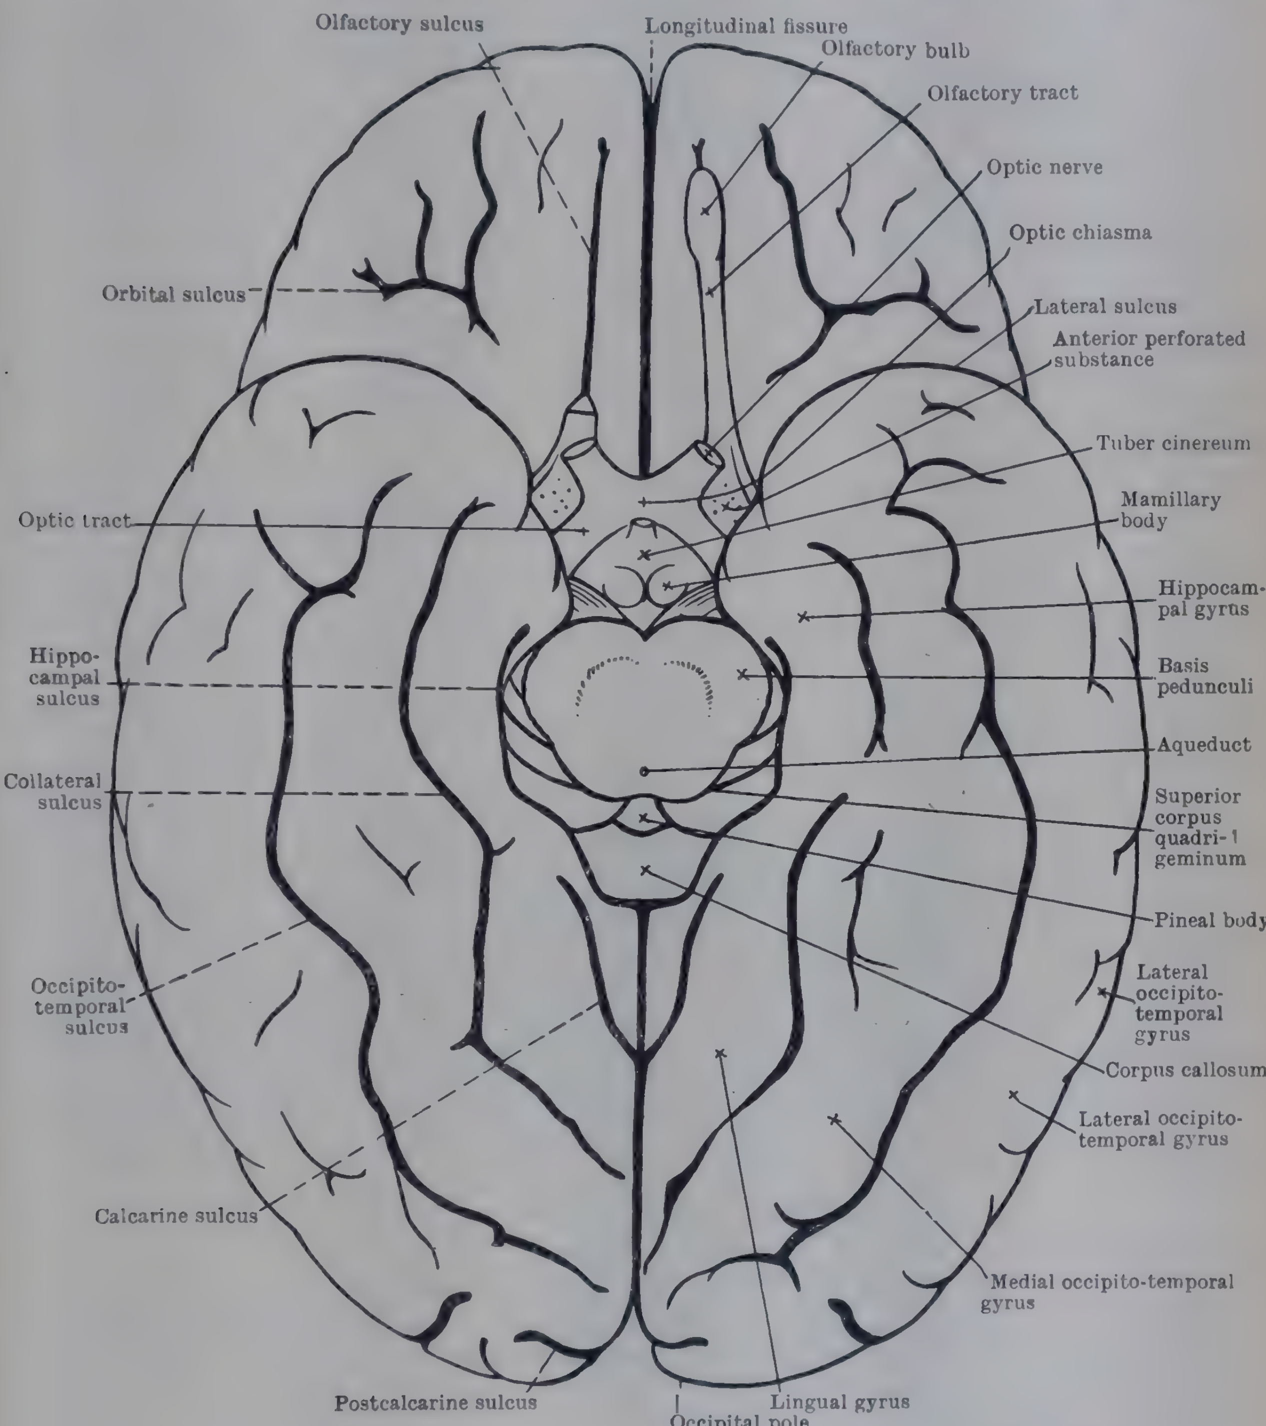

FIG. 869.—DIAGRAM OF SULCI AND GYRI ON INFERIOR SURFACE OF THE HEMISPHERES.

ventricle. Between the occipito-temporal and collateral sulci is the **medial occipito-temporal gyrus.**

On the medial aspect of the temporal pole is the hook-shaped piece of cortex called the **uncus**. It has been mentioned that the uncus is partly formed of olfactory cortex in which the lateral root of the olfactory tract terminates.

From the practical point of view, one of the most important elements of the temporal lobe is the auditory cortex, in which terminate the fibres of the auditory radiation conveying impulses from the cochlea by way of the medial geniculate body. At the fifth month of intra-uterine life (Fig. 867, B), as well as in every later stage up to the adult condition, an area on the upper surface of the temporal operculum

can be seen to slope medially towards the circular sulcus behind the insula. This area is the receiving centre for auditory impressions, and its extent is approximately marked on the surface by transverse elevations—the **transverse temporal gyri**. The auditory area is thus almost entirely buried within the lips of the lateral sulcus, but a small portion of its lateral margin may extend on to the exposed upper border of the middle third of the superior temporal gyrus.

In studying the brain-stem we have seen that a tract of fibres originating in the cochlear nuclei (in the medulla) crosses the median plane (corpus trapezoideum) and turns upwards in the lateral lemniscus of the other side (Fig. 821) to end in the medial geniculate body. From the medial geniculate body a new tract arises composed of tertiary auditory neurons, and passes laterally (Figs. 821 and 823) to end in the transverse temporal gyri. This tract is called the **auditory radiation.** It should be noted that the auditory reception area is of very limited extent, so that it is possible for a very small pathological lesion to affect the whole of it at once.

Apart from the auditory area, and a narrow strip of cortex along the lower border of the posterior ramus of the lateral sulcus behind it, which receives fibres from the pulvinar, no part of the cortex of the temporal lobe receives any ascending fibres from the thalamus. Herein the temporal lobe contrasts strongly with the other lobes of the cerebral hemisphere.

Nervous Mechanism of Hearing.—As with some other sensory mechanisms of the nervous system, the anatomy of auditory centres and paths is more precisely known in the higher than in the lower functional levels of this system. Thus, the position and extent of the auditory cortex have been determined with considerable accuracy in the human brain from clinico-pathological studies, and in the brains of lower mammals from cytological, experimental, anatomical, and oscillographic studies. It is known, also, that the auditory cortex receives its afferent connexions entirely from the medial geniculate body and that this projection involves some degree of spatial localization. The course and terminations of the auditory path (lateral lemniscus) in the mid-brain have been followed by the Marchi method, and it is now realized that previous studies of this tract have not always taken into account the fact that it is intermingled with other fibre-paths which have no apparent relation to hearing. The most uncertain part of the central nervous mechanism of hearing concerns the immediate termination of cochlear fibres in the brain-stem, and the question whether fibres of saccular origin end in the main cochlear nuclei. There is undoubtedly an intermingling of vestibular and cochlear fibres in the auditory nerve and the problem is to disentangle these in order to determine their end-stations. There is some inferential anatomical evidence that at least a part of the macula sacculi is concerned with hearing, but no final proof of this has yet been obtained. The problem is complicated anatomically by the presence of aberrant bundles of fibres which arise from the spiral ganglion of the cochlea, run a circuitous course with the vestibular part of the eighth nerve and subsequently rejoin the cochlear part. Conversely, some fibres (forming the ramus cochleo-saccularis) have their sensory endings in the saccule while their ganglion-cells lie in close relation to the spiral ganglion and seem to form a part of it (Fig. 1027, p. 1201). The destination of the proximal processes of these ganglion-cells is clearly of the greatest importance in connection with the functional significance of the macula sacculi.

OCCIPITAL REGION

We have already seen (Fig. 831) that each optic tract ends in the lateral geniculate body and sends a few fibres to the mid-brain. From the lateral geniculate body a tract arises which conveys visual impulses to the occipital lobe. This **optic radiation** is seen from various points of view in several of the accompanying figures, but it is possible (see Fig. 853) to expose it in a section which will display it in its relationship to the rest of the visual path (Fig. 870).

From this it will be seen that the fibres of the optic radiation, after emerging from the lateral geniculate body, bend backwards in the lateral wall of the posterior horn of the lateral ventricle and proceed to an extensive district of thin cortex on the medial surface and the pole of the occipital area. A section of the cortex in this area is distinguished by the presence of a very distinct white line, called the *visual stria* (Fig. 870), which was first noticed by Gennari (1782) in the year 1776.

If the visual receptive **striate area** (Figs. 866, 873) of the occipital cortex is excised and spread out in one plane it will be found to present an elongated ovoid form and a superficial extent of about 3000 sq. mm. (varying in different brains from about 2700 to 4000). The narrow end of the oval is a short distance behind and below the splenium of the corpus callosum; and from that point

the area extends horizontally backwards to the occipital pole, and beyond it to a slight extent on to the lateral aspect of the hemisphere. In the course of development the area striata becomes folded during the sixth month, and the furrow thus formed becomes the **calcarine** and **postcalcarine sulci**. The name "calcarine" was applied to the furrow by Huxley because its deep, anterior part indents the whole thickness of the medial wall of the hemisphere, and the swelling so produced in the posterior horn of the lateral ventricle resembles a cock's spur and was hence called the **calcar avis** (see Fig. 852, p. 968).

The calcarine sulcus is much deeper, more constant in form and position, and more precocious in development than the post-calcarine. The part of the area striata which is prolonged on to the lateral surface may also become folded in the line of its axis, and so give rise to a **sulcus calcarinus lateralis**.

There is a fundamental distinction between the calcarine and the post-calcarine sulci in their relations to the area striata. For the visual stria is found only in the inferior wall of the calcarine sulcus, which is therefore a sulcus limitans; whereas the stria extends throughout both walls of the postcalcarine sulcus, and in most cases beyond its lips on to the surface of the **cuneus** and the **lingual gyrus** (Figs. 871 and 873), *i.e.*, the exposed cortical areas above and below the postcalcarine sulcus.

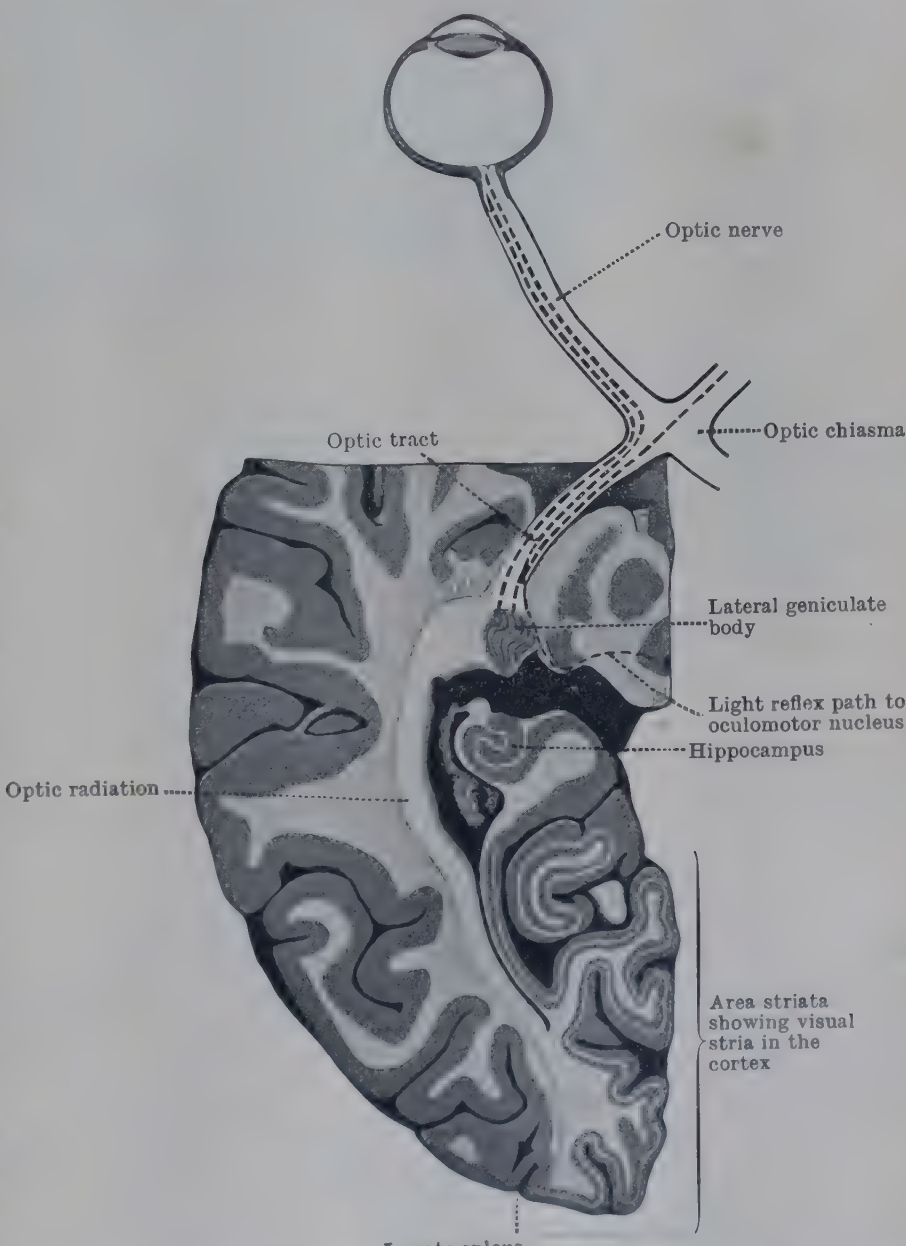

FIG. 870.—HORIZONTAL SECTION TO DISPLAY COURSE OF OPTIC TRACT AND OPTIC RADIATION IN LEFT HALF OF BRAIN.

On the lateral surface of the hemisphere a small semilunar furrow may develop a short distance in front of the anterior edge of the striate area. This is the **sulcus lunatus**. The larger the lateral extension of the striate area, the longer and deeper is the sulcus lunatus. In some cases it may be so conspicuous as to reproduce in the human brain the type of sulcus lunatus characteristic of the ape's brain.

The area striata is surrounded by a peripheral concentric band of cortex — the **area peristriata**. This area receives ascending fibres from the pulvinar. The lateral surface of the occipital lobe in front of the lunate sulcus is marked by a variable furrow called the **lateral occipital sulcus**.

The **parieto-occipital sulcus** (Fig. 872) is a deep furrow on the medial surface of the hemisphere which passes downwards and forwards from the supero-medial

border and appears to join the calcarine sulcus near its union with the post-calcarine, forming on the surface a >-shaped pattern, the stem of which is calcarine,

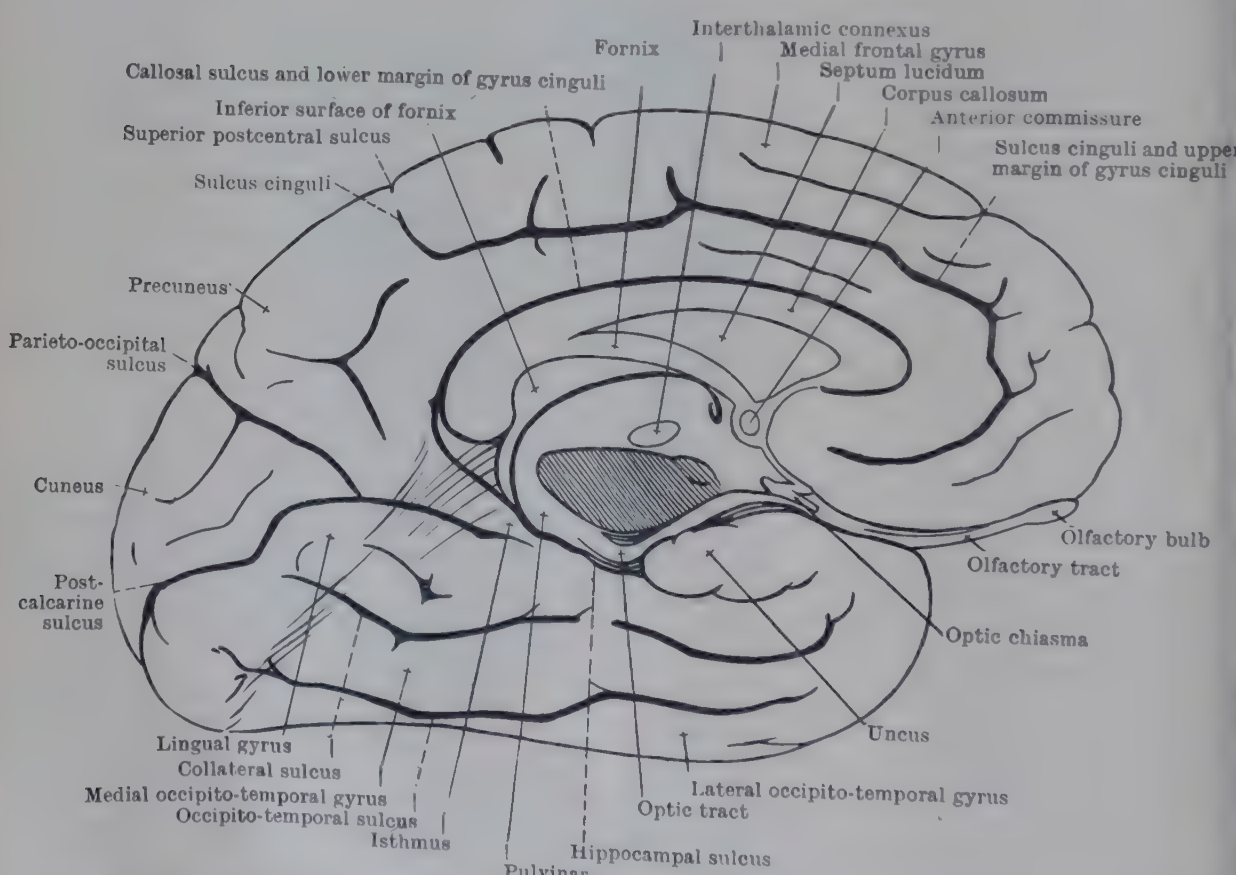

FIG. 872.—DIAGRAM OF SULCI AND GYRI ON MEDIAL AND TENTORIAL SURFACES OF HEMISPHERE.

the limbs postcalcarine and parieto-occipital, and the wedge-shaped area of cortex between the limbs the **cuneus** (Fig. 872).

If, however, the lips of the three furrows are separated (Fig. 871), the parieto-occipital depression will be found to be separated from the calcarine by a prominent submerged cortical ridge (gyrus cunei), and the parieto-occipital will be found to be something more than a mere sulcus. It is, in fact, a great fossa in which are submerged the anterior part of the peristriate area, and the posterior part of the parietal area known as the **precuneus**, as well as the sulci which separate those territories one from the other. It is a great trough formed by the splenium of the corpus callosum as in the course of its development it thrusts itself backwards and crumples up the cortex. When the corpus callosum fails to develop, no parieto-occipital sulcus makes its appearance.

Collateral Sulcus.—This is a strongly marked furrow on the tentorial surface of the brain. It begins near the occipital pole and extends forwards towards the rhinal sulcus, with which it sometimes becomes confluent. In its posterior part it is parallel to the calcarine and postcalcarine sulci, from which it is separated by the **lingual gyrus**.

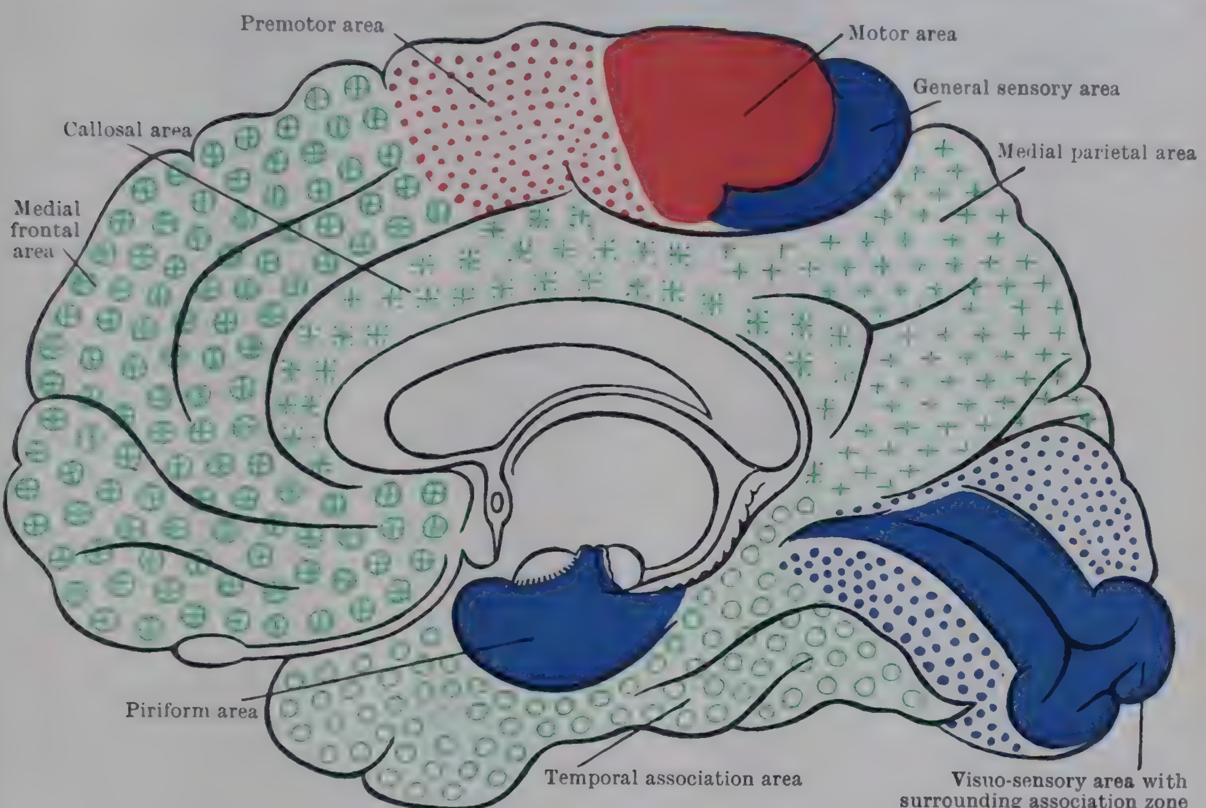

FIG. 873.—PRINCIPAL CORTICAL AREAS ON MEDIAL SURFACE OF CEREBRAL HEMISPHERE. Motor areas, *red* ; sensory areas, *blue* ; general association areas, *green*.

PARIETAL REGION

We have seen that the auditory pathway leads into the temporal region and the visual pathway into the occipital region. The facts of clinical medicine show that large areas in these two regions beyond the limits of the cortex in which the auditory and optic radiations end are in some way concerned with the functions of hearing and vision. The lower part of the parietal cortex is interposed between the temporal and occipital territories, and its integrity and normal functioning are necessary conditions for the proper performance of many acts, such as reading written or printed documents, in the appreciation of which both hearing and vision play some part. But the parietal region also includes the cortical area in which a part, at least, of the chief thalamo-cortical tract ends—the bundle of fibres that represents the third stage of the great sensory pathway, the first stage of which is formed by the spinal and cerebral sensory nerves and their central prolongations, and the second stage by the spino-thalamic tracts and the fibres which pass upwards in the medial lemniscus and end in the ventral nucleus of the thalamus. The sensory area in question forms part of the **postcentral gyrus**, which intervenes

between two oblique furrows—the **central** and **postcentral sulci**—which extend across the whole breadth of the hemisphere above the lateral sulcus (Fig. 866).

Central Sulcus.—During the sixth and seventh months of intra-uterine life the expanding postcentral area becomes raised up into a prominent ridge, and a similar ridge is formed immediately in front of it (Fig. 874) from the area which emits the great motor pyramidal tract. As these ridges become raised up a depression is left between them: this is the *central sulcus.* At first it is in two parts (an upper and a lower, Fig. 874, r^2 and r^1); but as a rule they become confluent later.

The central sulcus in the adult takes an oblique course across the supero-lateral surface of the hemisphere, and, intervening between the frontal and parietal regions, it forms the immediate posterior boundary of the motor area of the cortex. Its upper end cuts the supero-medial border of the hemisphere a short distance behind the mid-point between the frontal and occipital poles, and is then continued downwards and backwards for a short distance on the medial surface, whilst its lower end terminates above the middle of the posterior ramus of the lateral sulcus. In its general direction the sulcus is oblique, and it takes a sinuous course across the hemisphere. This is largely due to the varying breadth of the motor areas representing the lower limb, trunk, upper limb, and head, which are placed immediately in front of it.

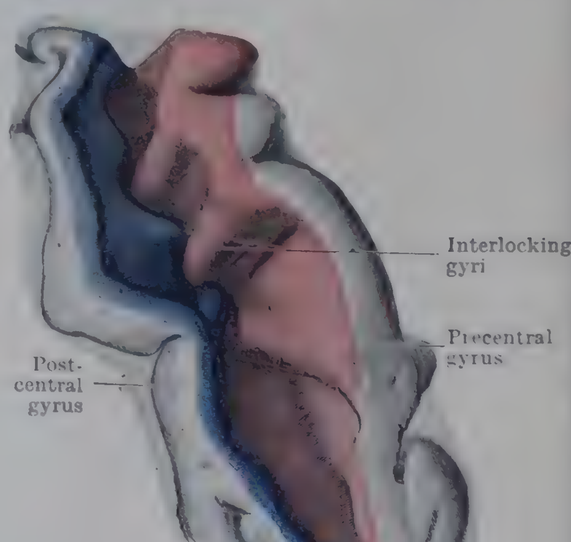

Fig. 875.—Right Central Sulcus fully opened up, to exhibit Interlocking and Deep Transitional Gyri.

Motor cortex coloured *red*, sensory cortex *blue*.

When the central sulcus is widely opened up, so that its bottom and its opposed sides may be fully inspected, it will be seen that the two bounding gyri are dovetailed into each other by a number of interlocking gyri which do not appear on the surface (Fig. 875). Further, two of these, placed on opposite sides of the sulcus, are frequently joined across the bottom of the sulcus in the form of a sunken bridge termed a *deep transitional gyrus.* The continuity of the sulcus is thus, to some extent, interrupted. This condition is related to the development of the sulcus. The deep interlocking gyri indicate a great exuberance of cortical growth in this situation in the early stages of the development of the sulcus; and the presence of the deep transitional gyrus is explained by the fact that the sulcus generally develops in two pieces which run into each other to form the continuous sulcus of the adult, viz., a part corresponding to the lower two-thirds, and a part which represents the upper third and appears at a slightly later date. In very rare cases the two parts of the sulcus fail to unite, and the deep transitional gyrus remains on the surface.

If a section is made at right angles to the central sulcus in a fresh brain (Fig. 876), it will be seen that its anterior and posterior walls present a marked contrast, and that the transition from the one type of cortex to the other takes

place at or near the bottom of the sulcus. The cortex of the anterior wall is thick (3·5 to 4 mm.) and is pervaded by white matter arranged in the form of three or four pale bands with blurred edges and multitudes of fine pencils of fibres passing to and fro between it and the white centre of the hemisphere. The cortex of the posterior wall is thin (1·5 mm.), and contains two narrow and sharply defined white lines.

The sensory area forms little more than the posterior wall of the central sulcus, and barely emerges on the surface to form the posterior lip of the sulcus (Fig. 875). Here, it becomes continuous with a slightly thicker cortex with doubled lines which are less dense than those of the sensory cortex ; this area forms the crest of the postcentral gyrus, and then gives place to another slightly modified type of cortex which forms the anterior wall of the postcentral sulcus.

The motor and sensory areas cross on to the medial surface of the hemisphere into a region known as the **paracentral lobule.**

Behind and parallel to the central sulcus is the **postcentral sulcus**, and between the two is the **postcentral gyrus.** The postcentral sulcus is often divided into upper and lower portions—the *superior* and *inferior postcentral sulci.*

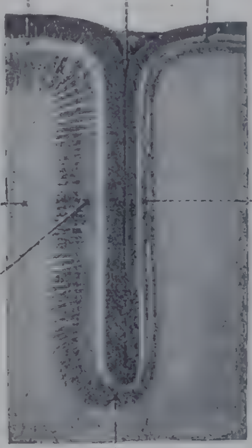

FIG. 876.—SECTION ACROSS SUPERIOR PART OF CENTRAL SULCUS IN FRESH BRAIN.

That portion of the parietal region which intervenes between the postcentral gyrus and the occipital region is usually subdivided into two distinct parts—the **superior and inferior parietal lobules**—by a horizontal furrow, called the **intraparietal sulcus.** This sulcus, which is variable in its form and disposition, commonly joins the inferior postcentral sulcus anteriorly, at least superficially. Posteriorly it extends into the occipital lobe, and here terminates in a short transverse fissure—the *transverse occipital sulcus.* The intraparietal sulcus serves to divide the parietal lobe into the superior and inferior parietal lobules.

The **superior parietal lobule** is composed of moderately thick cortex (2·5 to 3 mm.) placed between the intraparietal sulcus and the superior border of the hemisphere, where it becomes continuous with the precuneus on the medial surface. Each of these parts is subdivided by a transverse sulcus, the superior lobule by the **sulcus parietalis superior** (Fig. 865) and the precuneus by the **sulcus præcunei** (Fig. 872).

The latter sulcus usually joins a small inverted U-shaped furrow **(suprasplenial sulcus)** which encloses a cortical territory of distinctive structure—the **area parasplenialis** (**præcunei**).

The **inferior parietal lobule** is a region of great functional significance, and it is divided into three parts in relation to the upturned ends of three sulci that cut into it. The *anterior part* forms a convolution (supramarginal gyrus) surrounding the upturned extremity of the lateral sulcus. The *middle part* (angular gyrus) surrounds the extremity of the superior temporal sulcus ; and the *posterior part* is an area of cortex called the *post-parietal gyrus* related to the posterior extremity of the inferior temporal sulcus (Fig. 865).

The topographical boundary between the parietal and occipital lobes is commonly taken to be the parieto-occipital sulcus. This sulcus cuts the upper margin of the hemisphere and extends laterally for about half an inch.

FRONTAL REGION

The frontal region is the biggest of the main cortical areas—the so-called "lobes". On the supero-lateral surface it is bounded behind by the central sulcus and below, in part, by the lateral sulcus. It has a supero-lateral surface, a medial surface, and an inferior or orbital surface. The *supero-lateral surface* is broken up by a large number of variable furrows.

The **precentral sulcus** is approximately parallel with the central sulcus, and is usually divided into upper and lower parts.

The **precentral gyrus** is the long gyrus between the central and precentral sulci. Inferiorly it is continuous with the post-central gyrus below the lower end of the central sulcus.

The **superior frontal sulcus** extends forwards in a more or less horizontal direction from the upper part of the precentral sulcus and maps off the **superior frontal gyrus** between itself and the supero-medial border of the hemisphere.

The **inferior frontal sulcus** begins at or near the lower part of the precentral sulcus; it proceeds forwards towards the superciliary margin of the hemisphere and ends a short distance from that in a terminal bifurcation (Fig. 865). The **middle frontal gyrus** is the name given to the broad convolution which lies between the superior and inferior frontal sulci. The **inferior frontal gyrus** is the region in front of the lower part of the precentral sulcus and below the inferior frontal sulcus. Crossing its posterior extremity obliquely is the **diagonal sulcus.**

On the *medial surface* of the frontal region there are two gyri separated by the **sulcus cinguli** (Fig. 872). The larger, peripheral area is named the **medial frontal gyrus**, and the smaller inner part encircling the corpus callosum is the **gyrus cinguli.** The posterior part of the sulcus cinguli is generally distinct from the anterior part and, turning upwards towards the supero-medial border of the hemisphere, it circumscribes a broad area—the **paracentral lobule**—which is continuous with the precentral and postcentral gyri of the supero-lateral surface. It is important to note that the paracentral lobule accommodates the upper part of the motor area of the cortex, which is particularly concerned with the movements of the lower limb of the opposite side.

On the *orbital surface of the frontal region* there are two sulci, viz., the olfactory and the orbital. The **olfactory sulcus** is a straight furrow which runs parallel to the medial orbital border of the hemisphere. It is occupied by the olfactory tract and bulb, and it cuts off a narrow strip alongside the medial border named the **gyrus rectus**. The **orbital sulcus** is a composite furrow which assumes many different forms. It is essentially a U-shaped furrow, the convexity of which is directed forwards (Fig. 869), and one or two variable branches passing forwards from it.

The conventional manner of subdividing the cortex in front of the central sulcus into gyri, which has just been sketched, is apt to convey a misleading idea of the distribution of the anatomical areas of differentiated cortex.

The precentral gyrus together with the major portion of the paracentral lobule and the posterior part of the superior, middle and inferior frontal gyri form a natural subdivision of the cortex which is concerned with voluntary movement. It is composed of a series of areas of different structure. The posterior of these areas, often called the *motor cortex proper* (giant pyramidal area), is coloured solid red in Figs. 866, 873. It contains the giant pyramids of Betz, the axons of which (pyramidal fibres) have been followed to the motor nuclei of the fifth, seventh, tenth (nucleus ambiguus), eleventh (nucleus ambiguus), and twelfth cranial nerves, and to the cells of the anterior grey column of the spinal cord.

The area immediately in front of the motor cortex proper is called by many writers the premotor cortex. All the areas in the wide region defined above have been found to be electrically excitable, and so also have certain cortical areas behind the central sulcus. But the thresholds for the various areas differ and so does the nature of the muscular response obtained. In front of the premotor area is the frontal area of the cerebral cortex, which can be subdivided into a number of subsidiary areas on the basis of differences in histological structure. The frontal area as a whole is distinguished from the motor and premotor cortex by the presence in it of a distinct lamina granularis interna. It receives ascending fibres from the medial nucleus of the thalamus.

It has already been mentioned (p. 943) that the medial thalamic nucleus receives fibres from the hypothalamus; these ascend alongside the wall of the third ventricle and form a part of what is termed the "periventricular system of fibres". It seems clear, therefore, that the frontal area of the cortex is essentially a receptive area on which are projected impulses representing the resultants of hypothalamic activity. This fact is of importance for the consideration of the functions of the frontal area, particularly in relation to the operation of "*frontal leucotomy*" which is now frequently performed in an attempt to mitigate the emotional disturbances associated with certain types of mental disorder. The frontal area of the cerebral cortex is also intimately connected with the hypothalamus by efferent systems of fibres

which descend to terminate in the hypothalamus directly (including the paraventricular and supra-optic nuclei and the mamillary body), or indirectly by way of the medial nucleus of the thalamus (Le Gros Clark, 1948).

For a discussion of the general question of functional localization in the frontal lobes, see Fulton (1949).

MENINGES OF BRAIN AND SPINAL CORD

The brain and spinal cord are enclosed in three membranes or meninges named, from without inwards, dura mater, arachnoid mater, and pia mater. Between the dura and the arachnoid mater is the subdural space—a potential space only, for these two membranes are normally in direct apposition; the much more roomy interval between the arachnoid and pia mater is called the subarachnoid space; and the interval that separates the spinal dura mater from the walls of the vertebral canal is called the extradural space.

Dura Mater

The dura mater is a dense and strong fibrous membrane divisible into two parts—the spinal dura mater and the dura mater of the brain—which are continuous with each other at the foramen magnum.

Dura Mater of Brain.—This part of the dura mater is adherent to the inner

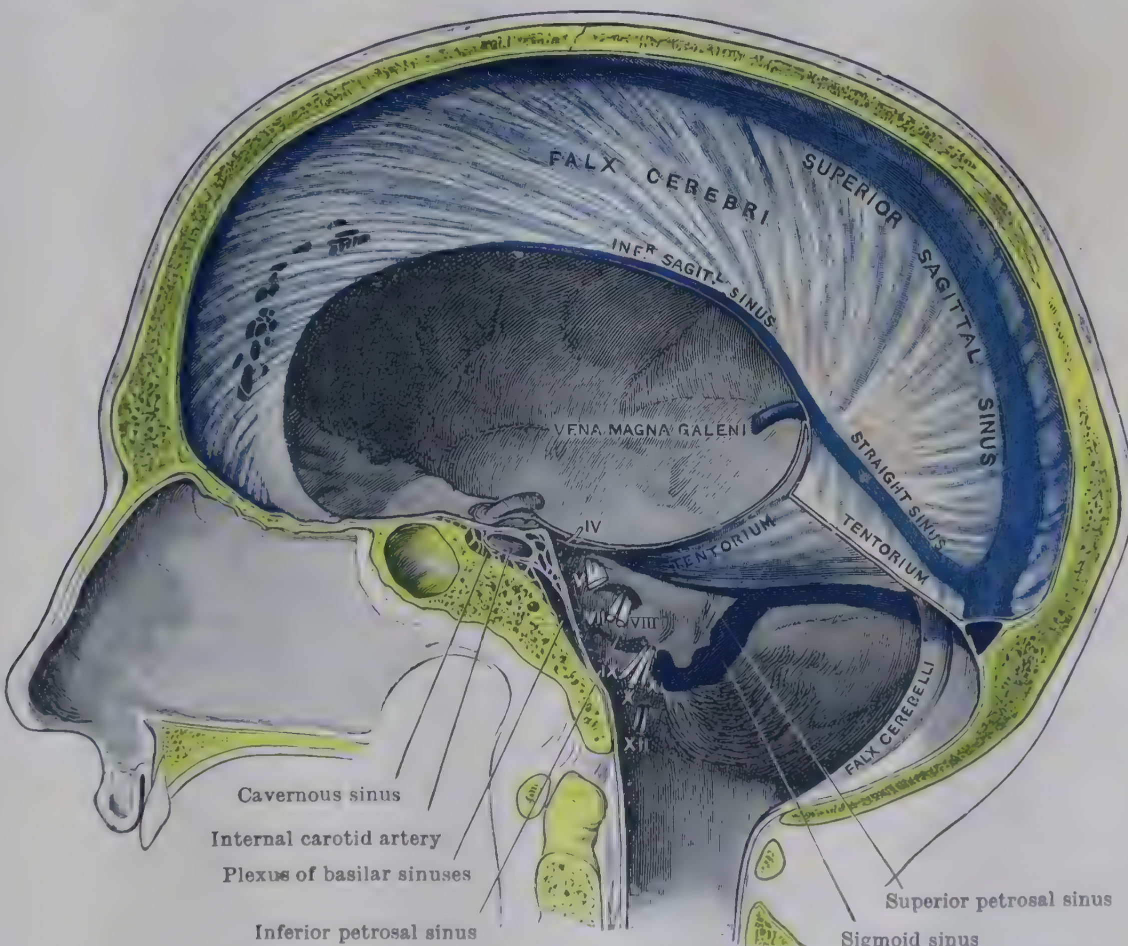

Fig. 877.—Sagittal Section of Skull, a little to Left of Median Plane, to show arrangement of Dura Mater.

Cranial nerves are indicated by numerals. Vena magna Galeni = Great cerebral vein.

surface of the cranial wall, and performs a double office. It serves as a periosteum for the intracranial aspect of the bones which it lines, and it constitutes an envelope for the brain. Its inner surface is smooth and glistening, and is covered with a layer of mesothelial cells. The outer surface, when separated from the cranial wall, is rough, owing to numerous fine fibrous processes and blood-vessels which pass between it and the bones. Its degree of adhesion to the cranial wall differs considerably in different regions. To the vault of the cranium,

except along the lines of the sutures, the connexion is by no means strong. So long as the sutures are open the dura mater is connected with the periosteum on the exterior of the skull by the sutural ligaments. Around the foramen magnum, and on the floor of the cranial cavity, the dura mater is very firmly adherent to the bone. This is more particularly marked in the case of the projecting parts of the cranial floor, as, for example, the petrous portions of the temporal bones, the clinoid processes, and so on. The firm adhesion in these regions is still further strengthened because the nerves, as they leave the cranium through the various foramina, are followed by sheaths of the fibrous dura mater. Outside the cranium the prolongations of the membrane blend with the fibrous sheaths of the nerves, and also become connected with the periosteum on the exterior of the skull. In the child, during the growth of the cranial bones, and also in old age, the dura mater is more adherent to the cranial wall than during the intervening portion of life.

The dura mater of the brain has two layers intimately connected with each other, but yet capable of being demonstrated in most regions; and along certain lines they separate to enclose channels lined with endothelium. These channels are the **venous blood-sinuses**, and they receive the blood from veins which come from various parts of the brain. They are described in the section dealing with the Vascular System.

Strong fibrous septa are given off along certain lines from the deep surface of the dura mater. They project into the cranial cavity, and divide it partially into compartments which all freely communicate with one another, and each of which contains a definite division of the brain. These septa are: (1) the falx cerebri; (2) the tentorium cerebelli; (3) the falx cerebelli; and (4) the diaphragma sellæ.

The **falx cerebri** is a sickle-shaped partition which descends in the great longitudinal fissure between the two hemispheres of the cerebrum. Its anterior end is narrow, and is attached to the crista galli of the ethmoid; it increases in its vertical measurement as it is traced backwards; its upper border is highly convex and is attached to the cranial vault along the median line from the crista galli to the internal occipital protuberance; the anterior and longer part of its lower border is concave and free, and comes into close relation with the splenium of the corpus callosum at its posterior end; the posterior part of this border is united to the tentorium cerebelli. The anterior part of the falx is often cribriform, and may form an open lacework. Along its borders it splits to enclose blood-sinuses—the superior sagittal sinus in the upper border, the inferior sagittal in the free part of the lower border, and the straight sinus along the attachment to the tentorium.

The **tentorium cerebelli** is a large crescentic partition which forms a membranous tent-like roof for the posterior cranial fossa, and thus intervenes between the posterior portions of the cerebral hemispheres and the cerebellum. It is accurately applied to the upper surface of the cerebellum. Thus, its highest point is in front and in the median plane, and thence it slopes downwards towards its attached border. It is kept at a considerable degree of tension, and this depends on the integrity of the falx cerebri which is attached to its upper surface in the median plane.

The *posterior border* of the tentorium is convex, and is attached to the horizontal ridge which marks the inner surface of the occipital bone. Beyond the occipital bone, on each side, it is fixed to the postero-inferior angle of the parietal bone, and then forwards and medially along the upper border of the petrous portion of the temporal bone. From the internal occipital protuberance to the postero-inferior angle of the parietal bone the border encloses the *transverse sinus*, whilst along the upper border of the petrous bone it encloses the *superior petrosal sinus*. The *anterior border* of the tentorium is sharp, free, and concave, and forms with the dorsum sellæ an oval opening shaped posteriorly like a pointed arch. The opening is called the **tentorial notch**, and within it lies the mid-brain. Beyond the apex of the petrous part of the temporal bone the two margins of the tentorium cross each other; the free margin is continued forwards to be attached to the anterior clinoid process, whilst the attached border proceeds medially to be fixed to the posterior clinoid process.

The **falx cerebelli** is a small, sickle-shaped ridge of dura mater which projects forwards from the internal occipital crest, and occupies the posterior notch of the cerebellum.

The **diaphragma sellæ** is a small area of dura mater which forms a roof for the hypophysial fossa. A small opening is left in its centre for the transmission of the infundibulum.

Innervation of Dura Mater in Skull.—Apart from sympathetic fibres which accompany the meningeal vessels, the dura mater of the brain is supplied by extremely fine branches from the trigeminal and vagus nerves. The distribution of these sensory nerves is of some importance in relation to headache. From the ophthalmic division of the trigeminal nerve recurrent branches (*nervi tentorii*) arise in the wall of the cavernous sinus. These run back into the tentorium cerebelli and here spread out in a fan-like arrangement, supplying also the posterior third of the falx cerebri and the dura on the outer surface of the posterior parieto-occipital region of the cerebral hemisphere (Fig. 878). The dura mater of the middle fossa of the skull is supplied mainly from branches of the second and third divisions of the trigeminal nerve. Of these, one twig, the *nervus spinosus*, frequently leaves the main trunk of the mandibular nerve outside the skull and enters through the foramen spinosum. A branch which may arise from the maxillary nerve inside the skull (*nervus meningeus medius*) accompanies the anterior branch of the middle meningeal artery. In the anterior fossa, fine branches of the anterior and posterior ethmoidal nerves supply the dura mater in the neighbourhood of the cribriform plate,

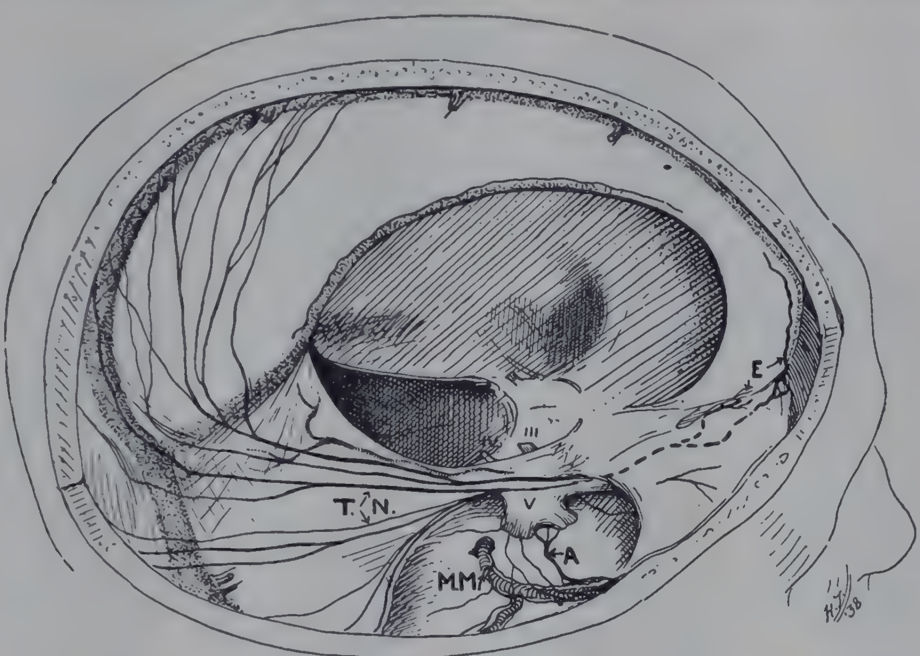

FIG. 878.—DISTRIBUTION OF SENSORY NERVES TO DURA MATER OF ANTERIOR AND MIDDLE CRANIAL FOSSÆ, FALX CEREBRI, AND TENTORIUM CEREBELLI. (Penfield & McNaughton, 1940.)

A. Nervus meningeus medius.
T.N. Tentorial nerves.
E. Branches of ant. and post. ethmoidal nerves to falx and sup. sagittal sinus.

and also the anterior extremity of the falx cerebri and superior longitudinal sinus. Lastly, the dura mater of the posterior fossa is innervated by recurrent branches of the vagus nerve, one of which usually passes up through the jugular foramen. It has been stated that the accessory and hypoglossal nerves also contribute to the supply of the dura mater at the base of the skull, but this is not certainly established.

Spinal Dura Mater.—In the vertebral canal the dura mater forms a tube which encloses the spinal cord, and extends from the foramen magnum above to the level of the second piece of the sacrum below. It is very loosely related to the spinal cord and the cauda equina; in other words, it is very capacious in comparison with the volume of its contents. Moreover, its calibre is not uniform. In the cervical and lumbar regions it is considerably wider than in the thoracic region, whilst in the sacral canal it rapidly contracts and finally ends blindly. At the upper end of the vertebral canal the spinal dura mater is firmly fixed to the second and third cervical vertebræ, and around the margin of the foramen magnum. In the sacral canal the filum terminale, which pierces it and drags off a sheath from it, extends downwards to blend with the periosteum on the back of the coccyx; the inferior end of the tube is thus securely anchored and held in its place.

Within the cranial cavity the dura mater is closely adherent to the bones, and forms for them an internal periosteum. As it is followed into the vertebral canal its two constituent layers separate. The inner layer is carried downwards as the long

cylindrical tube which encloses the spinal cord. The outer layer, which is much thinner, becomes continuous round the margin of the foramen magnum with the periosteum on the exterior of the cranium. The spinal dura mater, therefore, corresponds to the inner layer of the cranial dura mater, and to it alone. It is separated from the walls of the vertebral canal by an interval—the **extra-dural space**—which is occupied by soft fatty tissue and a plexus of thin-walled veins. In connexion with the spinal dura mater there are no blood-sinuses such as are present in the cranial cavity, but it should be noted that the veins in the extra-dural space, placed as they are between the periosteum of the vertebral canal and the tube of dura mater, occupy the same morphological plane as the cranial blood-sinuses. Another feature which serves to contrast the spinal dura mater with the

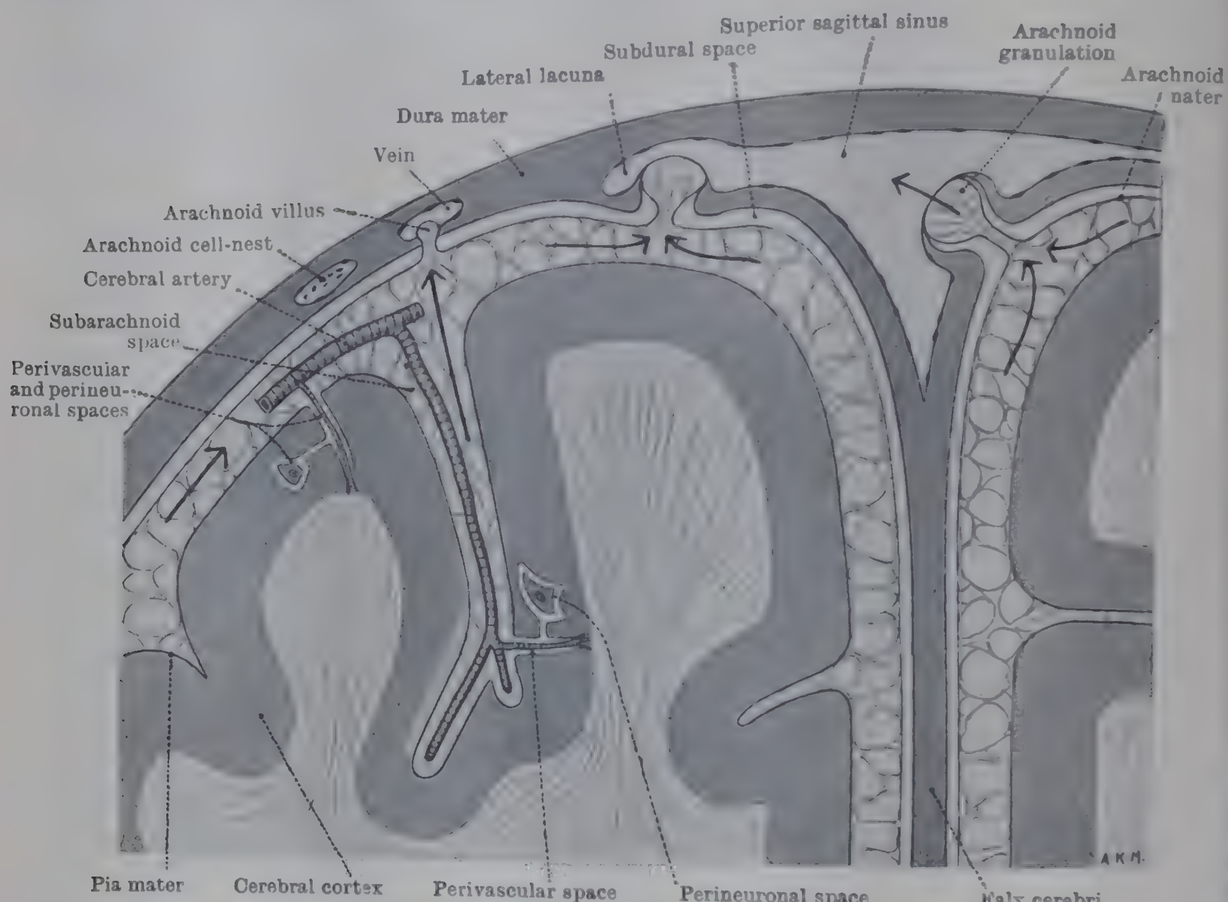

FIG. 879.—DIAGRAM TO SHOW RELATION OF MENINGES TO BRAIN AND OF SUBARACHNOID SPACE TO ARTERIES, NEURONAL ELEMENTS, AND VENOUS CHANNELS OF DURA MATER.

cranial dura mater is that it gives off no partitions or septa from its deep surface.

The spinal dura mater does not lie quite free within the vertebral canal. Its attachments, however, are of such a character that they in no way interfere with the free movement of the vertebral column. On each side the spinal nerve-roots, as they pierce the dura mater, carry with them into the intervertebral foramina tubular sheaths of the membrane, whilst in front loose fibrous prolongations—more numerous above and below than in the thoracic region—connect the tube of dura mater to the posterior longitudinal ligament of the vertebral column. No connexion of any kind exists between the dura mater and the posterior wall of the vertebral canal.

When the interior of the tube of spinal dura mater is inspected, the series of apertures of exit for the roots of the spinal nerves is seen. They are ranged in pairs opposite each intervertebral foramen.

Viewed from the inside of the tube of dura mater, each of the two roots of a spinal nerve is seen to carry with it a special and distinct sheath. When examined on the outside, however, the appearance is such that one might be led to conclude that both roots are enveloped in one sheath of dura mater. That is due to the fact that the two sheaths are firmly held together by areolar tissue. The two tubular sheaths remain distinct as far as the spinal ganglion and then blend with each other.

Subdural Space.—The dura mater and the arachnoid mater are closely applied to each other, and the capillary interval between them is termed the **subdural space.** It contains a film of fluid—just sufficient to moisten the opposed surfaces of the two membranes.

The subdural space in no way communicates with the subarachnoid space. It is carried outwards for a very short distance on the various cranial and spinal nerves; and, in the case of the optic nerve, the sheath of dura mater is carried along its whole length, and with it the subdural space is prolonged to the back of the eyeball.

Arachnoid Mater

The **arachnoid mater** is a very thin membrane, remarkable for its delicacy and transparency, which envelops both the brain and the spinal cord between the dura mater and the pia mater. The **arachnoid mater of the brain** is carried into the longitudinal fissure by the falx cerebri and into the stem of the lateral sulcus by the lesser wing of the sphenoid; but otherwise it does not dip into the sulci. In that respect it differs from the pia mater. It bridges over the inequalities on the surface of the brain. Consequently, on the basal aspect it is spread out in the form of a very distinct sheet over the medulla oblongata, the pons, and the hollow above the pons, and in certain of these regions it is separated from the brain-surface by relatively wide intervals.

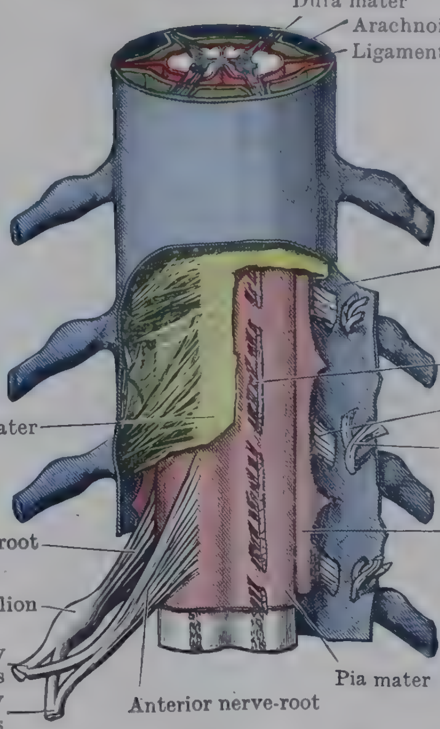

Fig. 880.—Membranes of Spinal Cord, and mode of Origin of Spinal Nerves.

The **spinal arachnoid mater**, which is directly continuous with that of the brain, forms a loose, wide investment for the spinal cord. The spinal arachnoid sac is most capacious towards its lower part, where it envelops the lower end of the spinal cord and the cauda equina.

As the cranial and spinal nerves pass outwards they receive an investment from the arachnoid which runs for a short distance upon them.

Subarachnoid Space.—The interval between the arachnoid and the surface of the brain or spinal cord receives the name of the **subarachnoid space.** It contains the cerebro-spinal fluid, and communicates freely, through apertures in the roof of the fourth ventricle, with the cavities in the interior of the brain.

Within the cranium the subarachnoid space is broken up by a meshwork of fine filaments and trabeculæ. On the surface of the brain, this meshwork is condensed to form what appears, on ordinary dissection, to be a fairly definite layer of tissue. This is the *pia mater*. It should be noted, however, that there is no clear distinction between the arachnoid tissue and the pial tissue. Where the arachnoid mater passes over the summit of a gyrus, and is consequently closely applied to the subjacent brain, the meshwork is so dense and the trabeculæ so short that it is hardly possible to discriminate between the two membranes. In the intervals between gyri, however, there are distinct angular spaces where the sub-arachnoid trabecular tissue can be studied to great advantage. These intervals on the surface of the cerebrum constitute numerous communicating channels which serve for the free passage of the cerebro-spinal fluid from one part of the surface of the brain to

another. The larger branches of the arteries and veins of the brain traverse the subarachnoid space; their walls are directly connected with the subarachnoid trabeculæ, and are bathed by cerebro-spinal fluid (Fig. 879).

In certain situations within the cranium the arachnoid is separated from the pia mater by intervals of considerable width and extent. These expanded portions of the subarachnoid space are termed **subarachnoid cisterns**. In them the subarachnoid tissue is much reduced. There is no longer a close meshwork; the trabeculæ take the form of long filamentous intersecting threads which traverse the spaces. All the subarachnoid cisterns communicate in the freest manner with one another and also with the narrow channels on the surface of the cerebrum.

Certain of these cisterns require special mention. The largest and most conspicuous is the **cerebello-medullary cistern**. It is formed by the arachnoid membrane bridging over the wide interval between the posterior part of the cerebellum and the medulla oblongata. It is continuous through the foramen magnum with the posterior part of the subarachnoid space of the spinal cord.

The **pontine cistern** is the continuation upwards on the floor of the cranium of the anterior part of the subarachnoid space of the spinal cord. In the region of the medulla oblongata it is continuous behind with the cerebello-medullary

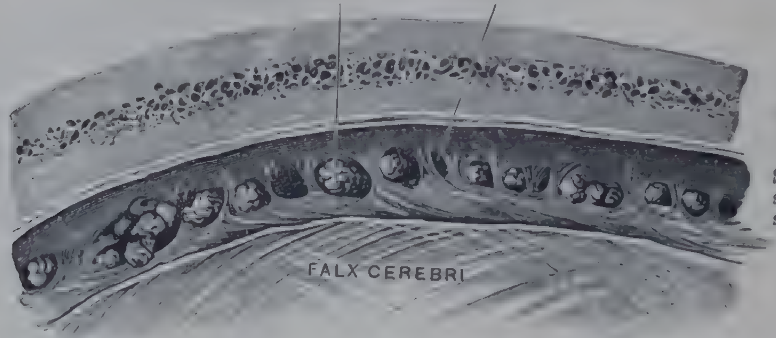

FIG. 881.—MEDIAN SECTION THROUGH CRANIAL VAULT IN FRONTAL REGION, *ENLARGED.*
Displays a portion of the superior sagittal sinus and the arachnoid granulations protruding into it.

cistern; therefore this subdivision of the brain, like the spinal cord, is surrounded by a wide subarachnoid space.

Above the pons the arachnoid mater bridges across between the temporal lobes, and covers in the deep hollow in this region of the brain. This space is called the **interpeduncular cistern,** and within it are placed the large arteries which take part in the formation of the circulus arteriosus. Leading out from the interpeduncular cistern there are certain wide subarachnoid channels. A pair of these are the **cisterns of the lateral sulci.** Each accommodates the middle cerebral artery. Anteriorly the interpeduncular cistern passes into a space in front of the optic chiasma, and from there it is continued into the longitudinal fissure above the corpus callosum. In this subarachnoid passage the anterior cerebral arteries are lodged.

The spinal part of the subarachnoid space is a very wide interval partially subdivided into compartments by three incomplete septa. One of these is a median partition which connects the pia mater covering the back of the spinal cord with the arachnoid. In the upper part of the cervical region this partition is imperfect, and is represented merely by some strands passing between the two membranes; in the lower part of the cervical region and in the thoracic region it becomes more complete. The other two septa are formed by the **ligamenta denticulata** which spread laterally one from each side of the spinal cord. They will be described with the pia mater.

Arachnoid Villi and Granulations.—When the surface of the dura mater is inspected after the removal of the calvaria, a number of small fleshy-looking excrescences, white or pink in colour, are seen ranged in clusters on each side of the superior sagittal sinus, and when the sinus is opened they are observed protruding into its interior. They are the arachnoid granulations, and they are found also, in smaller numbers and distinctly smaller size, in connexion with other blood-sinuses, such as the transverse sinus, the straight sinus, and the cavernous sinus.

At first sight they appear to belong to the dura mater, but in reality each granulation is a little bulbous protrusion of the arachnoid mater. It is attached to the arachnoid by a narrow pedicle, and into its interior there is prolonged through the pedicle a continuation of the subarachnoid space filled with cerebro-spinal fluid. The distal end of the protrusion passes between the interstices of the dura mater into contact with the endothelial lining of the sinus, with which the extremity of the diverticulum becomes fused. In this situation the subdural space is obliterated and the single membrane resulting from the fusion alone separates the blood from the cerebro-spinal fluid.

On each side of the superior sagittal sinus there are a number of irregular spaces in the dura mater which communicate with the sinus either by small apertures or narrow channels. These spaces are called the **lacunæ laterales**, and it is into these cavities that most of the arachnoid granulations insinuate themselves, a few only being invaginated directly into the sinus. The granulations enlarge with age, and the cranial wall overlying them becomes absorbed so that small pits are hollowed out on its internal surface for their reception, though of course the granulations do not come directly into contact with the bone but are separated from it by the periosteal layer of the dura, the lumen of the lacuna or sinus, and, except where the arachnoid is fused with endothelium, by the dura of the sinus floor and the subdural space.

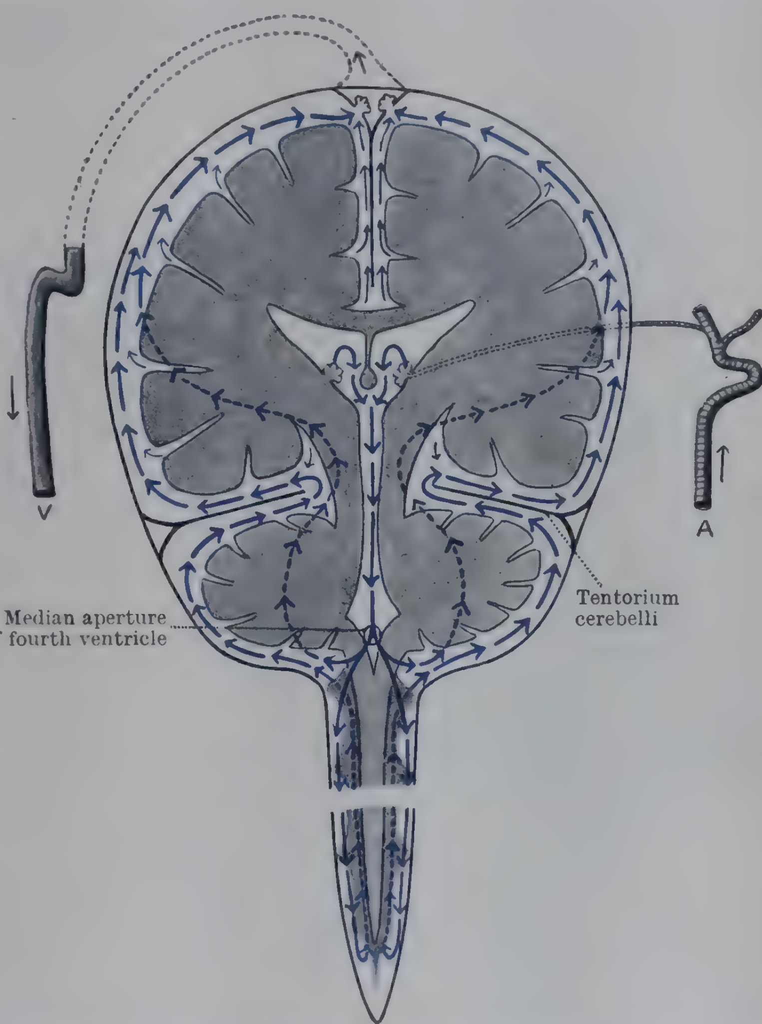

Fig. 882.—Diagram to show the Main Points relating to the Production, Course, and Absorption of the Cerebro-Spinal Fluid. (After Dott, 1928.)

Besides these macroscopic protrusions of the arachnoid mater there are innumerable microscopic processes of this membrane, called **arachnoid villi**, which have the same relation to the venous sinuses. It should be recognized, however, that there is no distinction at all between arachnoid granulations and arachnoid villi, except that of size. These arachnoid villi and arachnoid granulations form the most important pathway for the return of the cerebro-spinal fluid to the venous blood. This takes place by filtration through the membrane formed by the fusion of the arachnoid mater with the vascular endothelium. In infants very few arachnoid granulations are to be seen macroscopically, but as age advances some of the villi, especially those in relation to the posterior part of the superior sagittal sinus, become enlarged to form arachnoid granulations.

Production and Circulation of the Cerebro-Spinal Fluid

The main bulk of the cerebro-spinal fluid is formed within the lateral ventricles of the brain through the agency of the choroid plexuses. It is a clear, colourless fluid of low specific gravity and alkaline reaction which in health is almost free of

protein and cells (2 or 3 lymphocytes per c. mm.) but contains the same crystalloids as the blood. From the lateral ventricles this fluid passes by way of the interventricular foramina into the third ventricle. Here more fluid is added from the choroid plexus of the roof. Then the fluid passes through the aqueduct into the fourth ventricle, where further additions are made from the choroid plexuses in its roof. From the fourth ventricle the fluid escapes by the median and lateral apertures into the subarachnoid space, and is received into the adjacent cisterns which lie below the tentorium. Some of the fluid passes downwards into the spinal subarachnoid space, but the major part rises through the tentorial notch and finds its way slowly over the surface of the hemispheres to be absorbed mainly through the arachnoid villi and granulations into the venous system. Some cerebro-spinal fluid is carried away by the perineural lymphatics. The subarachnoid space is carried outwards for a short distance on the nerves in their arachnoid sheaths, and it is in the region where the arachnoid sheath comes to an end that the cerebro-spinal fluid gains access to the perineural lymphatic channels of the peripheral nerves. This connexion is more free in the olfactory, the optic, and the auditory nerves than in other nerves.

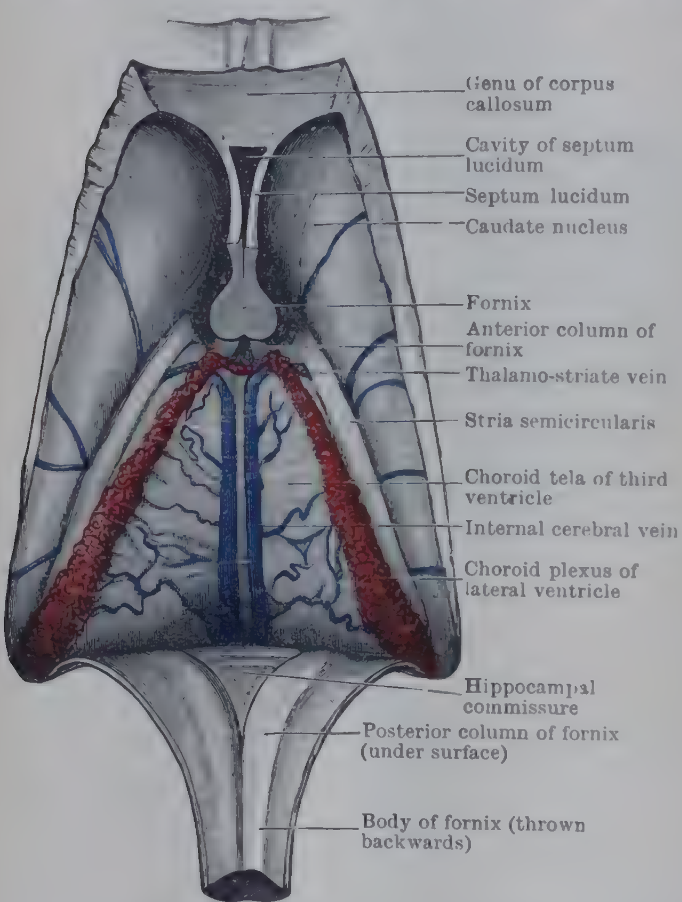

Fig. 883.—Dissection to show Tela Chorioidea of Third Ventricle and the Parts near it.

Each blood-vessel as it enters or leaves the brain-substance is surrounded by a tubular prolongation of the subarachnoid space by means of which cerebro-spinal fluid can follow all the vascular ramifications. The finest perivascular channels communicate ultimately with the perineuronal spaces and so lead the fluid into contact with the neurons themselves (Fig. 879). The normal flow of the cerebro-spinal fluid in these perivascular channels is from within outwards into the main subarachnoid space so that certain products of metabolism may be eliminated by these currents. It is into these channels also, in certain pathological conditions, that the brain capillaries discharge great numbers of leucocytes (in some diseases polymorphs, in others lymphocytes) which are passed out to the main subarachnoid space, thus altering the cellular content of the cerebro-spinal fluid.

For a general account of the relation of the cerebro-spinal fluid to the ventricular system and the meninges, see Weed, 1938.

Pia Mater

The pia mater is the name given to the condensation of subarachnoid tissue which immediately invests the brain and spinal cord, and it forms a delicate and very vascular membrane. The nerves that leave both the brain and spinal cord receive closely applied sheaths from the pia mater, which blend with the fibrous tissue sheaths of the nerves.

Pia Mater of the Brain.—The pia mater which covers the brain is finer and more delicate than that which clothes the spinal cord. It follows closely all the inequalities on the surface of the brain, and in the case of the cerebral hemisphere it dips into each sulcus in the form of a fold which lines it completely.

On the cerebellum the relation is not so intimate; it is only into the larger fissures that it penetrates in the form of definite folds.

The blood-vessels on the surface of the brain lie in the subarachnoid space, and the finer twigs ramify in the pia mater before they proceed into the substance of the brain. As they enter, they carry with them sheaths derived from the pia mater. When a portion of the membrane is raised from the surface of the brain, numerous fine processes are withdrawn from the cerebral surface. They are the blood-vessels with their sheaths, and they give the deep surface of the pia mater a rough and flocculent appearance.

Where the pia mater covers the lower part of the roof of the fourth ventricle it receives the name of the **tela chorioidea of the fourth ventricle**, and it is in connexion with this portion of the pia mater that the choroid plexuses of that cavity are developed. The **tela chorioidea of the third ventricle** is a fold of pia mater which has the appearance of having been invaginated into the brain, so that it comes to lie over the third ventricle and to project, in the shape of choroid plexuses, into the lateral ventricles. The invaginated fold requires special notice.

Tela Chorioidea of Third Ventricle.—This is a double layer of pia mater which intervenes between the body of the fornix, which lies above it, and the ependymal

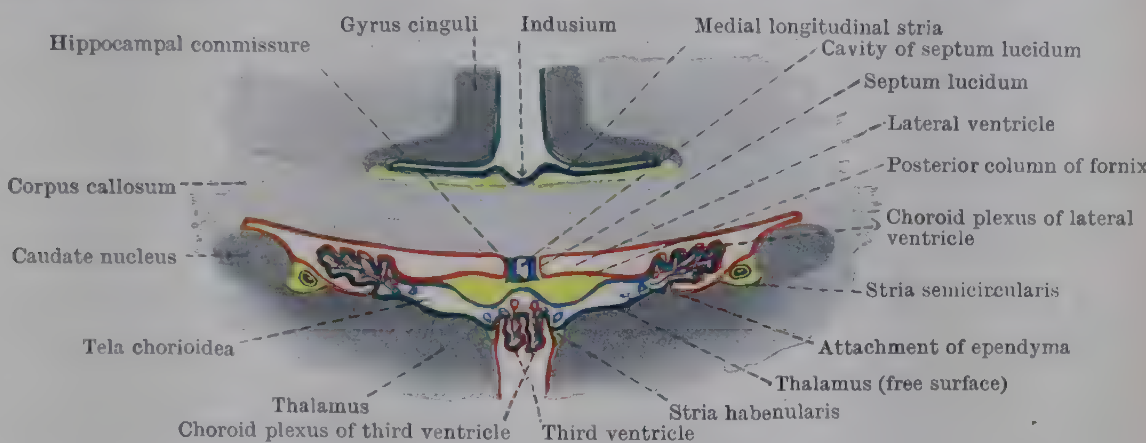

FIG. 884.—DIAGRAM OF CORONAL SECTION THROUGH TELA CHORIOIDEA OF THIRD VENTRICLE.

roof of the third ventricle and the two thalami, which lie below it. Between its two layers there are blood-vessels and some subarachnoid tissue. In shape it is triangular, and the narrow, anterior end or apex lies between the interventricular foramina. The base lies under the splenium of the corpus callosum, and here the two layers of the tela separate and become continuous with the pia mater on the surface of the brain by passing out through a cleft called the **transverse fissure.**

Along each margin the tela chorioidea of the third ventricle is bordered by the choroid plexus of the central part of the lateral ventricle, which projects into the ventricular cavity from under cover of the margin of the fornix. It should be borne in mind that the ependymal lining of the ventricle gives a complete covering to the choroid plexus. Posteriorly the choroid plexus is continuous with the similar structure in the inferior horn of the ventricle, whilst in front it narrows greatly, and becomes continuous across the median plane with the corresponding plexus of the opposite side, behind the ependymal layer which lines the interventricular foramen. From the median junction a pair of much smaller choroid plexuses run backwards on the under surface of the tela chorioidea, and bulge downwards into the third ventricle. They are the choroid plexuses of the third ventricle (Fig. 884).

The most conspicuous blood-vessels in the tela chorioidea are a pair of internal cerebral veins which run backwards, one on each side of the median plane (Fig. 883). In front, each is formed at the apex of the fold by the union of the thalamo-striate vein and a large vein that issues from the choroid plexus; behind, they unite to form the **great cerebral vein**, and this pours its blood into the anterior end of the **straight sinus** (Fig. 877, p. 997).

The continuous cleft through which the choroid plexuses are introduced into the lateral ventricle is called the choroid fissure, and is described on pp. 941, 955, 968.

Spinal Pia Mater.—The pia mater of the spinal cord is thicker and denser than that of the brain. This is largely due to the addition of an outer layer in which the fibres run chiefly in the longitudinal direction. The pia mater is very firmly adherent to the surface of the spinal cord, and in front it sends a fold into the anterior median fissure. The posterior median septum is firmly attached to its deep surface. In front of the anterior median fissure the pia mater is thickened in the form of a longitudinal glistening band, termed the **linea splendens**, which runs along the whole length of the cord and blends with the filum terminale below. The blood-vessels of the spinal cord lie in the deeper layer of the pia mater.

The **ligamentum denticulatum** is a strong fibrous band which stretches out like a wing from the pia mater on each side of the spinal cord and connects the pia mater with the dura mater. The pial or medial attachment of the ligament extends in a continuous line along the surface of the spinal cord between the anterior and posterior nerve-roots, from the level of the foramen magnum to the level of the first lumbar vertebra. Its lateral margin is serrated or denticulated, and for the most part free. From twenty to twenty-two denticulations may be recognized. They occur in the intervals between the spinal nerves, and, pushing the arachnoid before them, they are attached by their pointed ends to the inner surface of the dura mater, and by means of them the spinal cord is suspended in the middle of the dural tube (Fig. 880).

PERIPHERAL NERVOUS SYSTEM

by Archibald Durward, M.D., F.R.S.E.
Professor of Anatomy, University of Leeds

The Peripheral Nervous System, as distinct from the Central Nervous System comprising the brain and spinal cord, is broadly divisible into three series of fibres. (I) The **cranial nerves**, which are attached to the brain and pass through openings in the base of the skull to be distributed for the most part to the head region. (II) The **spinal nerves**, which are attached to the spinal cord, pass through the intervertebral foramina, and innervate the trunk and limbs, that is, the somatic area of the body. These two sets of fibres are sometimes grouped together as the cerebro-spinal system of nerves. (III) The **autonomic nervous system**, which is subdivided into (*a*) the sympathetic system and (*b*) the parasympathetic system. Each of these parts has a wide distribution and is composed of ganglia and nerve-fibres which in many localities form complicated plexuses. The sympathetic system is connected with spinal nerves in the thoracic and upper lumbar regions, whilst the parasympathetic system is associated with certain cranial and sacral spinal nerves. No one of the three groups can be considered wholly apart from the others, since, although presenting certain differences in structure, arrangement, and distribution, they are not independent or separate systems, and all are connected to the central nervous system. The subdivision is, however, the most convenient one for descriptive purposes (Hovelacque, 1927).

CRANIAL NERVES

The cranial nerves are twelve pairs of symmetrically arranged nerves which are attached to the brain, leave the skull through foramina at its base, and are in the main distributed to the various structures of the head and neck. The site where the nerve-fibres composing it (rootlets) enter or leave the brain surface is usually termed the **superficial origin** of the nerve, and the more deeply placed group of cells from which the fibres arise or around which they terminate is called the **nucleus of origin** or **of reception** respectively, and forms the **deep origin** of the nerve. It is also customary to trace the course of a nerve from its superficial origin to the periphery irrespective of the actual direction of the impulses carried by it. In this Section the cranial nerves are described from their superficial origins onwards; their deep origins and connexions are dealt with in the account of the Brain (pp. 924-939), and certain general points are also touched upon in the paragraphs introductory to the Nervous System (p. 835).

Classification of Cranial Nerves.—The nomenclature of the cranial nerves reflects the confusion that is associated with the history of their study. In the spinal cord a simple arrangement of dorsal (afferent) and ventral (efferent) nerve-roots is found. Comparable types of fibres comprise the cranial nerves, but there is little of the simplicity of arrangement that characterizes the spinal nerves. Although it may be presumed that some of the cranial nerves (*e.g.*, the hypoglossal) are originally based on some such simple plan, the complications imposed on the head-end of the organism in development have led to a suppression of some elements and fusion of others, with the resulting formation of a series of nerves of very mixed types. It is doubtful if other cranial nerves are even phylogenetically based on such a simple plan. The terminology employed to describe the various cranial nerves has varied from time to time, and even to-day the accepted nomenclature is not beyond reproach. Although no regrouping of the cranial nerves is here suggested, some brief reference to their classification will help to clarify certain points about some of them (see following Table).

COMPONENT AND FUNCTIONAL ANALYSIS OF CRANIAL NERVES

No.	Name	Components	Distribution	Functions
I.	**Olfactory**	Afferent	Olfactory mucous membrane.	Smell.
II.	**Optic**	Afferent	Retina.	i. Sight (*via* lat. genic. body to visuo-sensory cortex). ii. Light reflex (*via* pretectal nucleus).
III.	**Oculomotor**	Efferent : *i. Somatic*	Sup., med., and inf. recti, and inf. oblique muscles of eyeball; levator palp. sup. muscle.	Associated in conjunctive and disjunctive movements of eyes.
		ii. Parasympathetic	Ciliary ganglion; ciliary and sphincter pupillæ muscles of eyeball.	Pupillary constriction and accommodation.
		Afferent	The above muscles.	Proprioceptive (? *via* mesencephalic nucleus of V).
IV.	**Trochlear**	Efferent	Sup. oblique muscle of eyeball.	Associated in movements of eyes.
		Afferent	The above muscle.	Proprioceptive (? *via* mesencephalic nuc. V).
V.	**Trigeminal**	Efferent	Muscles of mastication.	Mandibular movements.
			Digastric (ant. belly) and mylo-hyoid muscles.	Mastication and deglution.
			Tensor palati.	Associated in movements of soft palate and pharyngo-tympanic tube.
			Tensor tympani.	Modifies movements of tympanic membrane and ossicles.
		Afferent	Skin of face and anterior scalp. Mucous membrane of mouth including gums and tongue (ant. $\frac{2}{3}$); teeth. Mucous membrane of nasal cavities and paranasal sinuses. Meninges.	General sensibility.
			Muscles of mastication and expression, and of tongue.	Proprioceptive (*via* mesencephalic nucleus).
VI.	**Abducent**	Efferent	Lateral rectus muscle of eyeball.	Lateral movement of eye, especially in conjugate deviation.
		Afferent	The above muscle.	Proprioceptive (? *via* mesencephalic nucleus of V.).
VII.	**Facial**	Efferent : *i. Branchial*	Muscles of face and scalp.	Facial expression.
			Digastric (post. belly) and stylo-hyoid muscles.	Elevation of hyoid bone.
		ii. Parasympathetic	Spheno-palatine ganglion; glands of nasal cavities, of hard and soft palates, and lacrimal gland. Submandibular and sublingual ganglia; submandibular and sublingual glands and glands of tongue (ant. $\frac{2}{3}$).	Secreto-motor and vaso-dilator.
		Afferent	Mucous membrane of tongue (ant. $\frac{2}{3}$) (excluding vallate papillæ).	Taste.
VIII.	**Auditory**	Afferent	From duct of cochlea.	Hearing.
			From maculæ of utricle and saccule. From ampullæ of semicircular canals.	Equilibration (statokinetic receptors).

COMPONENT AND FUNCTIONAL ANALYSIS OF CRANIAL NERVES—*continued*

No.	Name	Components	Distribution	Functions
IX.	**Glosso-pharyngeal**	Efferent:		
		i. Branchial	Stylo-pharyngeus muscle. Middle constrictor.	Pharyngeal and laryngeal movements.
		ii. Parasympathetic	Otic ganglion; parotid gland.	Secreto-motor and vaso-dilator.
		Afferent	Mucous membrane of pharynx and tongue (post. ⅓) including tonsillar region.	General sensibility.
			Mucous membrane of tongue (post. ⅓) (including vallate papillæ).	Taste.
			Mucous membrane of tympanic cavity and antrum.	General sensibility.
			Carotid body and carotid sinus.	Vaso-sensory (chemo-receptors and pressure receptors).
X.	**Vagus (and Cranial Root of Accessory)**	Efferent:		
		i. Branchial	Levator palati muscle.	Associated in movements of soft palate and pharyngo-tympanic tube.
			Pharyngeal muscles.	Deglutition and other pharyngeal movements.
			Laryngeal muscles.	Control of laryngeal apertures in respiration and phonation.
		ii. Parasympathetic	Plain muscle of œsophagus, stomach, intestine, and gall-bladder.	Movements of these viscera.
			Pancreas and gastric glands.	Secreto-motor.
			Heart (nodal tissue and cardiac muscle).	Cardiac depressor.
			Lungs (plain muscle of bronchi and bronchioles).	Broncho-constriction.
		Afferent	Mucous membrane of larynx and respiratory passages.	General and visceral sensibility.
			Region of epiglottis.	Taste.
			Part of auricle and ext. auditory meatus.	Cutaneous sensibility.
			Lungs.	Respiratory reflexes.
			Glomus aorticum and wall of aorta.	Vaso-sensory.
			Wall of alimentary canal.	? Visceral sensibility.
XI.	**Accessory (Spinal Root)**	Efferent	Trapezius and sterno-mastoid muscles.	Movements of head and shoulder. Fixation of scapula.
XII.	**Hypoglossal**	Efferent	Muscles of tongue.	Movements of tongue.

Two of the nerves, the olfactory and optic, are not nerves in the usually accepted sense but rather tracts of fibres belonging to the central nervous system, as will be pointed out in greater detail under the appropriate headings. The third, fourth, and sixth nerves, all associated with the extra-ocular muscles, are predominantly motor nerves; but the third contains important parasympathetic preganglionic fibres, and all three of them have a small admixture of sensory fibres—without, however, possessing any ganglia or separate sensory roots (Tozer & Sherrington, 1910). The fifth, seventh, and eighth nerves are all complex, and there are good reasons for considering each of these as comprising two (or more) separate nerves. The fifth has a large sensory component with very extensive distribution in the face and head and a smaller motor component (*nervus masticatorius*) of localized distribution which accompanies its mandibular division. Both, however, possess the same superficial origin from the brain-stem. The seventh or facial nerve possesses two portions, one the facial proper, a motor nerve to muscles of expression in the main, and the other a smaller mixed nerve, the "sensory" root of the seventh, which from the viewpoint of distribution and function has little in common with the facial proper; it is in part composed of afferent fibres subserving taste, and, in large measure, of preganglionic fibres of the parasympathetic system for certain glands of the head (secreto-motor). The eighth nerve is readily separable into two entirely different functional elements—the cochlear and vestibular nerves—which are both sensory, and in development are closely associated. The

ninth and tenth are both mixed nerves, the latter in particular containing a large proportion of parasympathetic fibres. The eleventh nerve comprises two quite different parts, the cranial portion, which is closely associated functionally with the vagus, and the spinal portion, of quite distinct and separate distribution. The twelfth or hypoglossal nerve represents the compounding of the motor supply to several occipital myotomes which form the basis of the tongue-musculature. This nerve has lost completely, or almost so, the elements which would correspond with the dorsal root of a spinal nerve. Reference may here be made to the first cervical nerve (*suboccipital nerve*) which emerges between the skull and the atlas. It is in series with the twelfth and, like it, is in the process of losing its sensory components, so that a dorsal root ganglion is commonly absent in the adult. It was originally classed as a cranial nerve by Willis (1664), and its inclusion amongst the cervical spinal nerves accounts for the presence of eight cervical nerves, the first lying above the first vertebra and the second emerging below it.

OLFACTORY NERVE

The pathway taken by olfactory impulses from the nasal mucosa to the brain may be considered in various parts: (1) a series of fine **nerves** which run to (2) the

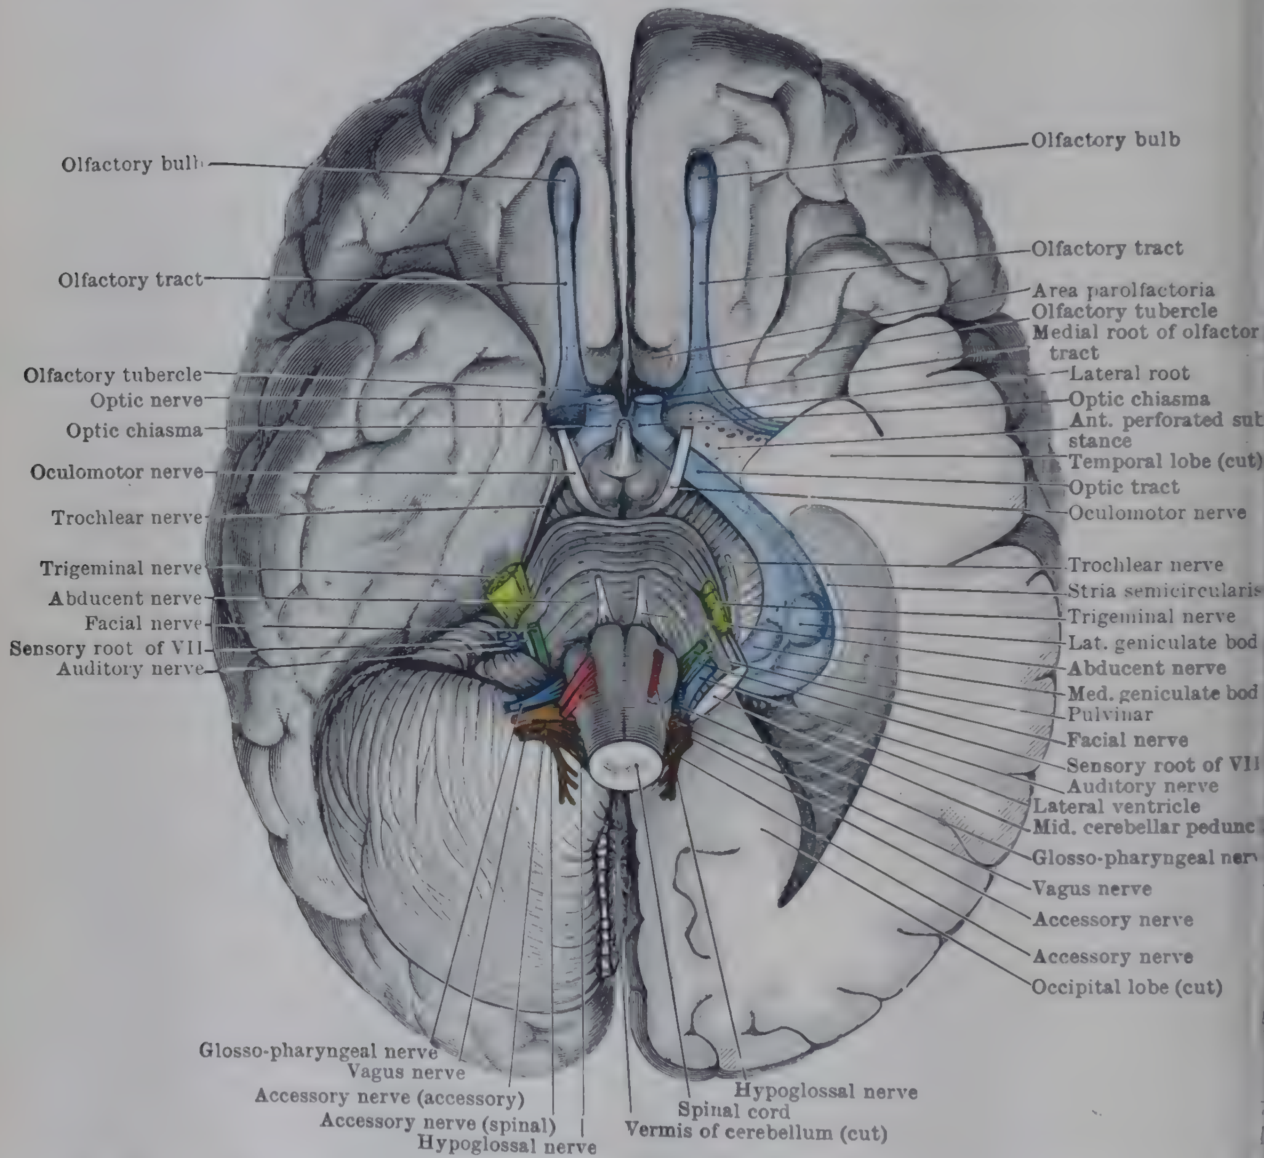

FIG. 885.—INFERIOR SURFACE OF BRAIN TO SHOW SUPERFICIAL ATTACHMENTS OF CRANIAL NERVES.
The lower portion of the left temporal and occipital lobes, and the left half of the cerebellum have been removed.

olfactory bulb; the bulb is connected by (3) the **olfactory tract** with the brain; to which it is attached by (4) two **roots** (Fig. 885).

The anatomy of the olfactory bulb, the olfactory tract and its roots is described on pp. 957 to 960; and the histology of the cells on p. 957.

The **olfactory nerve** consists of about twenty separate filaments which arise in the olfactory areas of the nasal mucosa and proceed to the olfactory bulb in the

anterior cranial fossa, passing in their course through the cribriform plate of the ethmoid bone. The fibres comprising these filaments are the central processes of bipolar nerve-cells which lie in the olfactory mucosa. They are exceedingly fine and are non-medullated. The filaments proceed by the shortest route to the holes in the cribriform plate and then direct to the olfactory bulb, on the surface of which they form an intricate plexus before terminating in the glomeruli of the bulb. In the region of the cribriform plate meningeal extensions are continued for a short way along the bundles of nerve fibres.

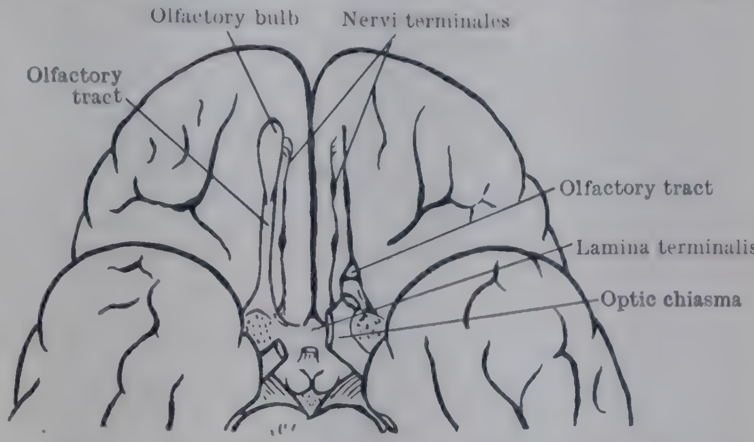

Fig. 886.—Diagram of part of Lower Surface of Adult Human Brain to show position of Nervi Terminales and their Relations to Olfactory Tracts and Gyri Recti. (After Brookover, 1914.)

The olfactory bulb and part of the tract have been removed on the left side, and the right optic nerve and the greater part of the optic chiasma have been cut away to expose the lamina terminalis.

The cell-bodies and the peripheral processes of the olfactory cells lie in the epithelium which covers the upper third of the nasal septum and nearly the whole of the superior concha (Figs. 893, 894). The cell-body is small with a rounded nucleus embedded in a scanty cytoplasm. The short peripheral process, or olfactory rod, is somewhat thicker than the central process and terminates at the surface in a small cup-shaped swelling; fine olfactory hairs project from the margin of the terminal swelling. (Le Gros Clark & Warwick, 1946)

Two other pairs of nerves have been found related to the olfactory system in lower vertebrates and in mammals with a well-developed sense of smell. Both are closely related to the olfactory nerve itself throughout its course. They are (1) the *vomero-nasal nerve*, which supplies the vomero-nasal organ, and in the domestic animals joins the olfactory nerve itself to terminate in an accessory olfactory bulb; in Man the vomero-nasal organ (p. 1208) is rudimentary after birth, and the nerve is absent; (2) the terminal nerve (Fig. 886).

The **terminal nerve** (*nervus terminalis*) has been found present in all groups of vertebrates, including Man. It is a very fine plexiform nerve consisting of non-medullated fibres with small groups of ganglion-cells, and may be discovered in the cranial cavity as two or three strands in the pia mater covering the gyrus rectus along the medial side of the olfactory tract. Peripherally (anteriorly) its fibres join the olfactory nerve-filaments and have a similar distribution to the nasal mucosa; in some mammals they have been traced to end in the walls of the anterior cerebral artery and in the vascular plexus of the nasal septum up to the region of the vomero-nasal organ. Centrally, the nerve strands pass over the medial root of the olfactory tract towards the anterior perforated substance. The evidence points to the conclusion that the nerve is functional in mammals, and, from the appearance of its fibres and ganglia, among other features, it may eventually be recognized as related in part at least to the autonomic system rather than as representing a separate nerve. (For further details, see Johnston, 1914; Brookover, 1914, 1917; M'Cotter, 1915; Larsell, 1918; Pearson, 1941).

OPTIC NERVE

The **second** or **optic nerve** consists of nerve-fibres which spring from the ganglion-cells of the retina, and converge to the optic disc, where they are grouped together to form the optic nerve. There is no adequate evidence of the presence of centrifugal fibres in the mammalian optic nerve (Bodian, 1937). Composed in this way of connector neurons, the optic nerve differs from other sensory nerves, which are composed of receptor neurons; it is, in reality, a tract of the brain, and the fibres comprising it lack the neurolemmal sheath of ordinary peripheral nerve-fibres, its place being taken by sheaths of neuroglial cells. The nerve pierces the outer layers of the retina, the choroid, and the sclera. Within the eyeball the fibres are non-medullated but acquire a myelin sheath as they penetrate the sclera. It pierces the sclera 3 mm.

(one-eighth of an inch) to the medial side of the posterior pole of the eyeball and slightly *above*[1] the horizontal meridian (Traquair, 1949), the nerve-fibres being divided into bundles by the lamina cribrosa, and enters the orbital fat, surrounded by the ciliary vessels and nerves. It then runs backwards and slightly medially towards the optic foramen, being crossed superiorly by the ophthalmic artery and naso-ciliary nerve, and is pierced on its inferior surface, usually about 1 cm. behind the eyeball, by the central artery and vein of the retina. It is surrounded by sheaths from all three membranes of the brain, that formed by the dura being especially robust, and by prolongations of the subdural and subarachnoid spaces which lie

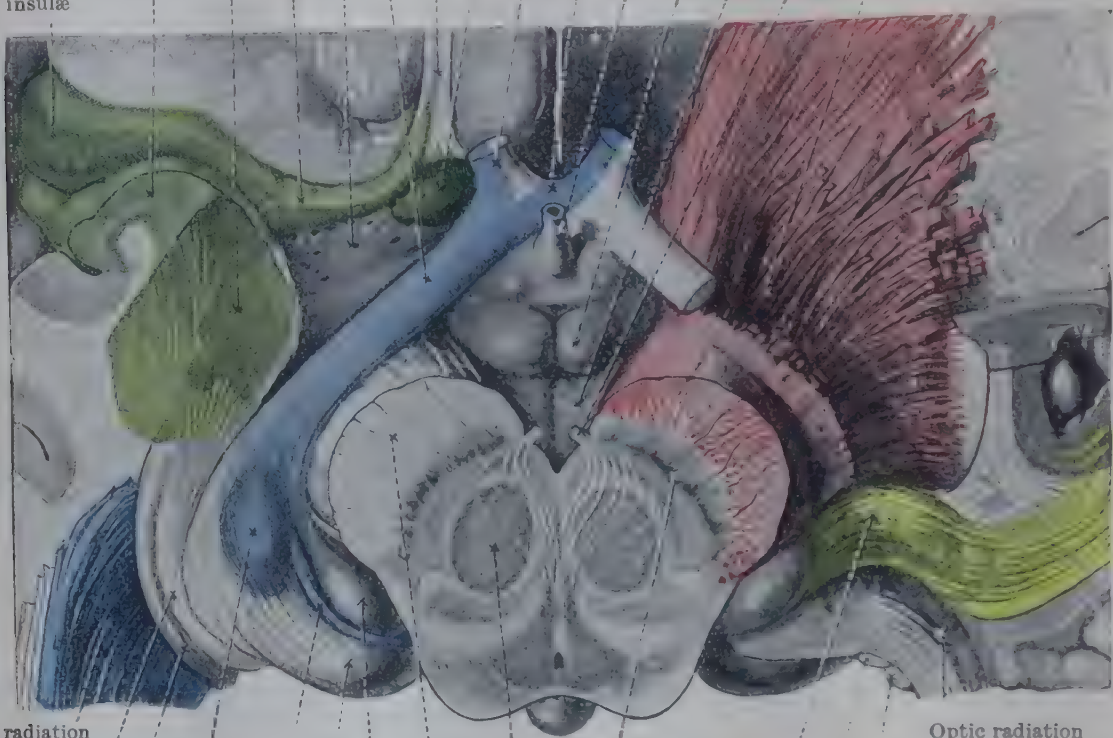

Fig. 887.—Part of Lower Surface of Fore-Brain, showing Olfactory and Optic Tracts. The mid-brain has been cut across. Olfactory area, *green*; optic fibres, *blue*; motor fibres, *red*; auditory fibres, *yellow*.

between them. To enter the optic foramen, it passes through the common tendinous ring from which the four rectus muscles of the eyeball arise. In the foramen it is separated from the sphenoidal air-sinus by only a thin plate of bone, the ophthalmic artery accompanies it on its lower and lateral sides, and the arteria retinæ centralis may enter it in this part of its course. It then enters the middle fossa of the skull and ends in the optic chiasma, which lies in the floor of the third ventricle of the brain, anterior to the interpeduncular area and between the right and left valleculæ of the cerebrum. The chiasma is in close relation on each side to the internal carotid artery (Fig. 889), but is a little distance above the hypophysis cerebri and the diaphragma sellæ.

From each of the two postero-lateral angles of the optic chiasma an optic tract sweeps round to the posterior part of the thalamus and to the mid-brain, between the

[1] It is usually stated that the optic head is below the level of the posterior pole, but Traquair maintains, with reference to the projection of the "blind spot", that it is above. (See also p. 1162.)

cerebral peduncle and the hippocampal gyrus of the corresponding side, and each tract terminates in connexion with the lateral geniculate body. Formerly it was thought that fibres of the optic tract terminated in all three lower visual centres

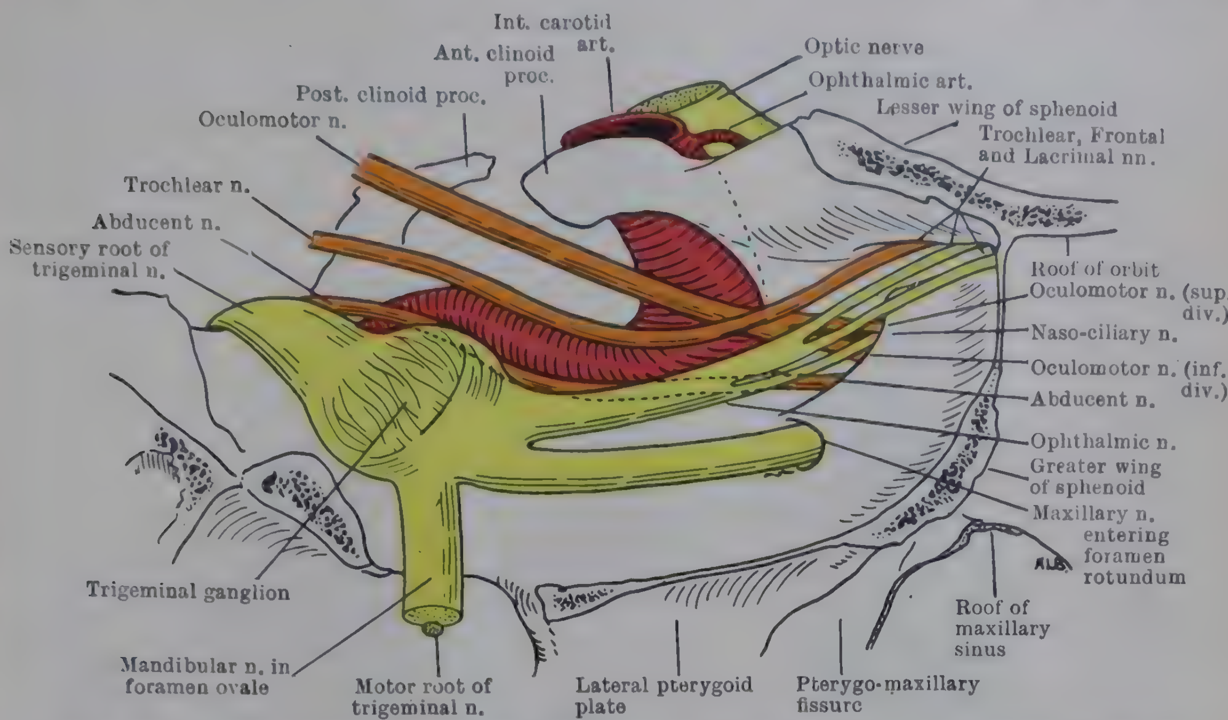

FIG. 888A.—RELATIONS OF STRUCTURES IN CAVERNOUS SINUS AND SUPERIOR ORBITAL FISSURE, VIEWED FROM THE RIGHT SIDE.

The section of the skull passes sagittally through the foramen ovale.

(the lateral geniculate body, pulvinar of thalamus and superior quadrigeminal body), but recent researches have shown that in Man, of the fibres concerned purely with vision, none go to the superior quadrigeminal body and probably none to the pulvinar, a change having been brought about in the arrangement of the fibres in consequence of the development of the macula of the retina and the increased functional importance of the visual cortex, which is connected with all three lower visual centres (Le Gros Clark, 1942). Fibres concerned with visual reflexes, however, do pass directly from the tract to the superior quadrigeminal body and the pretectal nucleus (see p. 952 and Fig. 835).

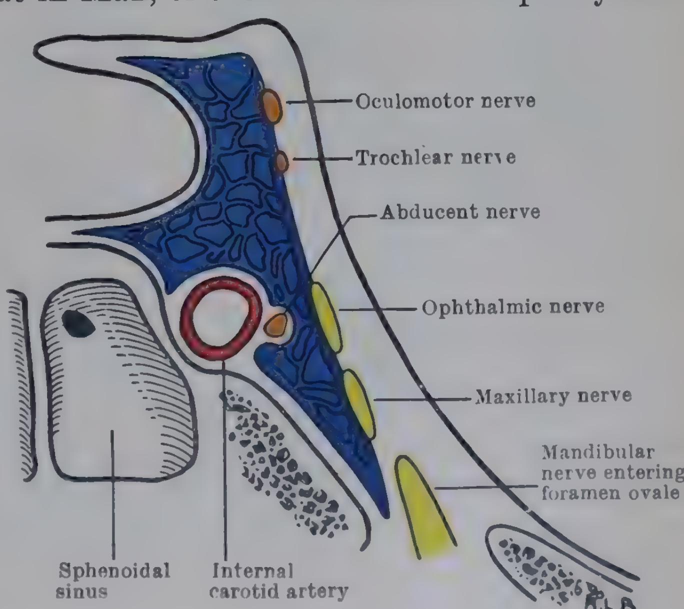

FIG. 888B.—DIAGRAMMATIC OBLIQUE CORONAL SECTION THROUGH THE RIGHT CAVERNOUS SINUS, VIEWED FROM BEHIND.

When the optic nerve reaches the optic chiasma the fibres from the lateral half of each retina, including the corresponding macular fibres, pass to the optic tract of the same side and the fibres from the medial half to the optic tract of the opposite side. Therefore, each optic nerve is connected with both sides of the brain in such a way that ipsilateral retinal areas, and therefore contralateral visual fields, are projected to the optic tracts (see p. 952 in Central Nervous System). Each optic tract, in addition, contains fibres unconnected with the visual apparatus. The connexions of such fibres (which constitute the commissure of Gudden in the chiasma) are not clear, but there are grounds for doubting the correctness of the classical view that Gudden's commissure connects the medial geniculate body and

the inferior quadrigeminal body of opposite sides (Woollard & Harpman, 1939; Magoun & Ranson, 1942).

OCULOMOTOR NERVE

The **third** or **oculomotor nerve** is predominantly a motor nerve and supplies the levator palpebræ superioris, and all the extrinsic ocular muscles, save the

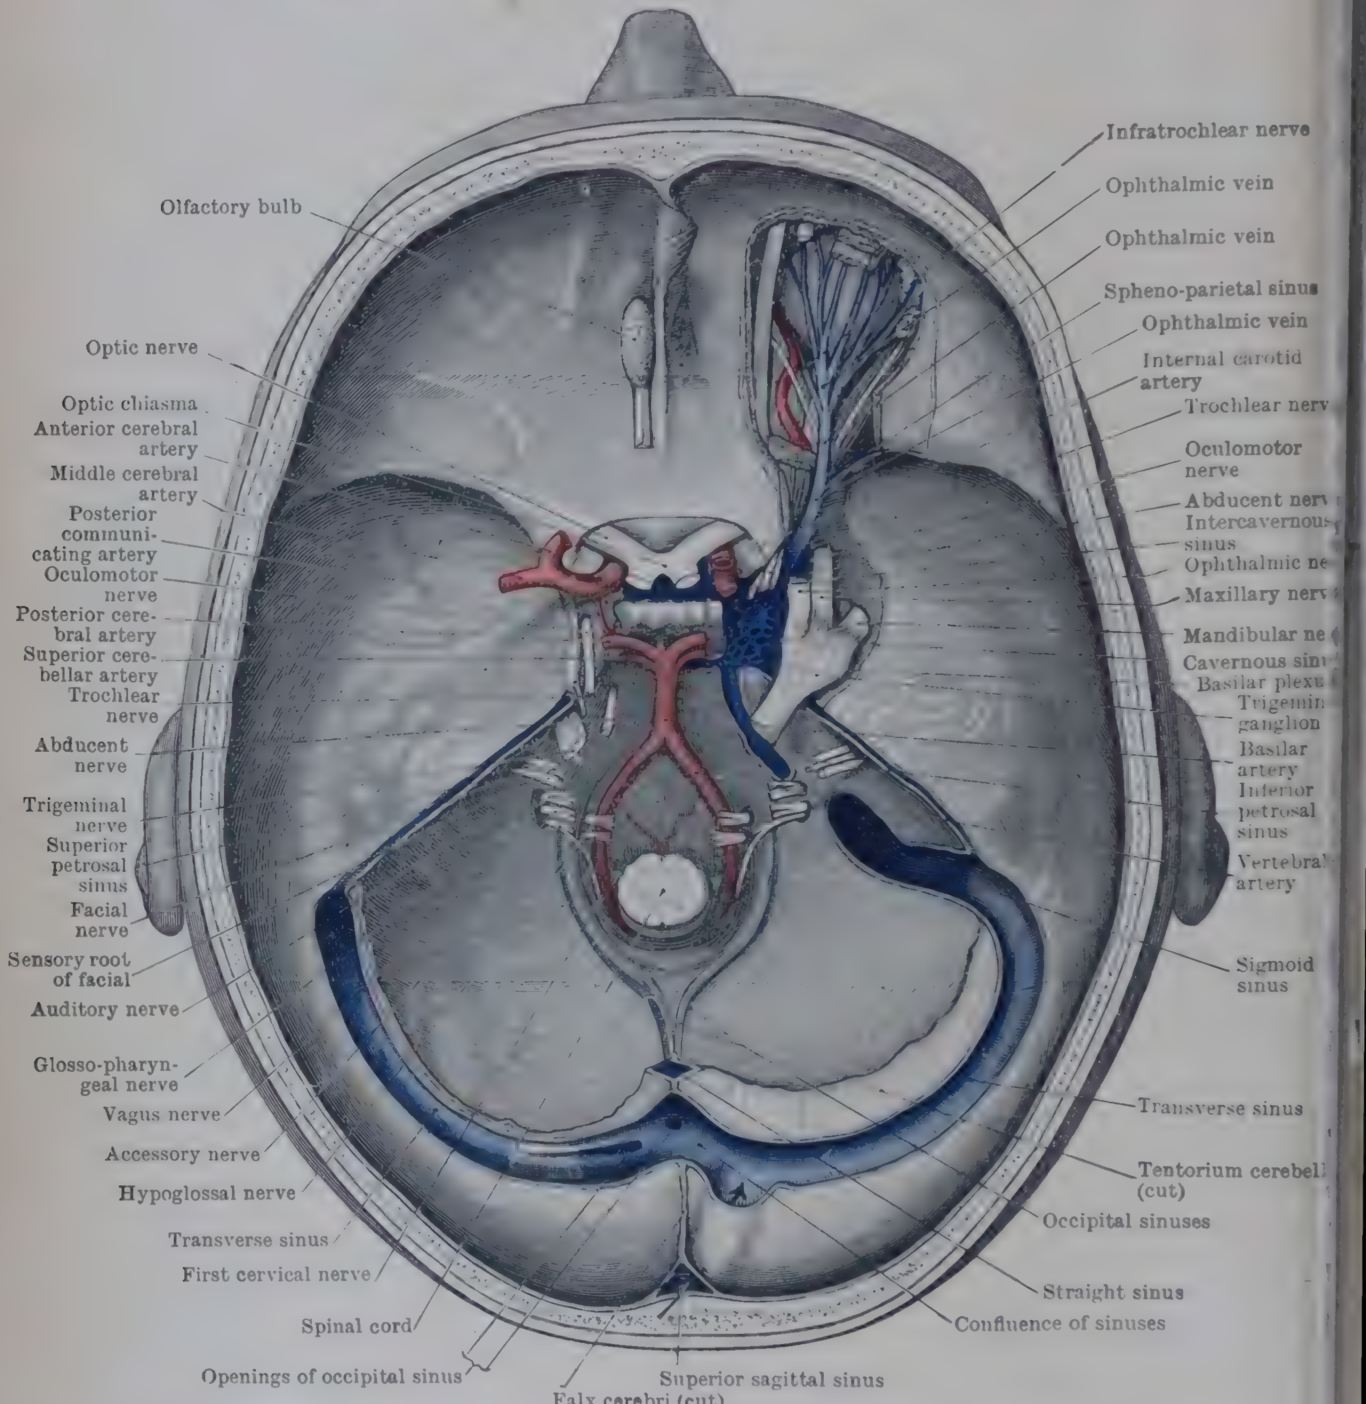

FIG. 889.—BASE OF SKULL, TO SHOW DURA MATER, VENOUS SINUSES, ARTERIES, AND NERVES.

lateral rectus and superior oblique; it supplies also certain intrinsic ocular muscles. Some afferent fibres are present carrying proprioceptive impulses from these muscles—possibly to the mesencephalic nucleus of the fifth nerve (p. 430). It arises from the brain, near the posterior perforated substance, by several rootlets which emerge from the medial sulcus of the cerebral peduncle, just above the pons (Figs. 885 and 813). (For deep origin, see p. 934.) Passing forwards, between and close to the posterior cerebral and superior cerebellar arteries, then along the lateral aspect of the posterior communicating artery through the interpeduncular cistern, the nerve pierces the dura mater antero-lateral to the posterior clinoid

process, in a small triangular space between the free and attached borders of the tentorium cerebelli. Embedded in the dura mater, the nerve courses through the lateral wall of the cavernous sinus, above the trochlear nerve, enters the orbit through the superior orbital fissure, and then lies within the common tendinous ring from which the four rectus muscles arise (Fig. 896). Just before the point of entry into the orbit the nerve divides into upper and lower branches, separated by the naso-ciliary nerve (Fig. 888 A). Sunderland & Hughes (1946) found that fibres concerned with constriction of the pupil were localized about the superior surface of the nerve from its point of emergence from the brain to the middle of the cavernous sinus; thereafter the pupillary fibres did not regularly adopt a fixed position relative to the rest of the third nerve.

Branches.—The **superior branch** of the nerve supplies two muscles of the orbit—the superior rectus and the levator palpebræ superioris.

The **inferior branch** passes forwards, and, after giving branches to the medial and inferior recti, ends in the inferior oblique muscle. From the branch which supplies the inferior oblique a filament (the parasympathetic root) extends to the ciliary ganglion and is concerned with the innervation of the ciliary and sphincter pupillæ muscles of the eyeball (Fig. 890).

Communications.—In the cavernous sinus the oculomotor nerve receives (1) filaments from the sympathetic plexus on the internal carotid artery, and (2) a slender communication from the ophthalmic division of the trigeminal nerve. Such communications are probably of a temporary nature.

Ciliary Ganglion.—This ganglion, which is a component of the cranial parasympathetic system, is a small reddish body about the size of a pin's head placed near the back of the orbit, between the lateral rectus muscle and the optic nerve, and in front of the ophthalmic artery. Some detached ganglionic cells may be found lying above the eyeball—see p. 1122. Joining the ganglion are several groups of fibres :—(1) The *parasympathetic root* derived from the nerve to the inferior oblique muscle. This root contains preganglionic parasympathetic fibres of the third nerve; they are non-medullated and are the only fibres to have synapses in the ciliary ganglion. (2) The *sympathetic root* composed of postganglionic fibres derived from the plexus on the internal carotid artery. These fibres may reach the ganglion independently or by way of the naso-ciliary nerve; and they pass uninterruptedly through the ganglion. (3) The *afferent root*, which is composed of afferent fibres that belong to the naso-ciliary branch of the fifth nerve; they are passing centrally from the eye to the fifth nerve without synaptic relay in the ganglion. It will be noted that the afferent and sympathetic roots have merely a relationship of contiguity with the ganglion cells (Fig. 890).

Passing away from the ciliary ganglion are twelve to fifteen **short ciliary nerves** which reach the eyeball in two groups above and below the optic nerve. These nerves (which are all medullated) convey (*a*) postganglionic parasympathetic fibres from the cells of the ganglion for the innervation of the ciliary muscle and the sphincter pupillæ muscle of the iris; (*b*) vasomotor sympathetic fibres to the vessels of the eye; and (*c*) afferent fibres from all parts of the eyeball. These will later reach the ophthalmic nerve through the sensory root of the ciliary ganglion.

TROCHLEAR NERVE

The **fourth** or **trochlear nerve** supplies only the superior oblique muscle of the eyeball. It arises at the side of the *frenulum veli* from the upper end of the superior medullary velum, just below the inferior quadrigeminal bodies (Fig. 802, p. 915). (For deep origin see p. 933.) It is extremely slender, and, since it emerges through the back of the brain-stem, its intracranial length is considerable. Passing round the lateral side of the cerebral peduncle immediately below the free margin of the tentorium, the nerve appears at the base of the brain behind the optic tract, in the interval between the cerebral peduncle and the temporal lobe of the brain, and between the superior cerebellar and posterior cerebral arteries. Continuing forwards, it then pierces the free border of the tentorium cerebelli,

postero-lateral to the oculomotor nerve, and proceeds forwards, in the lateral wall of the cavernous sinus (Fig. 888), to the superior orbital fissure, lying between the oculomotor nerve and the ophthalmic division of the trigeminal nerve. It enters the orbit above the muscles of the eyeball (Fig. 896), turns medially between the levator palpebræ superioris and the periosteum of the orbital roof, and terminates in the orbital surface of the superior oblique muscle.

Communications.—In the cavernous sinus the nerve communicates by slender branches (1) with the sympathetic plexus on the internal carotid artery, and (2) with the ophthalmic division of the trigeminal nerve. Such communications are probably of a temporary nature.

TRIGEMINAL NERVE

The **fifth** or **trigeminal nerve**, the largest of the cranial nerves, is the nerve of common sensation to the superficial and deep parts of the face, and is motor to the muscles of mastication (see summary of distribution on p. 1010). Proprioceptive impulses from these muscles as well as from the palate and the teeth are conveyed to the mesencephalic nucleus of the fifth nerve (Corbin & Harrison, 1940).

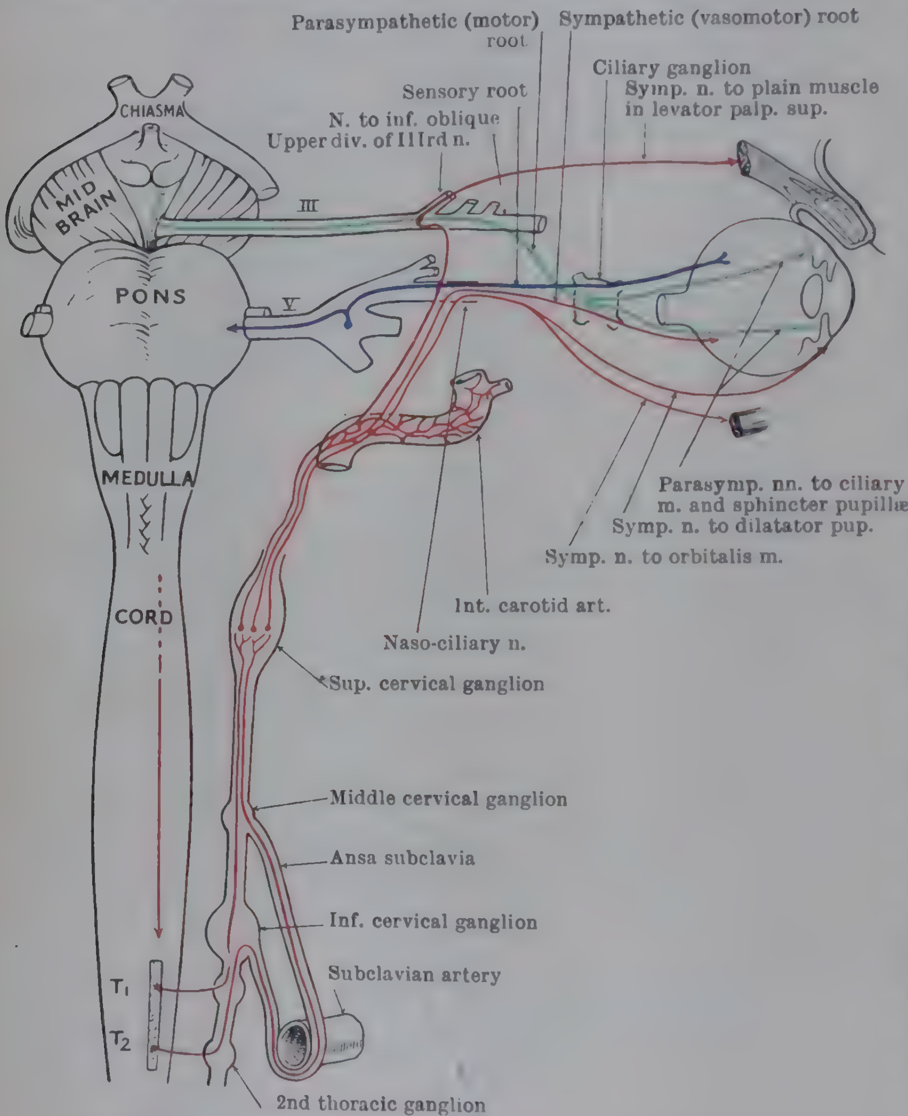

Fig. 890.—Diagram of Ciliary Ganglion and Connexions of Autonomic Nervous System with the Eye.

It is attached to the lateral part of the anterior surface of the pons by two roots—a large **sensory root** and a small **motor root** (Fig. 813, p. 925). (For deep origin see p. 931.) The two roots proceed forwards in the posterior fossa of the skull, and enter the middle fossa by passing beneath the attachment of the tentorium cerebelli to the upper border of the petrous part of the temporal bone; at this point the roots generally lie beneath the superior petrosal sinus. In the middle fossa they occupy a cavity in the dura mater (*cavum trigeminale*) on the anterior surface of the petrous bone. The sensory (afferent) root gradually conceals the motor (efferent) root in its course forwards, and expands within the cavum trigeminale into a large, flattened, and somewhat plexiform ganglion—the **trigeminal ganglion**. That ganglion occupies an impression on the petrous portion of the temporal bone near its apex; and the internal carotid artery and the posterior part of the cavernous sinus are on its medial side. From the ganglion three large trunks arise—the **ophthalmic** or first, the **maxillary** or second, and the **mandibular** or third **divisions** of the nerve. The motor

root of the nerve passes forward beneath the ganglion, and is incorporated wholly with the mandibular division of the nerve; on developmental and functional grounds the motor root is sometimes described as a separate nerve—the *nervus masticatorius*.

In the sensory root adjacent to the ganglion the fibres correspond, from medial to lateral, to the three divisions of the nerve, *i.e.*, ophthalmic, maxillary, and mandibular. Traced towards the pons, this arrangement tends to be obscured by a rotation of the whole nerve and some intermingling of fibres belonging to the three divisions. Nevertheless, at the origin from the pons the fibres of the ophthalmic division are mostly inferior in position and those of the mandibular division in the main superior (Davies & Haven, 1933).

OPHTHALMIC NERVE

The **ophthalmic nerve** passes forwards towards the orbit through the middle fossa of the skull, in the dura mater of the lateral wall of the cavernous sinus, at a lower level than the trochlear nerve. Near the superior orbital fissure it divides into three main branches—lacrimal, frontal, and naso-ciliary (Fig. 888A).

In the wall of the cavernous sinus the ophthalmic nerve gives off (1) a small recurrent branch to the dura mater (*n. to tentorium*, Fig. 878, p. 999), (2) small communicating sensory twigs to the trunks of the oculomotor, trochlear, and abducent nerves, and it receives branches from the sympathetic plexus on the internal carotid artery. Sunderland & Hughes (1946) describe these communicating twigs as being of a temporary nature and not involving the permanent transfer of fibres between the nerves concerned.

The **lacrimal nerve** enters the orbit through the lateral angle of the superior orbital fissure, above the orbital muscles. It passes forwards between the periosteum and the orbital contents to the anterior part of the orbit, and ends by supplying branches (*a*) to the lacrimal gland, (*b*) to the conjunctiva, and (*c*) to the skin of the lateral part of the upper eyelid.

The lacrimal nerve *communicates* in the orbit with the zygomatic branch of the maxillary nerve (Fig. 897) (whereby some secretory fibres are probably conveyed to the lacrimal gland), and on the face, by its terminal branches, with the temporal branches of the facial nerve.

The **frontal nerve** enters the orbital cavity through the superior orbital fissure, courses forwards above the ocular muscles, and divides at a variable point into two branches—a larger supra-orbital and a smaller supratrochlear nerve (Figs. 891 and 892).

The **supra-orbital nerve** passes directly forwards and leaves the orbit through the supra-orbital groove or foramen to reach the forehead. It gives off secondary branches which are distributed to: (1) the forehead and scalp, reaching backwards as far as the vertex; (2) the upper eyelid; and (3) the frontal sinus. On the forehead the supra-orbital nerve communicates with the temporal branches of the facial nerve.

The **supratrochlear nerve** courses obliquely forwards and medially, above the tendon of the superior oblique muscle, to reach the medial part of the supra-orbital margin, where it leaves the cavity of the orbit; it is distributed to the skin and fascia of the medial part of the forehead and the medial part of the upper eyelid.

It communicates with the infratrochlear branch of the naso-ciliary nerve, either before or after leaving the orbit.

The **naso-ciliary nerve** enters the orbit through the superior orbital fissure, and between the two divisions of the oculomotor nerve (Fig. 896). It crosses the orbital cavity obliquely to reach the anterior ethmoidal foramen, lying in its course below the superior rectus and superior oblique muscles and above the optic nerve and medial rectus muscle. The nerve is transmitted, under the name of *anterior ethmoidal*, through the anterior ethmoidal foramen into the cranial cavity, where it lies embedded in dura mater on the cribriform plate of the ethmoid bone. It enters the nasal cavity through the nasal slit, and terminates by dividing into medial and lateral **internal nasal branches**. The medial division supplies the

mucous membrane over the upper and anterior part of the nasal septum. The lateral branch, after supplying collateral offsets to the lateral wall of the nasal cavity, finally appears on the face, as the **external nasal branch**, between the nasal bone and the upper nasal cartilage, and supplies branches to the skin and fascia of the lower part of the dorsum and the tip of the nose. The anterior ethmoidal nerve supplies, then, the cartilaginous part of the nose, both internally and externally.

The **branches** of the naso-ciliary nerve may be divided into three sets, arising (*a*) in the orbit, (*b*) in the nose, and (*c*) on the face.

In the orbit the branches are given off in three situations—lateral to, above, and

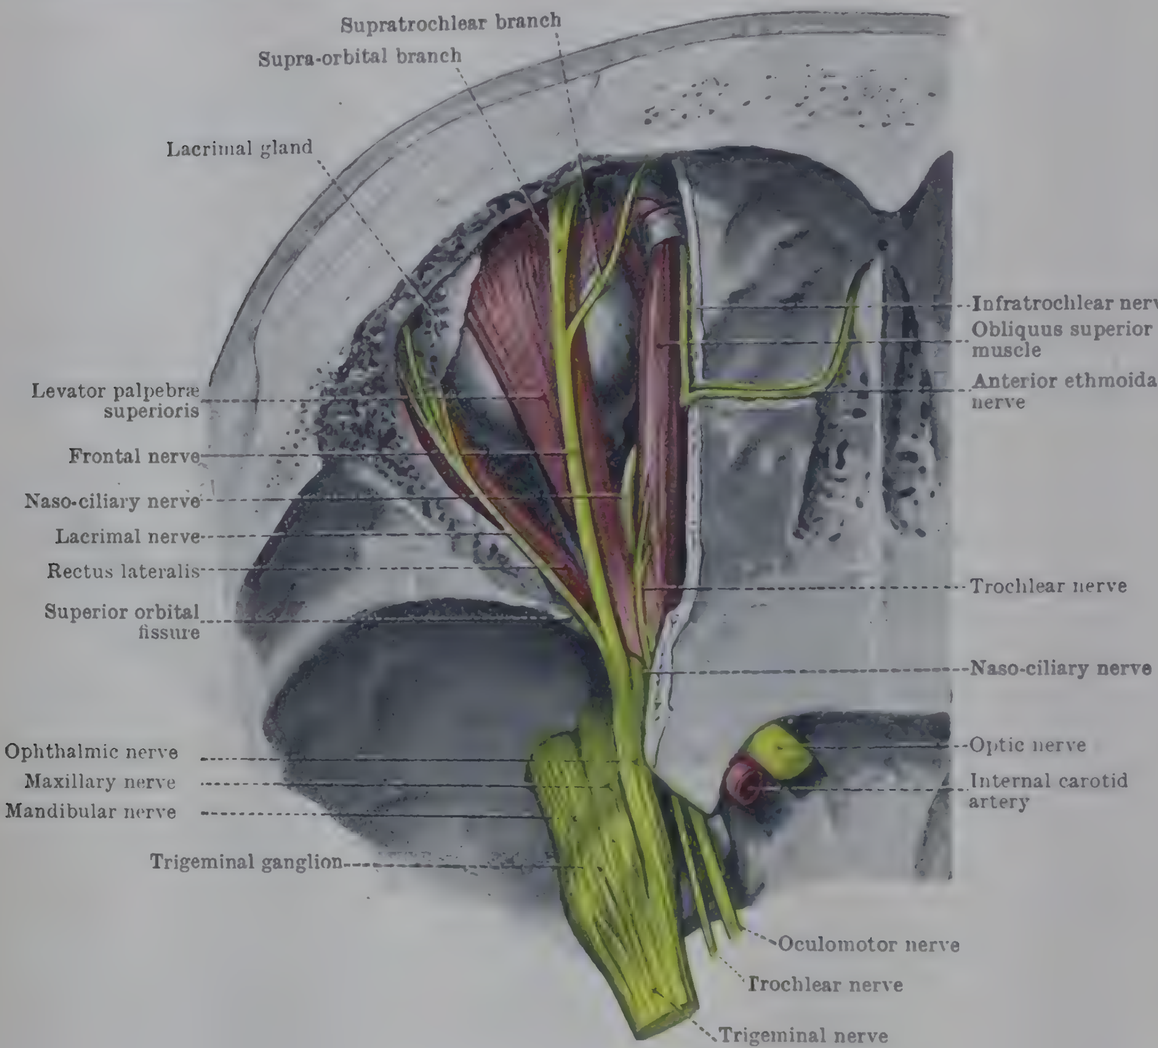

FIG. 891.—NERVES OF ORBIT FROM ABOVE.

medial to the optic nerve. (*a*) As the nerve lies on the lateral side of the optic nerve, it gives off the **ramus communicans** or afferent root to the ciliary ganglion. (*b*) As it crosses above the optic nerve, **two long ciliary nerves** arise and pass forwards alongside the optic nerve to the eyeball. They convey sympathetic fibres to the dilator pupillæ muscle and afferent fibres to the iris and ciliary body. (*c*) On the medial side of the optic nerve the **infratrochlear nerve** arises as a slender branch which courses forwards below the pulley of the superior oblique muscle to the front of the orbit. It ends on the face by supplying the skin of the root of the nose and the eyelids; and it communicates either in the orbit or on the face with the supratrochlear nerve. On the face it also communicates with zygomatic branches of the facial nerve. A minute *posterior ethmoidal branch* may arise from the nerve near the back of the orbit and enter the foramen of the same name to be distributed to the sphenoidal sinus and posterior ethmoidal sinuses.

In the nose the **medial internal nasal branches** supply the mucous membrane of the anterior part of the nasal septum; and **lateral internal nasal branches** supply the anterior part of the lateral wall of the nasal cavity.

In the face the terminal filaments of the **external nasal branch** are distributed to the skin and fascia of the lower half and tip of the nose. The terminal branch communicates with the zygomatic branches of the facial nerve.

MAXILLARY NERVE

The **maxillary nerve** courses forwards from the trigeminal ganglion through the middle fossa of the skull, in the dura mater, and in relation to the lower part of the cavernous sinus (Fig. 888, p. 1015). It passes through the foramen rotundum, traverses the pterygo-palatine fossa, and enters the orbit as the infra-orbital nerve through the inferior orbital fissure. In the orbit it occupies successively the infra-orbital groove and canal, and it finally appears on the face through the infra-orbital foramen (Fig. 898).

The branches and communications of this nerve occur (*a*) in the cavity of the cranium, (*b*) in the pterygo-palatine fossa, (*c*) in the infra-orbital canal, and (*d*) in the face.

(*a*) *In the cavity of the cranium* the nerve gives off a minute **meningeal branch** to the dura mater of the middle fossa of the skull (Fig. 878, p. 999).

(*b*) *In the pterygo-palatine fossa* the nerve gives off—(1) two short thick **ganglionic branches** to which the spheno-palatine ganglion is closely related. These nerves have, however, only a relationship of contiguity with the ganglion, for the fibres pass either close by it or through it without having any synaptic relation with the cells of the ganglion. As the fibres pass away from the ganglion or its vicinity they are commonly accompanied by the axons of cells within the ganglion (*i.e.*, parasympathetic fibres). In this way a number of small nerves appear to proceed from the ganglion and have commonly been called " branches of the ganglion "; but it must be understood that they are predominantly fifth nerve branches with only an admixture of fibres derived from the cells of the ganglion. A description of the spheno-palatine ganglion will be found on p. 1033 with the seventh nerve. These numerous branches (so-called branches of the ganglion) pass backwards to the pharynx, downwards to the palate, medially to the nasal cavity, and upwards to the orbit.

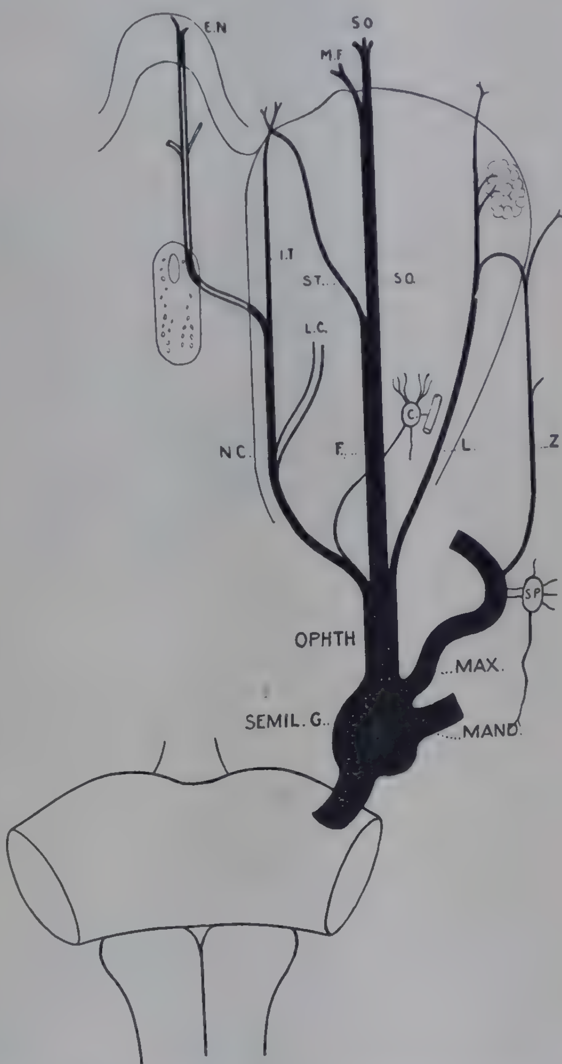

FIG. 892.—SCHEME TO SHOW THE DISTRIBUTION OF THE OPHTHALMIC NERVE.

F., frontal nerve, giving off supratrochlear branch (S.T.) and proceeding as supra-orbital (S.O.), which may divide before leaving orbit into a medial frontal branch (M.F.) and a lateral frontal or supra-orbital proper.

N.C., naso-ciliary nerve; gives off afferent root to ciliary ganglion (C.), two long ciliary nerves (L.C.) to eyeball, and, just before leaving the orbit through the anterior ethmoidal canal, the infratrochlear nerve (I.T.); the rest of its course up to its termination on the nose as the external nasal nerve (E.N.) illustrates the description given in the text.

L., lacrimal nerve, communicating with zygomatico-temporal branch of zygomatic nerve (Z.).

S.P., spheno-palatine ganglion.

(i) The **pharyngeal branch** passes backwards through the palatino-vaginal canal to supply the mucous membrane of the roof of the pharynx and the sphenoidal sinus.

(ii) The **palatine nerves**, three in number, are directed downwards to the palate through the palatine canals.

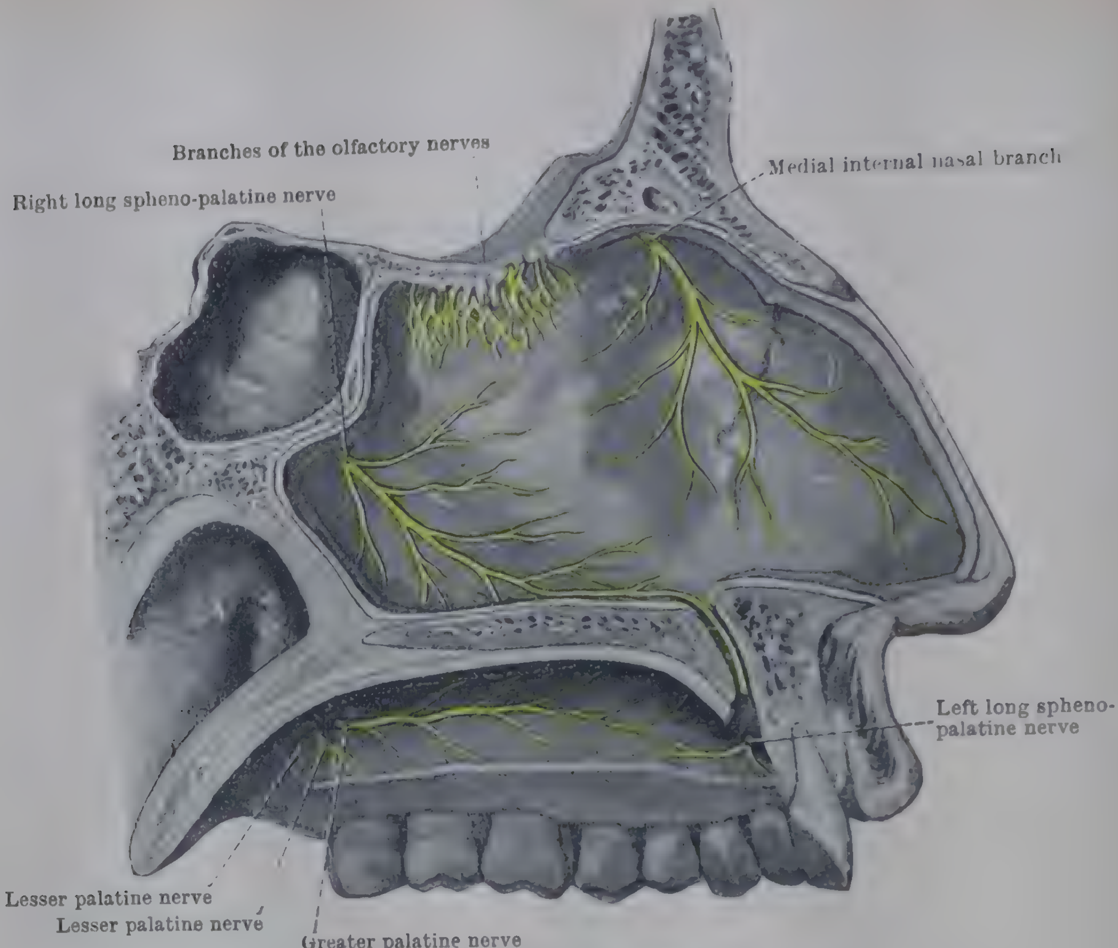

FIG. 893.—INNERVATION OF NASAL SEPTUM AND PALATE.

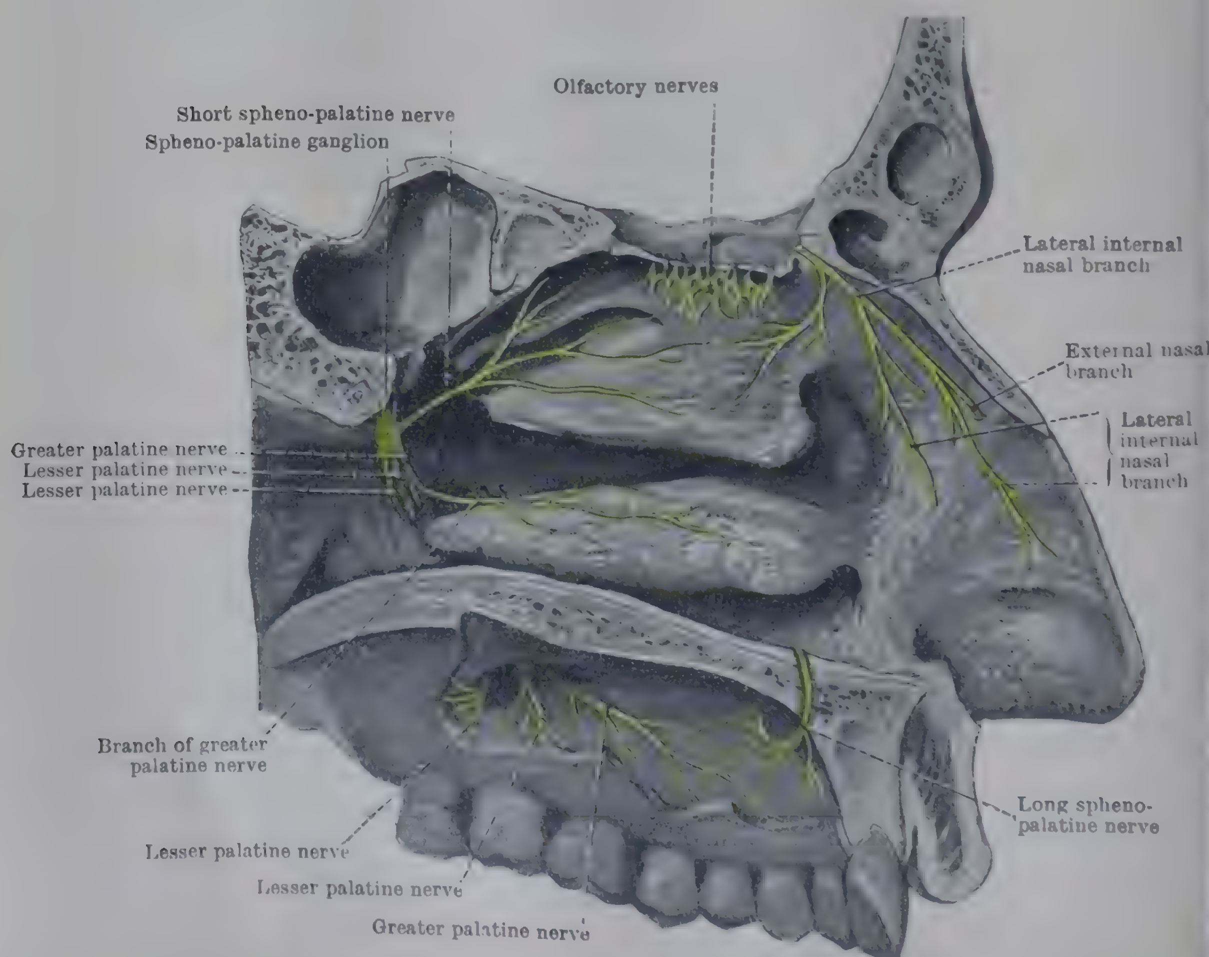

FIG. 894.—INNERVATION OF LATERAL WALL OF NASAL CAVITY AND PALATE.

The **greater palatine nerve** emerges on the under surface of the palate through the greater palatine foramen, and at once separates into numerous branches for the supply of the mucous membrane of the soft palate and the muco-periosteum of the hard palate, which they groove. Its anterior filaments reach to the incisor sockets and communicate with branches of the long spheno-palatine nerve. The main nerve gives off, as it lies in the palatine canal, small **nasal branches** which enter the nasal cavity and supply the mucous membrane of the inferior concha.

The **lesser palatine nerves** descend through the lesser palatine canals. The more medial emerges immediately behind the palatine crest and supplies branches to the soft palate. The more lateral is distributed to the soft palate and the adjacent part of the tonsil.

(iii) The branches directed medially from the spheno-palatine ganglion enter the nasal cavity through the spheno-palatine foramen. They are the long and short spheno-palatine nerves. (*a*) The **long spheno-palatine nerve**, after passing through the spheno-palatine foramen, crosses the roof of the nasal cavity, and extends obliquely downwards and forwards along the nasal septum, grooving the vomer in its course between the mucous membrane and periosteum, to reach the incisive fossa near the front of the hard palate. The nerves pass through the median incisive foramina, the left nerve in front of the right. In the incisive fossa the two nerves communicate. They then turn backwards and supply the mucous membrane of the hard palate. They communicate posteriorly with terminal filaments of the greater palatine nerves. In its course through the nasal cavity each long spheno-palatine nerve furnishes collateral branches to the mucous membrane of the roof and septum of the nose (Fig. 893). (*b*) The **short spheno-palatine nerves** are small branches distributed to the mucous membrane of the superior and middle conchæ, and to the postero-superior part of the nasal septum.

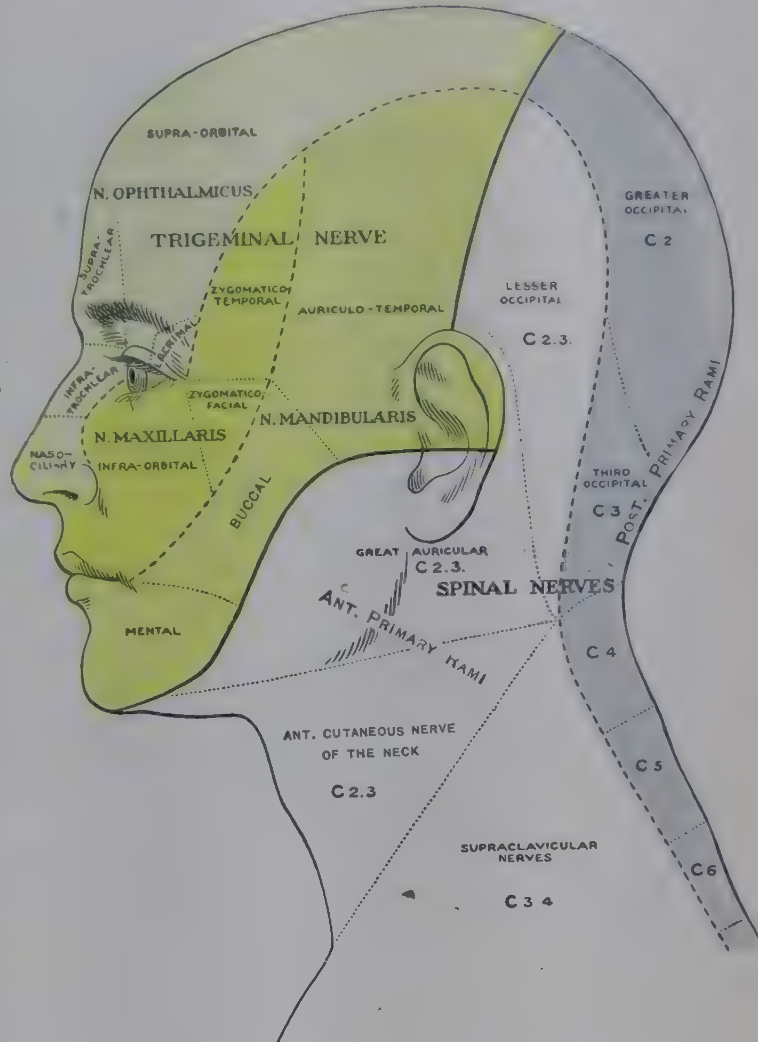

Fig. 895.—Distribution of Cutaneous Nerves to Head and Neck.

(iv) The **orbital branches**, one or more minute branches, pass upwards to supply the periosteum of the orbit and possibly convey some secreto-motor fibres to the lacrimal gland.

(2) **Posterior superior dental nerves**, generally three in number, descend through the pterygo-maxillary fissure to the posterior surface of the maxilla. One branch proceeds downwards to reach the gum and adjacent part of the cheek, while the other two branches enter fine canals in the bone and proceed with accompanying vessels to supply the teeth as far forwards as the canine (Wood Jones, 1939). The two canals run more or less horizontally round the maxillary sinus, the upper and smaller at the level of the zygomatic process and the lower and larger between this and the alveolar margin. They also supply branches to the mucous membrane of the sinus.

(3) A small orbital branch—the **zygomatic nerve**—enters the orbital cavity through the inferior orbital fissure, and, proceeding along the lateral wall, divides

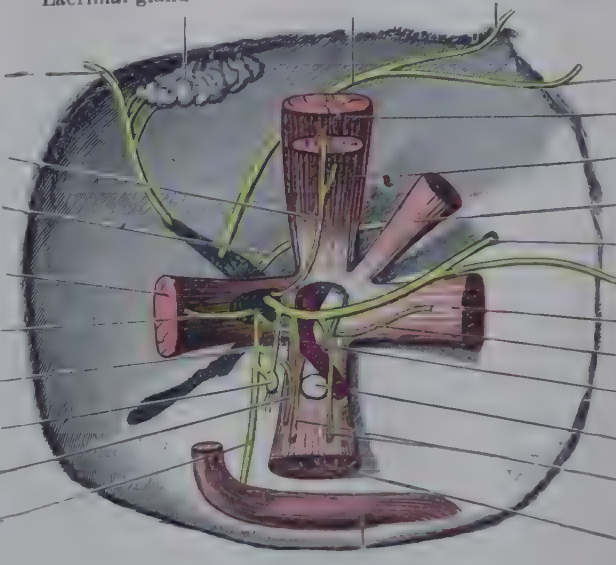

FIG. 896.—SCHEMATIC REPRESENTATION OF NERVES WHICH TRAVERSE THE CAVITY OF THE ORBIT.

Note that the lacrimal, frontal, and trochlear nerves, after entering the orbit through the superior orbital fissure, pass outside the common tendinous ring from which the recti muscles arise; whilst the oculomotor, abducent, and naso-ciliary nerves, together with the optic nerve and ophthalmic artery, enter the orbit within the ring, and therefore lie at first within the cone formed by the ocular muscles as they diverge forwards from it.

into two branches—(i) a *zygomatico-facial branch*, which appears on the face through the zygomatic foramen, after traversing the zygomatic bone, and supplies

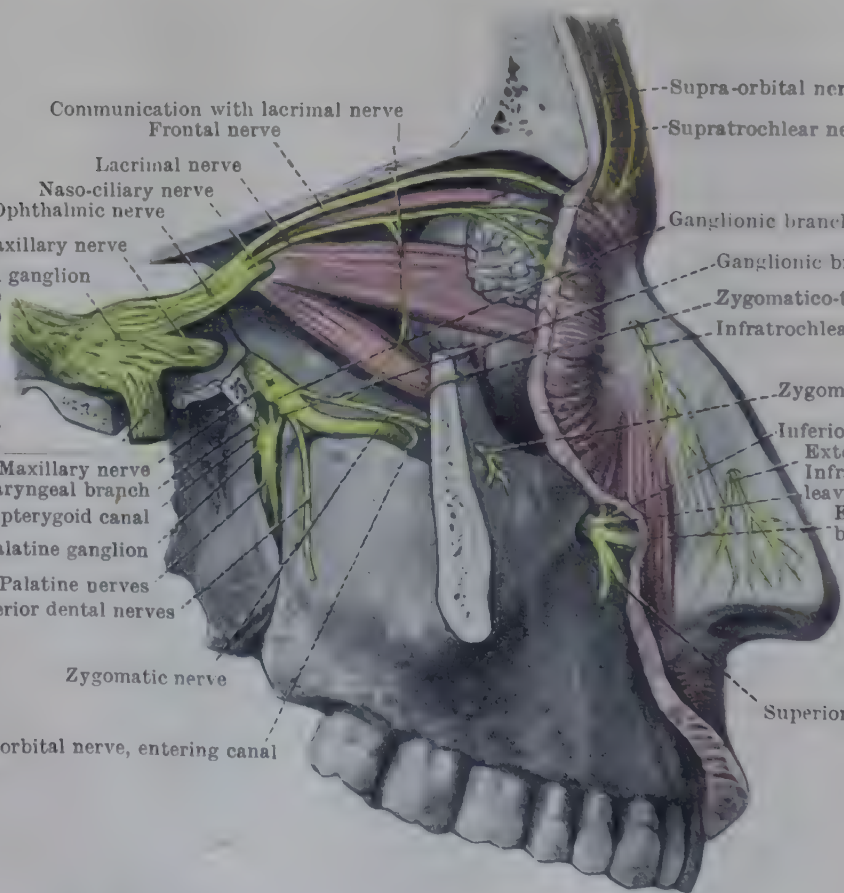

FIG. 897.—COURSE OF THE OPHTHALMIC AND MAXILLARY NERVES.

the skin and fascia over that bone; it communicates with the zygomatic branches of the facial nerve. (ii) A *zygomatico-temporal branch* perforates the temporal

surface of the zygomatic bone, or passes through the spheno-zygomatic suture, and is distributed, after piercing the temporal fascia, to the skin and fascia over the anterior part of the temple. In the orbit it communicates with the lacrimal nerve, and on the face with the temporal branches of the facial nerve. The filament which communicates with the lacrimal nerve probably contains some of the parasympathetic fibres from the spheno-palatine ganglion to the lacrimal gland. The zygomatico-temporal branch may be very minute, and not pass farther than the temporal fascia, between the two layers of which it may form a communication with the facial nerve.

The **infra-orbital nerve** is the terminal branch of the maxillary nerve, which

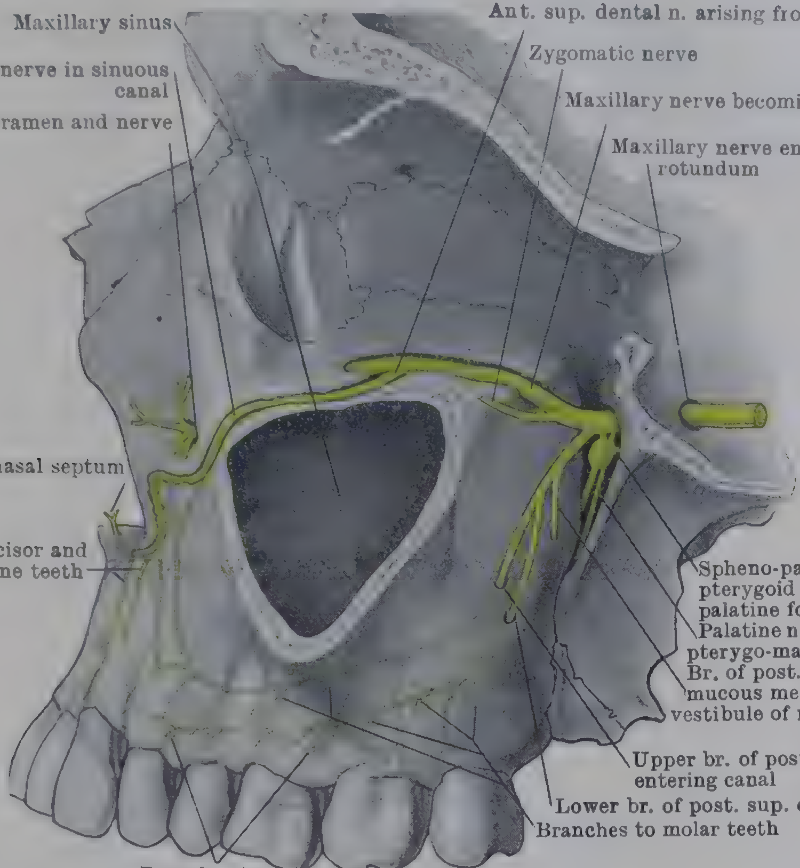

FIG. 898.—COURSE AND BRANCHES OF MAXILLARY NERVE.

enters the orbit through the inferior orbital fissure and traverses the infra-orbital canal to reach the face.

(*c*) About the middle of *the infra-orbital canal* the nerve gives off from its lateral side a stout branch—the **anterior superior dental nerve**. This nerve enters a sinuous canal (Wood Jones, 1939) which conveys it to the root of the anterior nasal spine. It first proceeds forwards to the orbital margin, which it reaches a short distance lateral to the infra-orbital nerve. Here it bends medially and runs in the anterior wall of the maxillary sinus below the infra-orbital foramen to reach the wall of the nose at the level of the anterior end of the inferior concha (Fig. 898). The canal now turns sharply downwards, conveying the nerve to the floor of the nose. The terminal branches of the nerve emerge from a small foramen close to the septum. During its descending course the nerve gives branches to the canine and incisor teeth, and nearer its termination to the lateral wall and floor of the nose and to part of the nasal septum. A branch of the infra-orbital artery accompanies the nerve in its canal. Within the maxillary sinus a bony ridge may be raised by the canal; but the most prominent ridge—in the angle between the roof and the anterior wall of the sinus—is due to the infra-orbital canal itself.

(*d*) *In the face*, after emerging from the infra-orbital foramen, the infra-orbital nerve divides into a number of radiating branches arranged in three sets—(1) **palpebral** for the skin and conjunctiva of the lower eyelid; (2) **nasal**, for the

skin and fascia of the side of the nose; and (3) **labial**, for the cheek and upper lip. These branches form communications with the zygomatic branches of the facial nerve, and form with them the *infra-orbital plexus* (Fig. 902).

MANDIBULAR NERVE

motor

sensory

The **mandibular nerve** is formed by the union of two roots; a large **afferent root** from the trigeminal ganglion, and the small **efferent root** of the trigeminal nerve, which is wholly incorporated with the mandibular trunk. The two roots pass together, in the dura mater of the middle fossa of the base of the skull, to the foramen ovale, through which they emerge into the infratemporal fossa. As they leave the skull they combine to form a single, short trunk which separates into anterior and posterior divisions immediately below the foramen ovale.

At its emergence from the skull the nerve lies deeply between the lateral

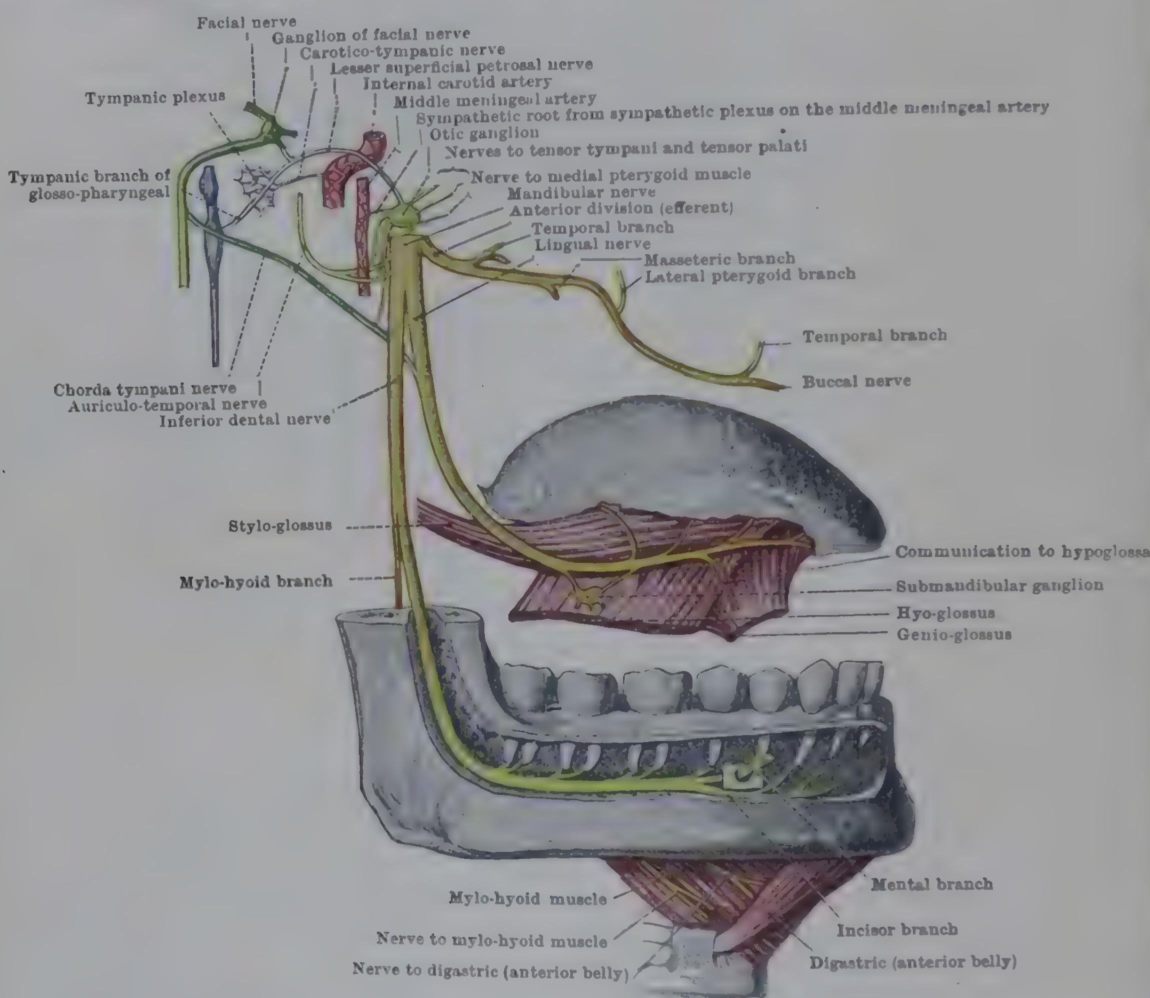

FIG. 899.—SCHEME OF DISTRIBUTION AND CONNEXIONS OF MANDIBULAR NERVE.

pterygoid and the tensor palati muscles; behind it lies the middle meningeal artery.

The branches of the nerve may be divided into two series—(1) those derived from the undivided nerve, and (2) those derived from its terminal divisions.

The branches of the undivided nerve are two in number; they arise from its medial aspect. (*a*) A small **nervus spinosus** arises just outside the skull. It accompanies the middle meningeal artery through the foramen spinosum, and supplies the dura mater and the mastoid cells. (*b*) A small branch for the supply of the **medial pterygoid muscle** and the **tensor tympani** and **tensor palati muscles.** As it passes medially this branch is in close contiguity with the otic ganglion.

The terminal divisions of the nerve are a small anterior and a large posterior trunk.

The small **anterior trunk** passes downwards and forwards medial to the lateral pterygoid muscle, and separates into the following branches: (1) A branch for the **lateral pterygoid muscle** which supplies it on its deep surface. (2) A branch to the **masseter muscle** which passes over the upper border of the lateral pterygoid and through the mandibular notch behind the temporalis muscle; it gives a filament to the mandibular joint. (3) and (4) Two **deep temporal branches**, an anterior (which often accompanies the buccal branch) and a posterior (with sometimes a third, the middle) to the temporal muscle, which also pass laterally above the lateral pterygoid muscle. (5) The **buccal nerve**, which passes obliquely forwards and laterally between the two heads of the lateral pterygoid and then runs downwards to reach the cheek. In the latter part of its course the nerve is closely associated with the anterior and medial aspect of the tendon of the temporalis muscle, being bound to it by fascia or occupying a groove in the tendon, or even piercing the tendon. Here the nerve is quite closely related to the posterior wall of the vestibule of the mouth where surgical approach may be effected. On reaching the cheek, the nerve divides, some of the branches being distributed to the skin and fascia of the cheek and there communicating with the facial nerve, while others perforate the buccinator muscle to supply mucous membrane of the cheek and gum and to assist in the supply of the premolar and the first molar teeth of the lower jaw. Though the buccal nerve penetrates the buccinator muscle, it takes no part in the motor supply of the muscle, which is by the seventh nerve.

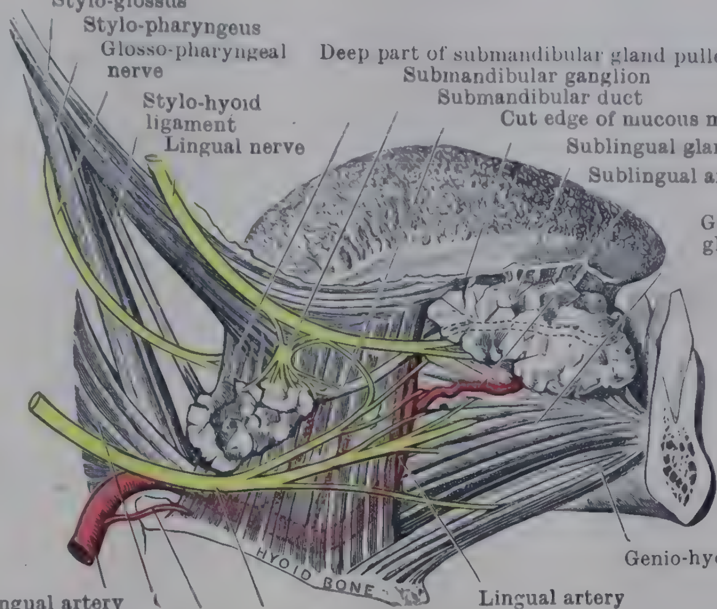

FIG. 900.—LINGUAL AND HYPOGLOSSAL NERVES IN THE SUBMANDIBULAR REGION.

The large **posterior trunk** extends a short way downwards medial to the lateral pterygoid muscle. After giving off, by two roots, the auriculo-temporal nerve, it ends by dividing into two—the lingual and the inferior dental nerves.

The **auriculo-temporal nerve** is formed by the union of two roots which embrace the middle meningeal artery. The nerve passes backwards and laterally medial to the lateral pterygoid muscle and between the spheno-mandibular ligament and the neck of the mandible. After passing through the uppermost part of the parotid gland or its fascia, it is directed upwards to the temple over the zygoma, immediately behind the superficial temporal artery. It is finally distributed as a cutaneous nerve of the temple and scalp, and reaches almost to the vertex of the skull (Fig. 895).

The auriculo-temporal nerve gives off the following branches: (1) A small branch to the mandibular joint. (2) Branches to the parotid gland. (3) A twig for the supply of the skin of the external auditory meatus and tympanic membrane. (4) Auricular branches to the upper half of the auricle on its lateral aspect. (5) Terminal temporal branches to the skin and fascia of the temple and scalp.

It has the following **communications** with other nerves: (1) Important communications are effected by the roots of the nerve, which are separately joined by small branches from the otic ganglion; these convey secretory fibres (parasympathetic) from the glosso-

pharyngeal nerve and sympathetic fibres to the parotid gland. The otic ganglion is described on p. 1037 with the ninth nerve. (2) The parotid and temporal branches of the nerve are connected with branches of the facial nerve in the substance of the parotid gland.

The **lingual nerve** is the smaller of the two terminal branches of the posterior division of the mandibular trunk. It proceeds downwards in front of the inferior dental nerve, medial to the lateral pterygoid muscle, and then between the medial pterygoid and the mandible. After emerging from between the medial pterygoid muscle and the ramus of the mandible the nerve passes beneath those fibres of the superior constrictor which are attached to the mandible and the pterygo-mandibular ligament. It now lies beneath the mucous membrane of the mouth; and, about half an inch below and behind the last molar, it may be palpated as it lies on the bone near the origin of the most posterior fibres of the mylo-hyoid muscle (Fig. 500, p. 583). In this region it is separated from the tongue by the alveolo-lingual groove, but as it proceeds forwards it loops downwards and medially beneath the groove and below the submandibular duct and so comes to lie on the hyo-glossus muscle medial to the duct. It then sends numerous terminal branches upwards and forwards to the mucous membrane over the anterior two-thirds of the tongue.

Three nerves communicate with the lingual nerve in its course to the tongue: (1) The **chorda tympani branch** of the facial nerve joins it from behind at an acute angle medial to the lateral pterygoid muscle, and is incorporated with it in its distribution to the tongue. The chorda tympani (p. 1032) contains parasympathetic preganglionic fibres and also gustatory fibres from the anterior two-thirds of the tongue. (2) At a lower level it usually communicates with the inferior dental nerve. (3) The **hypoglossal nerve** forms larger or smaller loops of communication with the lingual nerve as they course forwards over the hyo-glossus muscle.

Besides supplying the aforesaid branches to the mucous membrane over the sides and dorsum of the tongue in its anterior two-thirds, the lingual nerve supplies the mucous membrane of the floor of the mouth including the lingual aspect of the lower gum and the mucosa overlying the sublingual gland. Branches also assist in the supply of the premolar and first molar teeth. It supplies an afferent root to the submandibular ganglion and also, by virtue of parasympathetic fibres derived entirely from the chorda tympani branch of the seventh nerve, it supplies the parasympathetic root of the ganglion. This ganglion is described on p. 1034, with the facial nerve.

The **inferior dental nerve** is larger than the lingual nerve. It passes from beneath the inferior border of the lateral pterygoid muscle to reach the interval between the ramus of the mandible and the spheno-mandibular ligament. It enters the mandibular canal through the mandibular foramen in company with the inferior dental artery, traverses the substance of the ramus and body of the mandible, distributing branches to the teeth in its course, and it terminates by dividing into a mental and an incisor branch.

Branches.—(1) The **mylo-hyoid nerve** is a small branch that arises just before the inferior dental nerve enters the mandibular foramen. It pierces the spheno-mandibular ligament and grooves the ramus as it descends into the submandibular region, where it lies on the inferior surface of the mylo-hyoid muscle, deep to the submandibular gland. It is distributed to the mylo-hyoid muscle and the anterior belly of the digastric muscle. (2) The **dental branches** arise from the nerve in the mandibular canal, and form fine plexuses from which filaments supply the teeth; the molars and premolars receive their supply from an alveolar plexus, the incisors from an incisor plexus and the canine from either (Starkie & Stewart, 1931). Usually the lingual and the buccal nerves also assist in the innervation of the premolar and first molar teeth (Stewart & Wilson, 1928). (3) The **mental nerve** is a trunk of considerable size which arises from the inferior dental in the mandibular canal. It emerges from the mandible through the mental foramen, and is distributed by many branches to the skin of the chin and lower lip. It communicates, under cover of the facial muscles, with the mandibular branch of the facial nerve (Fig. 902). (4) The **incisor**

branch is the terminal part of the inferior dental nerve remaining after the origin of the mental branch. It forms a fine incisor plexus and supplies the canine tooth and the incisor teeth ; a few fibres may cross the median plane and take part in the innervation of the medial incisor of the opposite side.

Summary.—The trigeminal is the largest and most complex of the cranial nerves. (1) It is the chief afferent nerve for the face, the anterior half of the scalp, the orbit and eyeball, the nose and nasal cavity and paranasal sinuses, the lips, teeth, mouth, and anterior two-thirds of the tongue. (2) Its efferent fibres supply the muscles of mastication, the mylo-hyoid and anterior belly of the digastric, and the tensor tympani and tensor palati muscles. (3) It gives branches to the mandibular joint and the dura mater.

In its distribution to the skin of the face the branches of the fifth nerve present certain noteworthy features : (1) While the branches to the skin reach the surface at many points and in diverse ways, the three main divisions are severally, by their branches, responsible for the supply of three clearly demarcated cutaneous areas (Fig. 895, p. 1023). Moreover, since in embryonic life the general distribution of the nerve is outlined by the outgrowth from the trigeminal ganglion of the three main divisions (ophthalmic, maxillary, and mandibular) into the fronto-nasal, maxillary, and mandibular processes respectively, each nerve-trunk supplies, broadly speaking, the deeper structures of the face lying opposite its own area of cutaneous distribution. (2) In the face there are numerous communications with the seventh nerves, possibly for the distribution of proprioceptive fibres to the muscles of expression (p. 426). (3) The cutaneous branches of the fifth nerve receive sudomotor (sympathetic) fibres from the external carotid plexus for distribution to the sweat-glands (Wilson, 1936).

Though the **ganglia associated with the fifth nerve**, namely, the ciliary, spheno-palatine, otic, and submandibular, are frequently mentioned in their relations to its branches, it should be realized that functionally that nerve has less to do with them than any of the other cranial nerves with which they are connected, for the ganglia properly belong to the parasympathetic system. In structure they largely consist of the stellate or multipolar neurons characteristic of the autonomic system elsewhere ; and developmentally they are formed by cell-bodies which have migrated from the trigeminal ganglion along the branches of the trigeminal nerve—an origin paralleled by that of the ganglia of the sympathetic trunks. Moreover, the fibres they receive from other nerves (the ciliary ganglion from the oculomotor, the submandibular and spheno-palatine ganglia from the facial, and the otic ganglion from the glosso-pharyngeal) may be likened to the splanchnic efferent fibres received by the ganglia of the sympathetic trunk through the white rami communicantes of the spinal nerves. Their development is described together with that of the autonomic system on p. 1146.

Each of the ganglia contains three varieties of fibres: (1) afferent ; (2) parasympathetic efferent, derived from one of the cranial nerves ; and (3) sympathetic, which are derived from the superior cervical ganglion. Many of the so-called roots and branches are mixed, though they are generally named according to the predominating kind of fibres they contain. Lastly, it is to be noted that *only the parasympathetic paths have a cell-station in the ganglia* ; all the other fibres pass uninterruptedly through them. Each of these ganglia is described with the cranial nerve which conveys its preganglionic parasympathetic fibres to it.

ABDUCENT NERVE

The **sixth** or **abducent nerve** supplies only the lateral rectus muscle of the eyeball. It issues from the brain at the inferior border of the pons, just above the pyramid of the medulla oblongata (for the deep origin, see p. 931). It is directed forwards and upwards and usually lies behind the anterior inferior cerebellar artery but may be in front of it. It pierces the dura mater in the posterior fossa of the skull and crosses dorsal to, or may run through, the inferior petrosal sinus to reach the apex of the petrous temporal bone. Here it lies under the petro-clinoid ligament and presents a bend as it runs forward into the middle cranial fossa to enter the cavernous sinus (Fig. 888, p. 1015). In the sinus it is placed close to the lateral side of the internal carotid artery. After traversing the sinus it enters the orbit through the superior orbital fissure below the oculomotor and naso-ciliary nerves. At this point it lies within the tendinous ring from which the four rectus muscles arise. (Fig. 896, p. 1024). In the cavity of the orbit it supplies the lateral rectus muscle on its deep (ocular) surface.

Communications.—In the cavernous sinus the sixth nerve receives two communicating filaments : (1) from the carotid plexus of the sympathetic, and (2) from the ophthalmic division of the trigeminal nerve. Such communications are probably temporary and do not involve the permanent transfer of fibres from one nerve to another (Sunderland & Hughes, 1946).

FACIAL NERVE

The **seventh** or **facial nerve** is a mixed nerve and consists of two parts. The larger part or **motor root** supplies all the superficial muscles of the scalp, face, and neck (muscles of expression), and some of the deep ones. The smaller part is called the **sensory root**, but it contains not only afferent taste-fibres for the anterior two-thirds of the tongue but also efferent parasympathetic fibres connected with the spheno-palatine and submandibular ganglia for the supply of the lacrimal and some of the salivary glands. The ganglion of the facial nerve (see p. 1031) is the cell-station for the afferent fibres. The **motor root** emerges from the brain at the inferior border of the pons, medial to the auditory nerve (for the deep origin, see p. 930). Between it and the auditory nerve is the much smaller **sensory root** (Fig. 885, p. 1012). The facial nerve enters the internal auditory meatus, passes through the facial canal in the petrous portion of the temporal bone, emerges at the base of the skull by the stylo-mastoid foramen, and passes forwards through

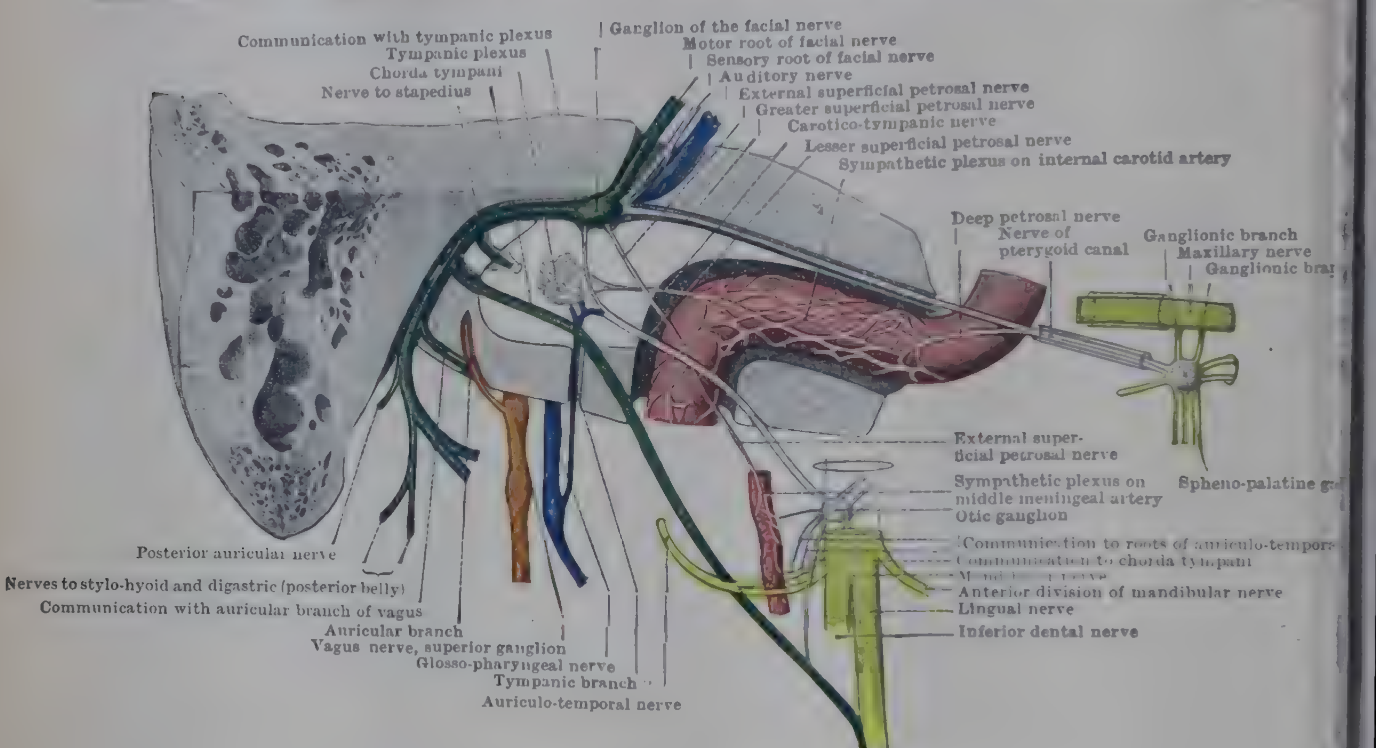

FIG. 901.—CONNEXIONS OF FACIAL NERVE IN THE TEMPORAL BONE.

the parotid gland to supply the muscles of the face. *In the internal auditory meatus* the nerve is placed above the auditory nerve, the sensory root intervening, and all three are surrounded by sheaths of the dura, arachnoid, and pia. *In the facial canal* the nerve first runs laterally between the cochlea and the bony vestibule to the hiatus in the canal for the greater superficial petrosal nerve, then abruptly backwards in the upper part of the medial wall of the tympanum above the fenestra vestibuli, and finally downwards behind the tympanum, lying in the bony septum that separates the middle ear from the tympanic antrum and mastoid air-cells. On emerging from the stylo-mastoid foramen the nerve lies under cover of the mastoid process and is therefore more exposed in the child, in whom this process is incompletely developed. The nerve then runs laterally and forwards between the styloid process and the digastric muscle (Fig. 1079, p. 1265) to enter the parotid gland on its postero-medial surface. *In the parotid gland* (see p. 582) it crosses the external carotid artery and the posterior facial vein superficially and breaks up into its terminal branches, which emerge through the ends and anterior border of the gland. In the face the branches radiate to the various facial muscles, which they supply on their deep surfaces (Fig. 902).

Branches and Communications.—(i) *In the internal auditory meatus* the sensory root lies between the motor root and the auditory nerve and sends communicating

branches to both of them. The branch to the auditory nerve probably separates from it again to join the ganglion of the facial nerve (Fig. 904).

(ii) *In the facial canal* the **ganglion of the facial nerve** is formed at the point where the nerve bends backwards at the 'genu'. It is an oval swelling on the nerve, from which three small branches arise. (1) The **greater superficial petrosal nerve** passes forwards through the hiatus in the canal for the facial nerve to the middle fossa of the skull and runs in the dura mater to the foramen lacerum, where it is

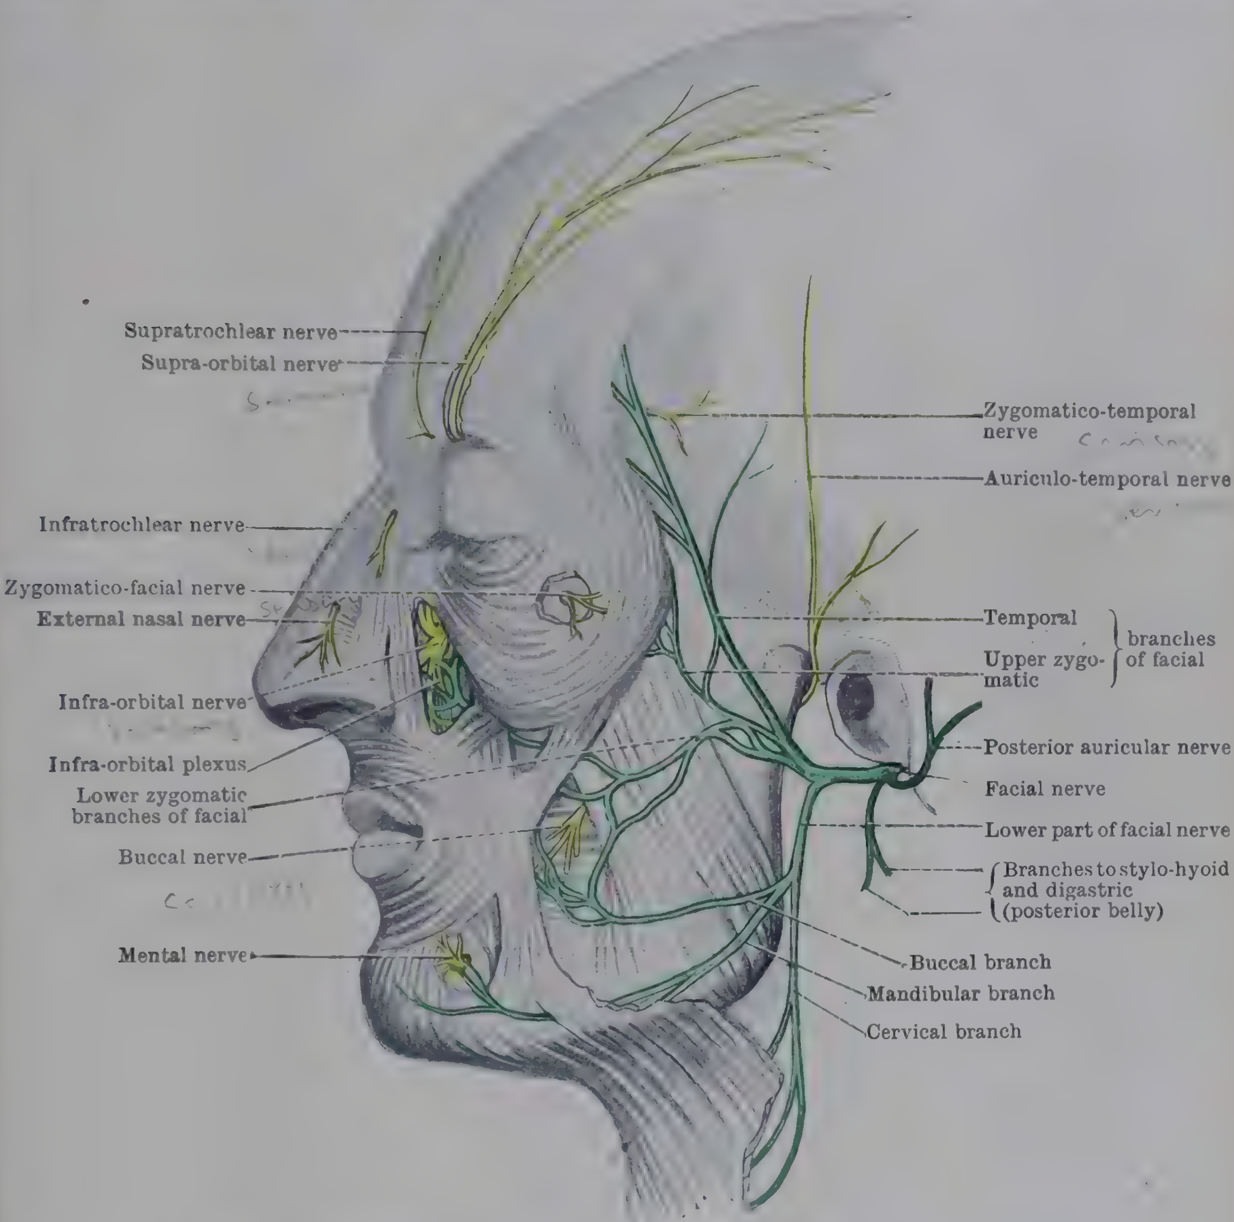

FIG. 902.—DISTRIBUTION OF TRIGEMINAL AND FACIAL NERVES ON THE FACE.

joined by the deep petrosal nerve—a sympathetic branch derived from the plexus on the internal carotid artery. The combined nerve—**the nerve of the pterygoid canal**—then runs forwards in the pterygoid canal of the sphenoid bone to reach the spheno-palatine ganglion (Fig. 903). (2) A minute filament which pierces the temporal bone and joins the much larger tympanic branch of the glosso-pharyngeal to form the **lesser superficial petrosal nerve**, which lies in the dura mater of the middle cranial fossa lateral to the greater superficial petrosal nerve. The lesser superficial petrosal nerve finally leaves the middle fossa by a small foramen medial to the foramen ovale and joins the otic ganglion. It is to be regarded essentially as a parasympathetic branch of the ninth nerve, and it will be discussed in connexion with the otic ganglion (p. 1037). (3) The **external superficial petrosal nerve** is a minute inconstant branch which joins the sympathetic plexus on the middle meningeal artery.

From the facial nerve in the descending part of its canal behind the tympanum, three branches arise: (1) The small **nerve to the stapedius** passes

forwards to that muscle. (2) A fine communicating branch which arises from the facial just before it leaves its canal and joins the auricular branch of the vagus. (3) The **chorda tympani** (containing taste and parasympathetic fibres) arises between these two smaller branches, enters the tympanic cavity through a *posterior canaliculus*, passes across the membrana tympani and the handle of the malleus, leaves the cavity by an *anterior canaliculus* and reaches the infratemporal fossa through the *petro-tympanic fissure*; medial to the lateral pterygoid muscle, after receiving a fine communication from the otic ganglion, it becomes incorporated with the lingual branch of the mandibular nerve, and in its further course is intimately associated with that nerve; it supplies the parasympathetic root to the submandibular ganglion, and is finally distributed to the side and dorsum of the tongue in its anterior two-thirds (excluding the vallate papillæ); it largely consists of afferent (taste) fibres derived from the ganglion of the facial nerve, but also contains some secreto-motor parasympathetic fibres which enter the submandibular ganglion and undergo synapse with postganglionic neurons which then supply the submandibular, sublingual, and lingual glands (Fig. 903).

(iii) *In the neck*, before it enters the parotid gland, the facial nerve gives off three muscular branches: (1) and (2) small branches, frequently arising together, supply the **stylo-hyoid** and the posterior belly of the **digastric**; the latter nerve sometimes communicates with the glosso-pharyngeal. (3) The **posterior auricular nerve** bends backwards and upwards over the anterior border of the mastoid process along with the posterior auricular artery. It divides into two branches—an *auricular branch* for the posterior auricular muscle and the intrinsic muscles of the auricle, and an *occipital branch* for the occipital belly of the epicranius muscle. The posterior auricular nerve, in its course, communicates with the great auricular, lesser occipital, and with the auricular branch of the vagus nerve.

(iv) *In the parotid gland* the facial nerve spreads out in an irregular series of branches which communicate in the substance of the gland with branches of the great auricular and auriculo-temporal nerves.

1. The **temporal branches** are of large size, and, sweeping out of the parotid gland over the zygomatic arch, are distributed to the orbicularis oculi, frontal belly of occipito-frontalis, auriculares anterior and superior. The temporal branches communicate in their course with the auriculo-temporal, zygomatico-temporal, lacrimal, and supra-orbital branches of the trigeminal nerve.

2. The **zygomatic branches** are in two sets. The **upper** are small, and sometimes are inseparable from the temporal or lower zygomatic branches. Extending forwards across the zygomatic bone, they supply the orbicularis oculi and zygomatic muscles, and communicate with the zygomatico-facial branch of the maxillary nerve.

The **lower** are of considerable size. Passing forwards over the masseter muscle, in company with the parotid duct, they supply the orbicularis oculi, the zygomaticus major, buccinator, and the muscles of the nose and upper lip. The **infra-orbital plexus** is formed by the union of these nerves with the infra-orbital branch of the maxillary nerve below the lower eyelid. Smaller communications occur with the infratrochlear and external nasal branches of the naso-ciliary nerve on the side of the nose.

3. The **buccal branch** (or branches) extends forwards to the angle of the mouth to supply the muscles converging on the mouth, including the buccinator. It communicates with the buccal branch of the mandibular nerve in front of the masseter muscle.

4. The **mandibular branch** passes along the mandible to the interval between the lower lip and chin, and supplies the depressor anguli oris, depressor labii inferioris, and orbicularis oris. It communicates with the mental branch of the inferior dental nerve.

5. The **cervical branch** emerges from the parotid gland near its lower end, and sweeps forwards below the angle of the mandible to the front of the neck. It runs deep to the platysma, supplying it and forming loops of communication with the anterior cutaneous nerve of the neck.

No mention has been made of cutaneous afferent fibres in the seventh nerve, but clinical evidence is suggestive of the fact that some sensory fibres—with their cell-bodies in the facial ganglion—reach the skin in the mastoid region and the external auditory meatus.

When inflammation attacks the ganglion, a herpetiform eruption (similar to "shingles", see p. 1053) may affect this area. It is not suggested, however, that the cutaneous area mentioned is exclusively supplied by the seventh nerve. Some consider that proprioceptive afferent fibres from the facial musculature travel in the seventh nerve, but it is possible, and perhaps more probable, that they do so through the fifth.

Though the facial nerve is commonly described as above, as a mixed nerve, the sensory root can be considered, on the basis of its origin and distribution, as well as on the really mixed nature of its fibres, as a separate nerve, the **glosso-palatine**. Under this term are included the sensory root of the facial, the ganglion of the facial nerve, chorda tympani, and part of the greater superficial petrosal nerve. Its central connexions and peripheral distribution resemble those of the glosso-pharyngeal nerve, and suggest that it is an aberrant part of the latter.

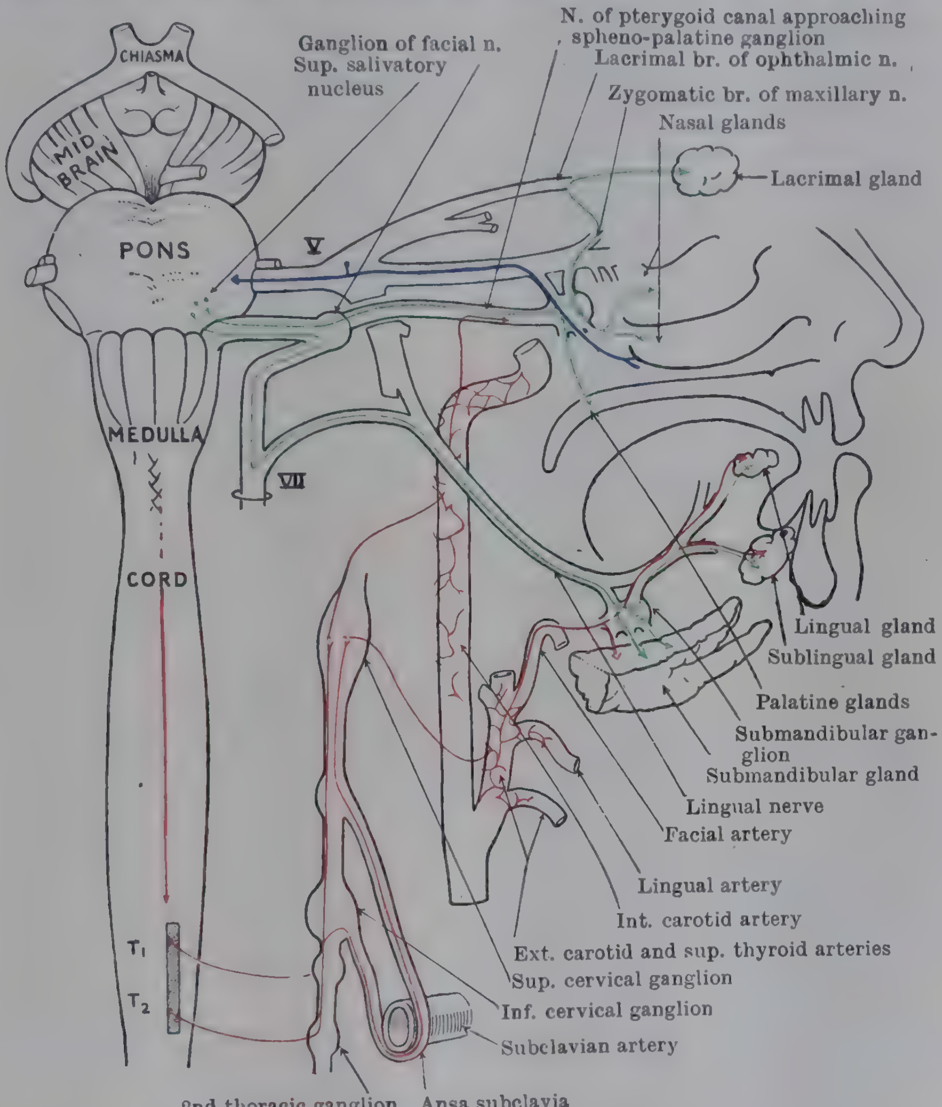

Fig. 903.—Diagram of Connexions of Spheno-Palatine and Submandibular Ganglia with Distribution of Parasympathetic Components of Seventh Cranial Nerve.

Spheno-Palatine Ganglion.—This ganglion is a component of the cranial parasympathetic system. It is situated deeply in the upper part of the pterygo-palatine fossa close to the spheno-palatine foramen and is a small reddish body lying in close relationship with the ganglionic branches of the maxillary nerve. Various groups of nerve-fibres have an association with this ganglion :—(*a*) The *parasympathetic root*, composed of preganglionic fibres from the seventh nerve, reaches it by way of the greater superficial petrosal nerve and the nerve of the pterygoid canal. (*b*) The *sympathetic root* contains fibres derived from the internal carotid plexus which reach the ganglion by way of the nerve of the pterygoid canal, but are already postganglionic fibres of the superior cervical sympathetic ganglion and do not therefore have any synaptic relation with the cells of the spheno-palatine ganglion. (*c*) Fibres derived from the maxillary nerve reach the ganglion in the ganglionic branches of that nerve and constitute an *afferent root.* These fibres likewise are merely passing by or through the ganglion

and have no relationship with it other than one of contiguity. They leave the ganglion in the form of numerous branches which pass upwards to the orbit, downwards to the palate, and medially to the nasal cavity and thus serve as pathways along which the postganglionic neurons may reach the lacrimal, palatine, and nasal glands (a detailed account of these branches of the fifth nerve is given on pp. 1021-1023). Thus, the lacrimal gland receives its secreto-motor supply by fibres which accompany the zygomatic nerve and later the lacrimal nerve, and possibly by some fibres that run with the orbital branches of the maxillary nerve. The glands of the palate and the nasal cavity are supplied by fibres which accompany palatine, nasal, and naso-palatine branches (Fig. 903).

Some afferent fibres—presumably gustatory—proceed centrally through the palatine nerves, the spheno-palatine ganglion and the greater superficial petrosal nerve to reach the facial ganglion where their cell-bodies are situated.

Submandibular Ganglion (see note on p. 1029).—This ganglion is a small reddish structure placed on the hyo-glossus muscle, between the lingual nerve and the duct of the submandibular gland (Fig. 900). It is suspended from the lingual nerve by two **communicating branches**, consisting for the most part of fibres of the lingual and chorda tympani nerves which at that point separate from the lingual nerve and pass to the ganglion. The **roots** of the submandibular ganglion are: (1) an *afferent root*, from the lingual nerve; (2) a *parasympathetic root*, from the chorda tympani; and (3) a *sympathetic root*, from the sympathetic plexus on the facial artery. Only parasympathetic fibres are relayed in the ganglion (Fig. 903).

The **glandular branches from the ganglion** are distributed to the submandibular gland and duct and, by fibres which become reunited with the trunk of the lingual nerve, to the sublingual gland and the glands of the anterior part of the tongue; they are secreto-motor and vaso-motor to the glands. Small detached portions of the submandibular ganglion are not uncommonly found along the course of its branches or buried in the glands (*e.g.*, the ganglion described by Langley, 1921).

AUDITORY NERVE

The **eighth** or **auditory nerve** is entirely sensory and consists of two functionally quite different parts—the *vestibular nerve* concerned with equilibra-

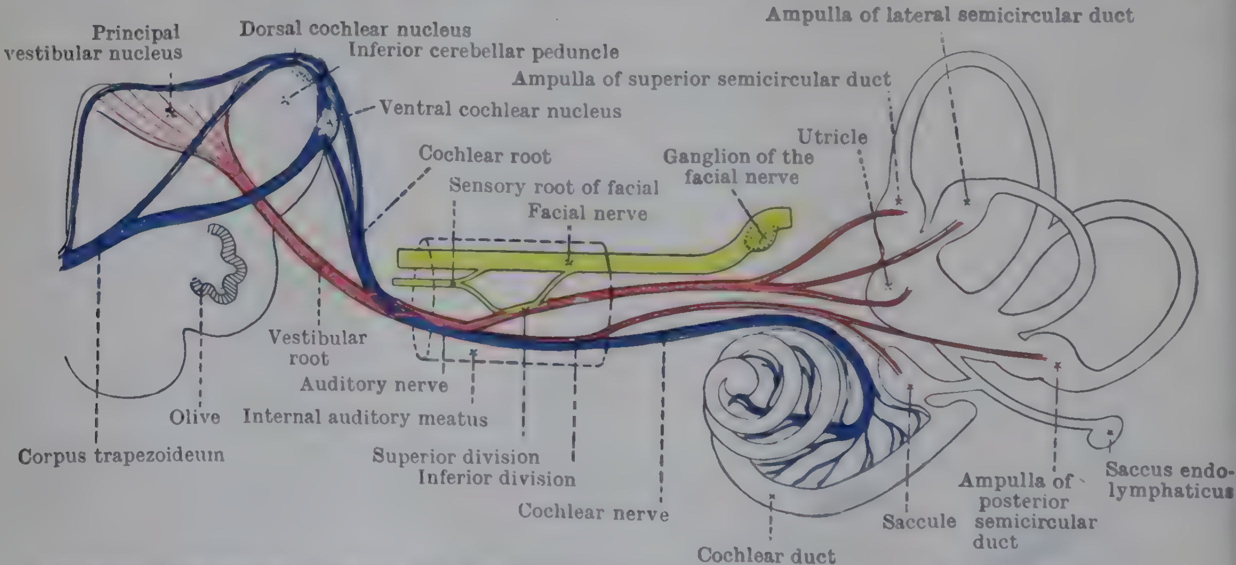

FIG. 904.—SCHEME OF ORIGIN AND DISTRIBUTION OF AUDITORY NERVE (cf. Fig. 1027, p. 1201).

The bundle of fibres (blue) shown coursing across the floor of the fourth ventricle are not auditory; they are the striæ medullares (p. 887) and are probably aberrant ponto-cerebellar fibres.

tion, and the *cochlear nerve*, the true nerve of hearing; they differ also in their peripheral endings and central connexions. (See also p. 1200.)

The combined trunk is attached to the brain by two roots, medial and lateral. The **medial, vestibular root** emerges between the olive and the inferior cerebellar peduncle. The **lateral, cochlear root**, is attached to the brain-stem on the lateral side

of the inferior cerebellar peduncle where two accumulations of nerve-cells give rise to the dorsal and ventral cochlear nuclei. (For deep connexions, see p. 903.) The two roots unite with each other to form the trunk of the auditory nerve, which is attached to the brain on the lateral side of the roots of the facial nerve, at the lower border of the pons (Fig. 813, p. 925).

The nerve passes laterally through the internal auditory meatus, lying below the roots of the facial nerve (Fig. 901). In the meatus the trunk separates into two divisions, an upper consisting of vestibular fibres only, and a lower which consists mainly of cochlear fibres but contains also some vestibular fibres. The divisions subdivide, and their branches pierce the fundus of the internal auditory meatus to supply the several parts of the labyrinth (Fig. 1027, p. 1201).

The **superior division** usually receives fibres in the meatus from the sensory root of the facial nerve, and gives off a communicating branch to the ganglion of the facial nerve. It then separates into three terminal branches which pierce the lamina cribrosa. (1) The **utricular nerve** supplies the macula of the **utricle.** (2) and (3) The **superior** and **lateral ampullary nerves** supply the ampullæ of the **superior** and **lateral semicircular ducts.**

The **inferior division** gives off (1) a **saccular nerve** to the macula of the **saccule** which pierces the inferior vestibular area, (2) an **inferior ampullary nerve** to the ampulla of the **posterior semicircular duct** which pierces the foramen singulare, and (3) is continued as the **cochlear nerve**, which is distributed through the modiolus and osseous spiral lamina to the spiral organ in the cochlea.

Both the vestibular and cochlear nerves contain among their fibres collections of bipolar nerve-cells, forming in each nerve a distinct ganglion —the **vestibular ganglion** on the vestibular trunk at the bottom of the internal auditory meatus, and the **spiral ganglion** on the cochlear trunk within the modiolus. The cells of these ganglia give origin to the fibres of the vestibular and cochlear parts of the nerve respectively.

GLOSSO-PHARYNGEAL NERVE

The **ninth** or **glosso-pharyngeal nerve** is a mixed nerve, consisting of a large afferent part which supplies the pharynx and tongue and also the carotid sinus and body, and a smaller efferent part which supplies the stylo-pharyngeus muscle (branchial efferent fibres) and also sends preganglionic parasympathetic fibres to the otic ganglion.

It is attached to the brain by five or six fine rootlets which are attached to the side of the medulla oblongata, close to the facial nerve above, and in series with the rootlets of the vagus nerve below (Fig. 813, p. 925; for the deep connexions, see p. 927). The rootlets combine to form a nerve which

passes through the jugular foramen along with the vagus and accessory nerves but enveloped in a separate sheath of dura mater (Fig. 889, p. 980). In the neck, the nerve first descends medial to the styloid process and between the internal carotid artery and the internal jugular vein; it then curves forwards to the side of the pharynx above the level of the hyoid bone. As it runs forwards it curves round the posterior border of the stylo-pharyngeus muscle and passes superficial to that muscle and usually deep to the stylo-hyoid ligament, to the posterior border of the hyo-glossus muscle, and then onwards deep to the hyo-glossus. The terminal branches are distributed to the region of the oro-pharyngeal isthmus, the tonsil, and the pharyngeal part of the dorsum of the tongue (Fig. 905).

The **branches** of the nerve may be classified in three series according to their origin—(i) in the jugular foramen, (ii) in the neck, (iii) in relation to the tongue.

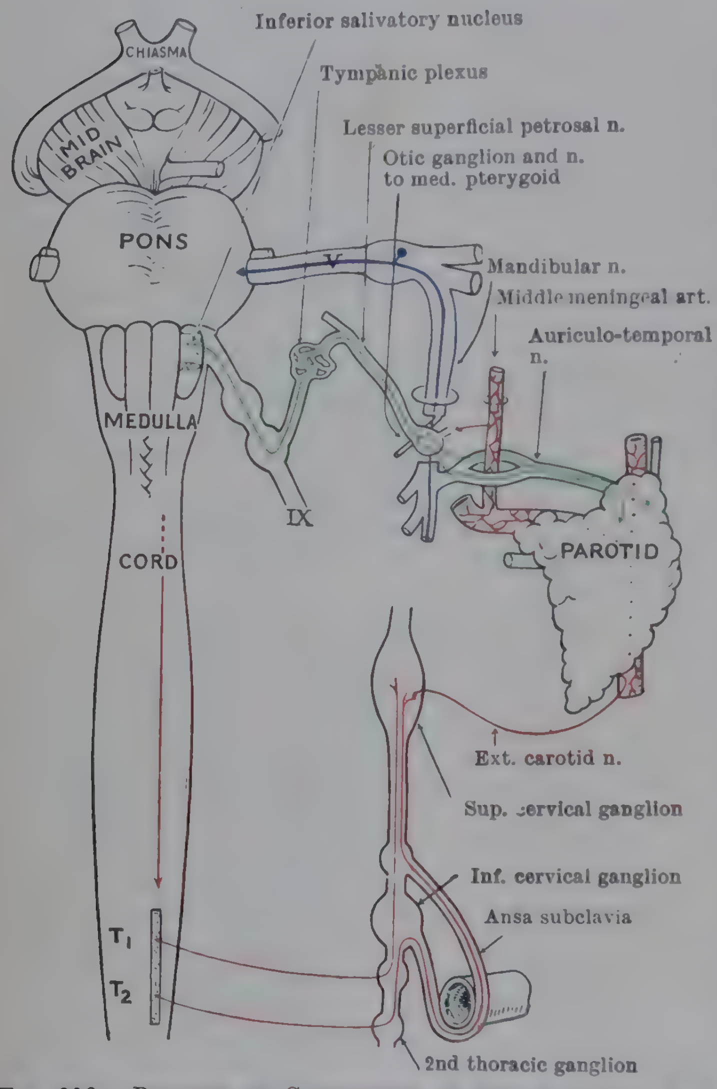

FIG. 906.—DIAGRAM OF CONNEXIONS OF OTIC GANGLION WITH DISTRIBUTION OF PARASYMPATHETIC COMPONENTS OF NINTH CRANIAL NERVE.

In the jugular foramen there are two enlargements on the trunk of the nerve — the superior and inferior ganglia—which contain the cell-bodies of the afferent fibres. The **superior ganglion** is small, and does not implicate the whole width of the nerve; it may be fused with the inferior ganglion, or even be absent altogether. No branches arise from it.

The **inferior ganglion** is distinct and constant. It is placed on the nerve at the lower part of its course through the jugular foramen.

Branches and Communications of Inferior Ganglion.—The **tympanic branch** is the most important offset from this ganglion. It passes through a small canal in the bridge of bone between the jugular foramen and the carotid canal to reach the cavity of the tympanum, where it breaks up into branches to help to form the **tympanic plexus**, in which they are associated with the superior and inferior carotico-tympanic branches from the internal carotid plexus of the sympathetic, and a twig from the ganglion of the facial nerve. The plexus lies on the promontory of the medial wall of the middle ear, and supplies the mucous lining of the tympanum, mastoid air-cells, and pharyngo-tympanic tube (Fig. 901). Some fibres of the tympanic branch of the glosso-pharyngeal nerve become reunited and, in the substance of the temporal bone, they join with a small branch from the ganglion of the facial nerve to form the **lesser superficial petrosal nerve**, which emerges from the temporal bone and pierces the base of the skull to join the otic ganglion (Fig. 906).

Besides its communications by the tympanic branch, the inferior ganglion of the glosso-pharyngeal nerve communicates with three other nerves: (1) with the superior cervical ganglion of the sympathetic; (2) with the auricular branch and sometimes with the superior ganglion of the vagus; and (3) sometimes with the facial nerve.

In the neck the glosso-pharyngeal nerve gives off the following branches:—(1) As it crosses over the **stylo-pharyngeus muscle** it supplies the nerve to that muscle, some fibres of which pierce the muscle to reach the mucous membrane of the pharynx. (2) The **pharyngeal branches** supply the mucous membrane of the pharynx either directly after piercing the superior constrictor muscle, or indirectly after joining with the pharyngeal offsets from the vagus and the superior cervical ganglion of the sympathetic to form the **pharyngeal plexus** (Fig. 905). (3) The *ramus caroticus* consists of afferent fibres which innervate the carotid sinus and body (Fig. 689, p. 808). It runs downwards in front of the internal carotid artery and in its course has communications with vagal and sympathetic branches which lie rather behind the artery (Sheehan, Mulholland & Shafiroff, 1941).

The **terminal branches** of the nerve supply the mucous membrane of the tongue and adjacent parts. A **tonsillar branch** forms a plexus to supply the mucous membrane covering the tonsil, the adjacent part of the soft palate, and the palatine arches. The **lingual branches** contain taste-fibres, as well as ordinary sensory fibres, for the posterior third of the tongue including the circumvallate papillæ.

Otic Ganglion.—The otic ganglion is a small body situated medial to the mandibular nerve just below the foramen ovale at the posterior border of the medial pterygoid muscle. It is a component of the cranial parasympathetic system. Various groups of fibres come into relationship with it and are generally described as the roots of the ganglion:—(1) A *parasympathetic root* composed of preganglionic fibres derived from the ninth nerve through its tympanic branch, the tympanic plexus, and the lesser superficial petrosal nerve. Some parasympathetic fibres from the 'genu' of the facial nerve join the tympanic plexus and proceed to the otic ganglion in the lesser superficial petrosal nerve. The parasympathetic root—composed predominantly of fibres of the ninth nerve—contains the only fibres which form synapses with the cells of the otic ganglion. (2) A *sympathetic root* composed of fibres derived from the plexus on the middle meningeal artery. These are already postganglionic fibres derived from the cervical sympathetic chain and have no synaptic association with the cells of the ganglion. (3) A so-called *efferent root* composed of motor fibres of the mandibular nerve on their way to supply the medial pterygoid muscle and the tensor palati and tensor tympani muscles. It must be clearly understood that these mandibular fibres have merely a relationship of contiguity with the ganglion.

Passing away from the ganglion are its postganglionic parasympathetic fibres as well as the sympathetic fibres which have traversed the ganglion. The most important group consists of those fibres which join the auriculo-temporal nerve (Fig. 906) to be carried in it to the parotid gland as its secreto-motor and vasomotor supply. Other small twigs from the ganglion communicate with the nerve of the pterygoid canal and the chorda tympani nerve.

VAGUS NERVE

The **tenth** or **vagus nerve** is a mixed nerve. It contains a large number of parasympathetic fibres (afferent as well as efferent), and is the most widely distributed of the cranial nerves, for it passes through the neck and thorax into the abdomen. It supplies afferent fibres chiefly to the pharynx, œsophagus, stomach, larynx, trachea, and lungs; efferent fibres to the plain musculature of the same series of organs; and special fibres to the heart and abdominal viscera. The cranial portion of the eleventh cranial nerve contributes efferent fibres to the vagus for the innervation of most of the voluntary muscles of the larynx and pharynx. Each nerve is connected with the seventh, ninth, eleventh, and twelfth cranial nerves, with the first and second cervical spinal nerves, and with the sympathetic system.

It is attached by numerous rootlets to the side of the medulla oblongata, in series with the glosso-pharyngeal nerve above and the accessory nerve below it (for the deep connexions, see p. 927). The rootlets unite to form a single trunk which emerges into the neck through the jugular foramen.

In the jugular foramen the nerve occupies the same sheath of dura mater as the accessory nerve; it is placed behind the glosso-pharyngeal nerve and a small ganglion—the **superior ganglion**—is developed on it.

In the neck the vagus nerve pursues a vertical course in front of the vertebral column. It occupies the carotid sheath, lying between and behind the internal and common carotid arteries and the internal jugular vein. It enters the thorax behind the large veins: *on the right side*, after crossing in front of the first part of the subclavian artery; *on the left side*, in the interval between the left common carotid and subclavian arteries. In the upper part of the neck, immediately below the jugular foramen, a second and larger ganglion—the **inferior ganglion**—is developed on the trunk of the nerve. Both ganglia give origin to afferent fibres.

In the thorax the nerves pass through the superior and posterior mediastina, and their relations are different on the two sides. (*a*) *In the superior mediastinum* the *right nerve* continues its course alongside the trachea, and behind the right innominate vein and superior vena cava, to the posterior surface of the root of the lung. The *left nerve* courses downwards between the left common carotid and subclavian arteries, and behind the left innominate vein and the phrenic nerve. It passes across the left side of the aortic arch and then proceeds to the posterior surface of the root of the left lung. (*b*) *In the posterior mediastinum* the vagi nerves are concerned in the formation of two great plexuses—the pulmonary and the œsophageal. Behind the root of the lung each vagus nerve breaks up to form the **posterior pulmonary plexus**, from the lower part of which two nerves emerge. Those two nerves on the right side pass anterior to the vena azygos; on the left side anterior to the descending thoracic aorta. Both series reach the œsophagus and divide into small communicating branches which form the **œsophageal plexus**, which lies mainly *on* the œsophagus, though some branches may descend within its wall. At the œsophageal opening of the diaphragm two single nerves (the anterior and posterior gastric nerves) become separated from the plexus, and, having entered the abdomen, they terminate by supplying the stomach and other abdominal organs. Fibres from the vagi of both sides enter into the formation of each nerve which extends from the œsophageal plexus into the abdomen (M'Crea, 1924; Jackson, 1949).

The **communications** and **branches** of the vagus nerve may be described as (i) ganglionic, (ii) cervical, (iii) thoracic, and (iv) abdominal (Fig. 907).

Superior Ganglion.—The **superior ganglion** of the vagus is small and spherical. It lies in the jugular foramen, and gives off two branches—meningeal and auricular.

The **meningeal branch** passes backwards to supply the dura mater of the posterior fossa of the skull.

The **auricular branch** enters the mastoid canaliculus through the lateral wall of the jugular fossa, and, escaping from it through the tympano-mastoid fissure, it is distributed to the back of the auricle, the floor of the external auditory meatus, and the lower part of the tympanic membrane. It receives, near its origin, a twig from the tympanic branch of the glosso-pharyngeal nerve, and, as it traverses the temporal bone, usually communicates with the facial nerve by a branch which arises from that nerve in its canal; it communicates superficially with the posterior auricular nerve.

Communications.—Besides supplying the meningeal and auricular branches, this ganglion receives communications from: (1) the superior cervical ganglion of the sympathetic; (2) the accessory nerve; and (3) (sometimes) the inferior ganglion of the glosso-pharyngeal nerve.

Inferior Ganglion.—The **inferior ganglion** of the vagus, placed immediately below the preceding, is large and fusiform. Like the superior ganglion, it has two branches—the pharyngeal and superior laryngeal nerves.

The **pharyngeal branch** (often double) receives its efferent fibres (through the ganglion) from the accessory nerve. It passes obliquely downwards and medially to the pharynx between the internal and external carotid arteries, and combines with the pharyngeal branches from the glosso-pharyngeal and superior cervical ganglion of the sympathetic to form the **pharyngeal plexus**, which lies on the wall

of the pharynx at the level of the middle constrictor (Fig. 905). From this plexus the muscles of the pharynx and soft palate (except the stylo-pharyngeus and tensor palati) are supplied. The **lingual branch** is a minute nerve which separates itself from the plexus and joins the hypoglossal nerve in the anterior triangle of the neck.

The **superior laryngeal nerve** passes obliquely downwards and medially, medial to the external and internal carotid arteries, towards the thyroid cartilage. It is joined by twigs from the sympathetic and the pharyngeal plexus, and is said to give a filament to the internal carotid artery. It ends by dividing in its course into two unequal parts—a larger internal and a smaller external laryngeal branch.

The **internal laryngeal nerve** passes medially into the pharynx. It pierces the thyro-hyoid membrane, in company with the corresponding branch of the superior laryngeal artery under cover of the thyro-hyoid muscle, and divides into three branches. These supply the mucous membrane of the larynx, reaching upwards to the epiglottis and the posterior part of the dorsum of the tongue. The lowest branch forms communications on the medial side of the lamina of the thyroid cartilage with the branches of the recurrent laryngeal nerve.

The **external laryngeal nerve** passes downwards deep to the infrahyoid muscles and upon the inferior constrictor muscle of the pharynx. It supplies branches to that muscle, and ends in the **crico-thyroid** muscle.

Communications.—Besides supplying the pharyngeal and laryngeal nerves, the ganglion has the following communications with other nerves: (1) with the superior cervical ganglion of the sympathetic; (2) with the hypoglossal; (3) with the loop between the first and second cervical nerves; and (4) with the accessory nerve, which applies itself to the ganglion, and thereby supplies to the vagus nerve the efferent fibres for the muscles of the larynx, except the crico-thyroid.

Beevor & Horsley (1888), on the basis of a series of experiments on monkeys, came to the conclusion: (1) that the glosso-pharyngeal nerve supplies the stylo-pharyngeus and the middle constrictor; (2) that the vagus supplies no muscles in the head and neck; (3) that the cranial portion of the accessory nerve supplies the levator palati and the muscles of the pharynx and larynx.

Branches of Vagus in the Neck.—In the neck the vagus nerve supplies cardiac branches and (on the right side) the recurrent laryngeal nerve (Fig. 907).

The **cervical cardiac branches** are **upper** and **lower.** *On the right side* both cardiac branches pass downwards into the thorax behind the subclavian artery, and along the side of the trachea to the deep cardiac plexus. *On the left side* the two nerves separate on reaching the thorax. The *upper nerve* passes deeply alongside the trachea to join the deep cardiac plexus. The *lower nerve* accompanies the vagus nerve across the aortic arch, along with the cardiac branch of the superior cervical ganglion of the sympathetic, to end in the superficial cardiac plexus.

The **right recurrent laryngeal nerve** arises at the root of the neck as the vagus crosses in front of the first part of the subclavian artery. It hooks round the artery, and passes obliquely upwards and medially behind the subclavian and the common carotid, and either in front of or behind the inferior thyroid artery; it then ascends in the groove between the œsophagus and trachea, along the medial side of the corresponding lobe of the thyroid gland. It finally disappears under cover of the inferior border of the inferior constrictor muscle to end in **laryngeal branches** which supply all the intrinsic muscles of the larynx except the crico-thyroid.

In its course it gives off the following branches:—

(1) **Cardiac branches** arise as the nerve winds round the subclavian artery, and descend alongside the trachea to end in the deep cardiac plexus.

(2) **Communicating branches** to the inferior cervical ganglion of the sympathetic arise from the nerve behind the subclavian artery.

(3) **Muscular branches** supply the trachea, œsophagus, and the inferior constrictor of the pharynx.

(4) **Terminal branches** supply the muscles of the larynx (except the crico-thyroid)

and communicate medial to the lamina of the thyroid cartilage with branches of the internal laryngeal nerve (p. 696). Sensory fibres are supplied to the mucous membrane of the larynx below the level of the vocal folds.

Branches of Vagus in the Thorax.—In the thorax the vagi form the great pulmonary and œsophageal plexuses. The right nerve, in addition, furnishes cardiac branches; and the left nerve gives off the recurrent laryngeal nerve.

The **left recurrent laryngeal nerve** differs from the nerve of the right side mainly in its point of origin and in the early part of its course. It springs from the vagus as it crosses the aortic arch, and, after hooking below the arch, behind the *ligamentum arteriosum*, it passes upwards in the superior mediastinum to the neck, where its course and relations are similar to those of the nerve of the right side. The branches of the nerve are the same as those of the right nerve. The **cardiac branches** are larger; they arise below the aortic arch and pass to the deep cardiac plexus.

The **thoracic cardiac** branches on the right side are derived from the trunk of the vagus as it lies beside the trachea; on the left side they arise from its recurrent branch. All join the deep cardiac plexus.

Branches of Vagus in the Abdomen.—From the lower end of the œsophageal plexus two gastric nerves (each containing fibres from both vagi) pass on the walls of the gullet through the diaphragm into the abdomen. The **posterior gastric nerve** is distributed to the posterior surface of the stomach and sends communicating offsets to the cœliac, splenic, and renal plexuses of the autonomic system. The **anterior gastric nerve** applies itself to the anterior surface and lesser curvature of the stomach, to which it is distributed. It sends communicating offsets between the layers of the lesser omentum to the hepatic plexus, and fine filaments from these offsets pass in the omentum to the pylorus and first part of the duodenum.

Vagal fibres are thus distributed either directly to viscera (*e.g.*, the stomach from the gastric nerves) or indirectly through the great plexuses in the abdomen. All vagal fibres which enter the abdomen, although largely non-medullated, are to be regarded as preganglionic; they meet their postganglionic neurons in the intramural or terminal plexuses situated in the walls of the gut and other viscera (*e.g.*, myenteric and submucous plexuses of intestine, p. 625). The distribution in the abdomen extends as far as the descending colon, at which level the area of distribution of the sacral parasympathetic begins. The terminal branches of distribution are generally associated with sympathetic fibres and both sets commonly run alongside blood-vessels to the gut or other viscus supplied. Besides innervating the muscular walls of the hollow abdominal viscera, vagal fibres are also secreto-motor to the glands of the stomach and intestine.

Certain **asymmetrical features** of the two vagus nerves are explained by a reference to the process of development. The course of the recurrent laryngeal nerves is explained by the absence of neck in the early embryo, and by the primitive aortic arches between which they passed, having occupied a higher position before the heart descended into the thorax, when it dragged these branches of the nerves down with it. The corresponding arches (the fourth pair), beneath which they originally passed, develop into the subclavian artery on the right side, the aorta on the left (see Fig. 1133, p. 1373). Variations in the pattern of arterial development may impose corresponding alterations in the course of the recurrent nerve.

Thoracic Plexuses

Of the plexuses formed by the vagus nerves in the thorax—cardiac, pulmonary, and œsophageal—the **cardiac plexuses** are described under the autonomic system, on p. 1138. The fibres of the vagus which take part in the formation of thoracic and abdominal plexuses belong to the parasympathetic system.

Pulmonary Plexuses.—As already stated, the vagus nerve on each side, on reaching the back of the root of the lung, breaks up into numerous plexiform branches for the formation of the posterior pulmonary plexus. From each nerve a few fibres pass to the front of the root of the lung, above its upper border, to form the much smaller anterior pulmonary plexus. These plexuses communicate freely with each other, fibres connect the plexuses of the two sides, they

are intimately connected with the cardiac plexuses, and they receive branches from the sympathetic. Reference is made to the pulmonary plexuses in the section dealing with the autonomic system (see p. 1138).

The **anterior pulmonary plexus** on each side is joined by a few fibres from the corresponding part of the deep cardiac plexus, and on the left side from the superficial cardiac plexus as well. It surrounds and supplies the constituents of the root of the lung anteriorly.

The **posterior pulmonary plexus**, placed behind the root of the lung, is formed by the greater part of the vagus nerve, reinforced by fine branches from the second, third, and fourth thoracic ganglia of the sympathetic.

Numerous branches extend from the anterior and posterior pulmonary plexuses into the substance of the lung. The entering fibres, arranged in a plexiform manner, form three groups. One accompanies the bronchi, another the vessels, and a third is distributed to the pulmonary pleura.

Œsophageal Plexus.—The œsophagus in the thorax is supplied by the vagus nerves both in the superior and posterior mediastina. *In the superior mediastinum* it receives branches from the vagus nerve on the right side, and from the recurrent laryngeal nerve on the left side.

In the posterior mediastinum the gullet is surrounded by the œsophageal plexus, formed from the trunks of the vagus nerves emerging from the posterior pulmonary plexuses. That part of the œsophagus also receives fibres from the greater splanchnic nerve and the splanchnic ganglion. From the œsophageal plexus branches supply the muscle and mucous membrane of the wall of the œsophagus.

A few filaments also pass from the plexus to the posterior surface of the pericardium.

The thoracic plexuses described above are to be regarded as predominantly vagal, *i.e.*, parasympathetic. The ganglion-cells found in them are the cell-bodies of postganglionic neurons whose fibres innervate the heart, its coronary vessels, and the tissues of the lung. Afferent fibres are present whose cell-bodies are located in the vagal ganglia. Impulses carried from the heart, the great veins, and the aorta (including the glomus aorticum, p. 1145) by such afferent fibres have considerable importance in vasosensory reflex mechanisms.

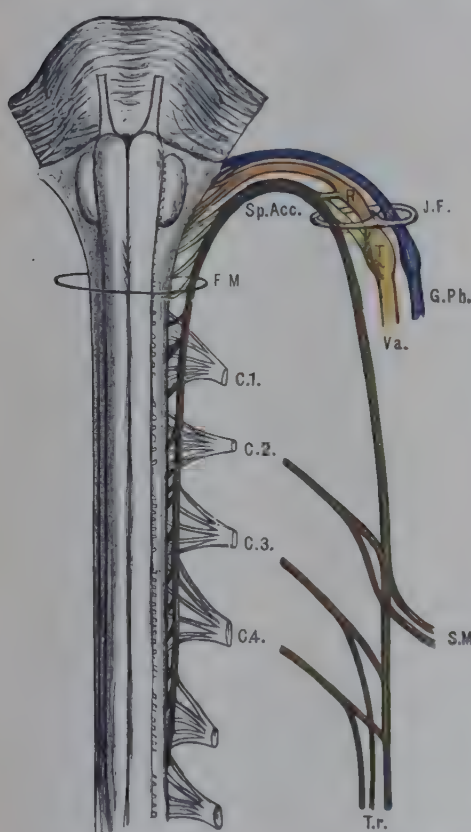

Fig. 908.—Scheme of the Origin, Connexions, and Distribution of the Accessory Nerve.

Sp.Acc., Accessory nerve; C.1-4, First four cervical nerves (posterior roots); Va., Vagus nerve; R, Superior ganglion; T, Inferior ganglion; G.Ph., Glosso-pharyngeal nerve; S.M., Nerves to sterno-mastoid; Tr., Nerves to trapezius; F.M., Foramen magnum; J.F., Jugular foramen.

ACCESSORY NERVE

The **eleventh** or **accessory nerve** consists of two essentially separate parts, different both in origin and in distribution. One, the **bulbar portion, is accessory to the vagus nerve**, and arises by the *cranial root* in series with the rootlets of that nerve, from the side of the medulla oblongata; its fibres are contributed to the pharyngeal and laryngeal branches of the vagus for the supply of the constrictors of the pharynx and the intrinsic muscles of the larynx. The other, the **spinal portion**, arises by the *spinal root* from the side of the spinal cord between the anterior and posterior roots of the spinal nerves, its origin extending from the level of the cranial root as low as the origin of the fifth or sixth cervical nerve (for the deep origin, see p. 927). This portion of the nerve supplies the sterno-mastoid and trapezius muscles. Successively joining together, the rootlets form a trunk which ascends in the subarachnoid

space of the vertebral canal, behind the ligamentum denticulatum, to the foramen magnum. Approaching the jugular foramen, the spinal and cranial roots unite into a single trunk which leaves the cranial cavity through the jugular foramen in the same compartment of dura mater as the vagus nerve (Fig. 889, p. 1016).

In the jugular foramen the part **accessory to the vagus** (after furnishing a small branch to the superior ganglion of the vagus) applies itself to the inferior ganglion. At this point some fibres join the ganglion and the rest become incorporated in the trunk of the vagus beyond the ganglion. Its fibres are distributed in certain branches of the vagus indicated above. See also p. 1040.

The **spinal portion** of the nerve extends into the neck, where at first it lies along with other nerves in the interval between the internal carotid artery and the internal jugular vein. It then passes obliquely downwards and laterally superficial (sometimes deep) to the vein, under cover of the posterior belly of the digastric; still descending, it pierces the deep part of the sterno-mastoid muscle or lies close to its deep surface, and it supplies the muscle. It appears at the posterior border of the sterno-mastoid at or below the junction of the upper and middle thirds, and about the level of the upper border of the thyroid cartilage. It runs obliquely downwards and backwards in the fascial roof of the posterior triangle to reach the anterior border of the trapezius muscle, under which it passes and which it helps to supply in conjunction with branches of the cervical plexus. The accessory nerve communicates with nerves from the cervical plexus in three situations: (1) in or under cover of the sterno-mastoid, with the branch for the muscle derived from the second cervical nerve; (2) in the posterior triangle, with branches to trapezius from the third and fourth cervical nerves; (3) deep to the trapezius, with the same branches.

In its course beneath the sterno-mastoid and in the posterior triangle the accessory nerve has important and intimate relations with lymph-glands.

HYPOGLOSSAL NERVE

Motor Nv

The **twelfth** or **hypoglossal nerve** is a predominantly efferent nerve, which supplies all the muscles of the tongue, both intrinsic and extrinsic, except the palato-glossus. It arises by numerous rootlets from the front of the medulla oblongata between the pyramid and the olive (Fig. 885, p. 1012; for the deep origin, see p. 926). The rootlets arrange themselves in two bundles which separately pierce the dura mater, and unite in the anterior condylar canal, or after emerging from the skull. Immediately below the base of the skull it is closely associated with the glosso-pharyngeal, vagus, and accessory nerves, and lies, with them, medial to and between the internal carotid artery and the internal jugular vein, and deep to the posterior belly of the digastric and the stylo-hyoid muscle. In this part of its course it is joined by fibres of the first and second cervical nerves. As it descends it becomes more superficial and, winding round the vagus nerve, it is closely attached to the lateral surface of its inferior ganglion. Midway between the posterior belly of the digastric and the greater horn of the hyoid bone it turns forwards, through the angle between the occipital artery and its sterno-mastoid branch, and passes to the floor of the mouth. In its course forwards it lies superficial to the internal carotid artery, the occipital artery, the external carotid artery, and to the loop of the lingual artery (which separates it from the middle constrictor muscle). Farther forward it lies between the posterior belly of the digastric muscle laterally and the hyo-glossus medially and then between the mylo-hyoid laterally and the hyo-glossus medially, where it breaks up into terminal branches which continue onwards between the mylo-hyoid and genio-glossus muscles. The terminal branches communicate with filaments of the lingual nerves.

Communications.—Near the base of the skull the hypoglossal nerve is connected by small branches with: (1) the superior cervical ganglion of the sympathetic; (2) the inferior ganglion of the vagus; (3) by a larger branch, with the loop between the first two cervical nerves; (4) as it crosses the external carotid artery it receives a communication from the pharyngeal plexus (*lingual branch of the vagus*); and (5) medial to the mylo-hyoid

muscle, at the anterior border of the hyo-glossus, it forms loops of communication with the lingual branch of the mandibular nerve.

The **branches** of the nerve are: (1) Meningeal; (2) Descending; (3) Thyro-hyoid; and (4) Terminal.

The **meningeal branch** passes from the nerve near its origin to supply the

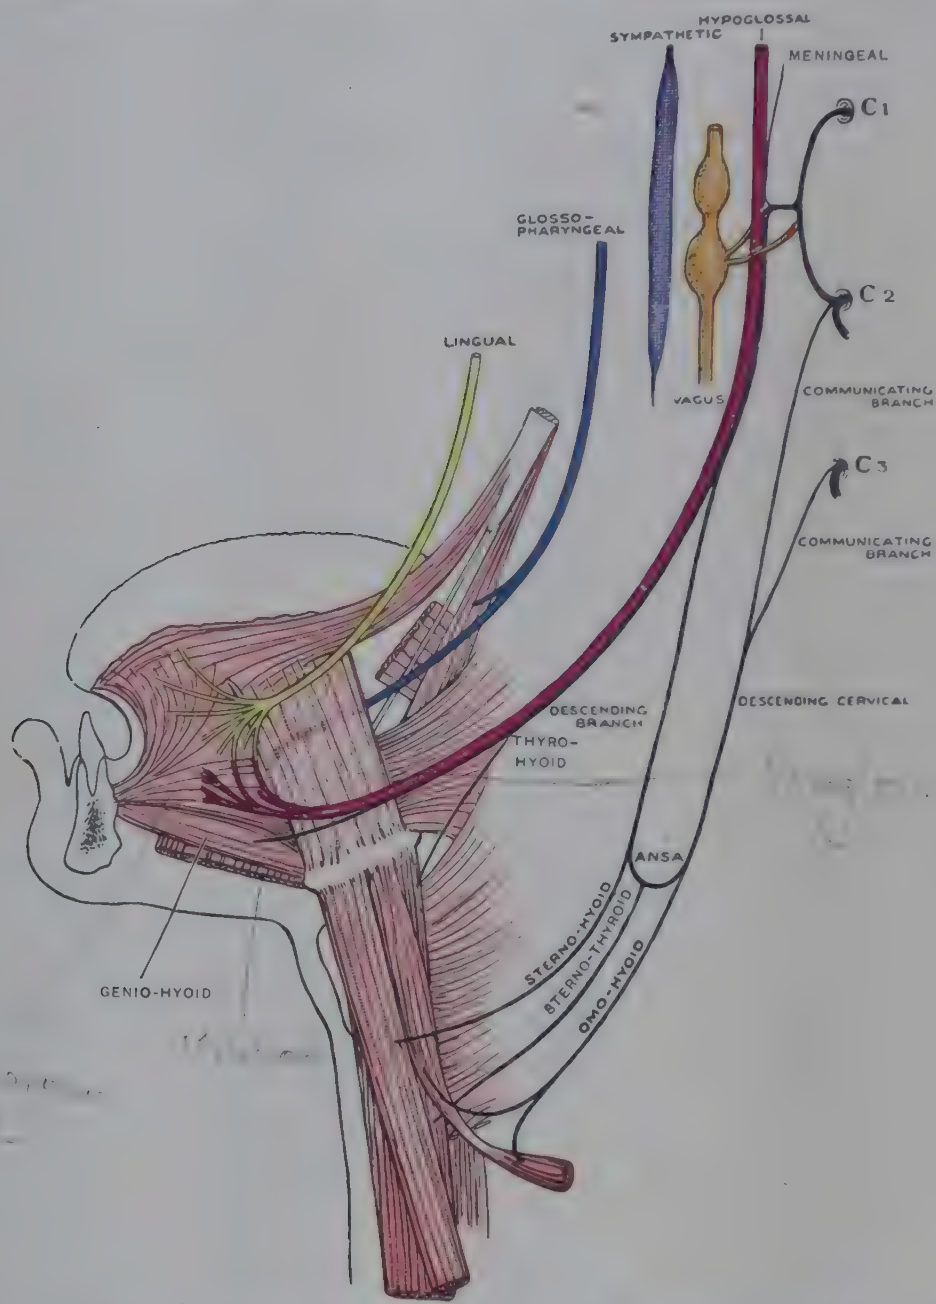

FIG. 909.—MUSCLES OF HYOID BONE AND STYLOID PROCESS, AND EXTRINSIC MUSCLES OF THE TONGUE, SHOWING CONNEXIONS AND DISTRIBUTION OF HYPOGLOSSAL NERVE.

dura mater of the posterior fossa of the skull. It probably derives its fibres from the communication with the first and second cervical nerves.

The **descending branch of the hypoglossal nerve** is the chief branch given off in the neck. It arises from the hypoglossal nerve as it crosses the internal carotid artery, and descends in the anterior triangle superficial to the carotid sheath. It is joined about the middle of the neck by the **nervus descendens cervicalis** (from the second and third cervical nerves). By their union the **ansa hypoglossi (hypoglossal loop)** is formed, from which branches are distributed to both bellies of the omo-hyoid, the sterno-hyoid, and the sterno-thyroid. The descending branch of the hypoglossal nerve derives its fibres from the communication to the hypoglossal nerve from the loop between the first and second cervical nerves; the ansa hypoglossi therefore is made up of fibres of the first three cervical nerves.

The **nerve to the thyro-hyoid muscle** is a small branch which arises from the

hypoglossal nerve before it leaves the carotid triangle. It descends behind the greater horn of the hyoid bone to reach the muscle. When traced backwards this nerve is found associated with the loop between the first and second cervical nerves.

The **terminal branches** of the hypoglossal nerve are distributed to the hyoglossus, stylo-glossus, genio-hyoid, and genio-glossus, and to all the intrinsic muscles of the tongue. The nerve to the genio-hyoid is said to be derived from the loop between the first and second cervical nerves.

COMPONENT FIBRES OF CRANIAL NERVES

The third, fourth, sixth, eleventh, and twelfth pairs are composed of large and small medullated fibres; non-medullated fibres have been found in the fifth, sixth, ninth, eleventh, and twelfth, of which those in the sixth, eleventh, and twelfth are probably all derived from the sympathetic system. As regards the function of the fibres, although the cranial nerves are usually broadly classified as efferent and afferent, as well as mixed nerves, it is now recognized that few of them consist exclusively of one or the other order of fibres. The optic nerve, though long supposed to contain some centrifugal fibres, is to be regarded as purely afferent in the mammal (Bodian, 1937). The third, fourth, and sixth nerves are not purely efferent in function, but contain also some afferent (somatic afferent, *proprioceptive*) fibres (Tozer & Sherrington, 1910), as well as fibres from the sympathetic system, and the same may prove true for the eleventh and twelfth nerves. Indeed the cranial nerves vary greatly in their functional composition, and, moreover, no nerve, save the olfactory, optic and auditory, is made up of one functional order of fibres.

The animal body is naturally divided into two different areas or regions—the **somatic** area, forming the body-wall and limbs, and the **splanchnic** or visceral area, comprising the chief viscera contained within the body cavity. In the head and neck an additional factor has to be considered owing to the presence of the series of pharyngeal or branchial arches, for in connexion with that series there have been developed not only an additional set of visceral muscles, requiring motor innervation (*e.g.*, the muscles of mastication, and of the face, palate, and pharynx), but also visceral sense-organs (taste-buds). In a regional classification of the nerves on these lines those that supply the derivatives of the branchial region may be termed *special* in contrast with the *general* nerves of the rest of the visceral area; similarly in the somatic area the introduction of the ear as a specialized sensory area results in the presence of a special set of somatic afferent fibres. Combining the regional distribution with the function of the fibres (*efferent* and *afferent*) the nerve-fibres may be tabulated as follows (after Herrick, 1938):—

Sensory: General somatic afferent (sensory from the skin).
Special somatic afferent (cochlear and vestibular nerves).
General splanchnic afferent (from visceral mucous membrane).
Special splanchnic afferent (from organs of taste).
Motor: General splanchnic efferent (to plain musculature).
Branchial efferent (to branchial muscles).
General somatic efferent (to skeletal muscles).

It is worthy of note that such a classification serves rightly to emphasize the central connexion, practical continuity, and function of the peripheral nervous system as a whole, since many of the fibre-paths designated under this nomenclature traverse both the cerebro-spinal and autonomic systems on their way to their destinations.

DEVELOPMENT AND MORPHOLOGY OF CRANIAL NERVES

In the early human embryo, when the neural plate is folded in to form the neural tube, the cells that form its lateral margins are left as a **neural crest**, lying above the tube and connecting it with the surface ectoderm. From the cells of the crest there are developed not only all of the cerebro-spinal and sympathetic ganglia, together with the chromaffin bodies, but all of the *afferent* fibres of the cerebro-spinal system (except those of the first and second cranial nerves and a few fibres in connexion with the seventh, ninth, and tenth nerves to be mentioned later), whilst from the walls of the **neural tube** all of the *efferent* fibres arise.

At a later stage the lateral walls of the neural tube become differentiated into three layers—the **ependymal**, **mantle**, and **marginal zones**—and the neural canal is more or less rhomboidal in transverse section, its lateral angles marking the division of the walls into a dorsal part (the **alar lamina**) and a ventral part (the **basal lamina**). Into the alar lamina grow the central processes of the cells situated in the cerebro-spinal ganglia, which have been derived from the neural crest, and it may, therefore, be considered *afferent* in function, whilst the basal lamina, from whose cells there grow out long peripheral fibres, may be termed *efferent*. Furthermore, in the middle or mantle zone (grey matter) of each lamina the developing neuroblasts become arranged in two longitudinal columns, one having **somatic** (body-wall) and the other **splanchnic** (visceral) peripheral connexions. Thus, the grey matter of each lateral wall of the neural tube shows four longitudinal cell-columns (Figs. 730, 910), which, from their presence throughout the whole length of the neural tube, their peripheral connexions, and their functions, may be called:

1. General somatic afferent cell-column } in the Alar lamina,
2. General splanchnic afferent cell-column }
3. General splanchnic efferent cell-column } in the Basal lamina,
4. General somatic efferent cell-column }

corresponding to Gaskell's four primary functional divisions of the activities of the organism.

In the hind- and mid-brain regions, however, other cell-columns are added, consequent upon the presence of (1) the great **special sense organs** (nose, eye, ear) which demand specialized somatic afferent connexions, and (2) the **branchial system** and its derivatives, which, as a specialized part of the visceral area, demand special splanchnic connexions, both afferent and efferent. In the developing brain-stem, therefore, three additional cell-columns are to be found (Fig. 911) :—

1. Special somatic afferent cell-column } in the Alar lamina,
2. Special splanchnic afferent cell-column }
3. Branchial efferent cell-column in the Basal lamina.

As is pointed out above in the discussion of their components, few of the cranial nerves are composed exclusively of fibres of one functional order; in most, however, there is such a preponderance of one type that we are justified in grouping them into three series :—

Somatic Afferent.	Somatic Efferent.	Branchial and Splanchnic (Afferent and Efferent)
I. Olfactory.	III. Oculomotor.	V. Trigeminal.
II. Optic.	IV. Trochlear.	VII. Facial.
VIII. Auditory.	VI. Abducent.	IX. Glosso-pharyngeal.
	XII. Hypoglossal.	X. Vagus.
		XI. Accessory.

Though this grouping is purely *functional*, it is, as we might expect, reflected anatomically in development, for the somatic afferent group of nerves (I, II, and VIII) is connected with the alar lamina, corresponding in this respect to the posterior roots of the spinal nerves, whilst the somatic efferent group (III, IV, VI, and XII) arises from the medial part of the basal lamina in line with the anterior roots of the spinal nerves. The splanchnic group (V, VII, IX, X, and XI), which is composed of afferent and efferent nerves specialized in connexion with the branchial system, forms an intermediate series between the other two. It must be said, however, that though there is some degree of correspondence between cranial and spinal nerves, any attempt to show a strict homology leads to insuperable difficulties.

Somatic Afferent Group

Of the three cranial nerves in this group, the eighth only is developed from the neural crest, and is to that extent comparable to the posterior root of a spinal nerve. It is quite probable, however, that some of its fibres come from cells developed from the ectoderm of the auditory vesicle, and, moreover, its distribution is limited to a specialized sensory area of the ectoderm. The first and second nerves are developed in connexion with outgrowths of the brain; and it is obvious that neither of them is strictly comparable to any of the other nerves, cranial or spinal.

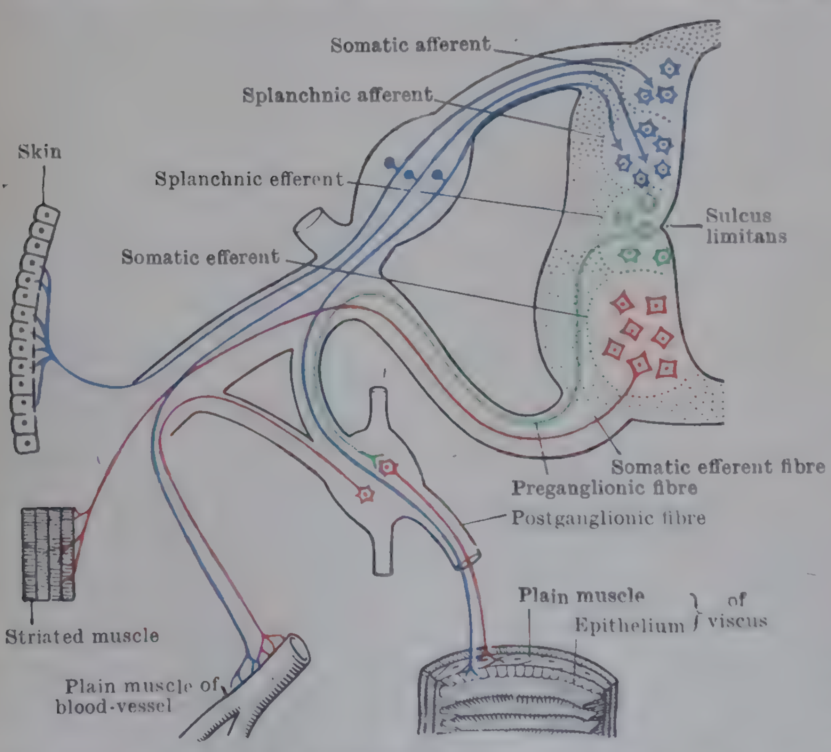

Fig. 910.—Diagram of Components of Spinal Nerve and their Relation to Nuclei of Origin or Termination in Section of Embryonic Spinal Cord. Compare with components of cranial nerves in Fig. 911 and also with Fig. 963, p. 1129.

I. Olfactory Nerve.—At the end of the fourth week an olfactory plate becomes differentiated in the ectoderm lying under the fore-brain on each side. By the growth of the medial and lateral nasal processes around it, the plate comes to form the roof of the olfactory pit. The sensory cells of the plate now take on the character of true nerve-cells, and send in basal fibres which arborize around the cells of the olfactory bulb. At first the olfactory plates are directly in contact with the bulb, which is developed from the fore-brain, but later, by the development of the cribriform plate and meninges, they become pushed apart, and the fibres

connecting them are lengthened to form the true olfactory nerves. These nerves are peculiar in that the cell-bodies, which are bipolar, lie in the mucous membrane and are not aggregated into ganglia. The fibres proceeding to the olfactory bulb are non-medullated.

II. Optic Nerve.—The optic nerve is developed in the stalk of the optic vesicle—an outgrowth from the fore-brain, and, morphologically, is a part of the central nervous system. When the optic cup is formed (see under Development of the Eye) its inner or retinal layer becomes differentiated into the rods and cones (the true neuro-sensory cells, corresponding to the olfactory cells) and nerve-cells, the processes of which grow back along the optic stalk to form the optic nerve, chiasma, and tract. These nerve-cells are true intercalated neurons, corresponding to those of the grey matter of the central nervous system, and their fibres, lacking the typical neurolemmal sheath of peripheral nerves, are supported by neuroglia.

VIII. Auditory Nerve.—The internal ear first arises as an ectodermal plate lying dorsal to the

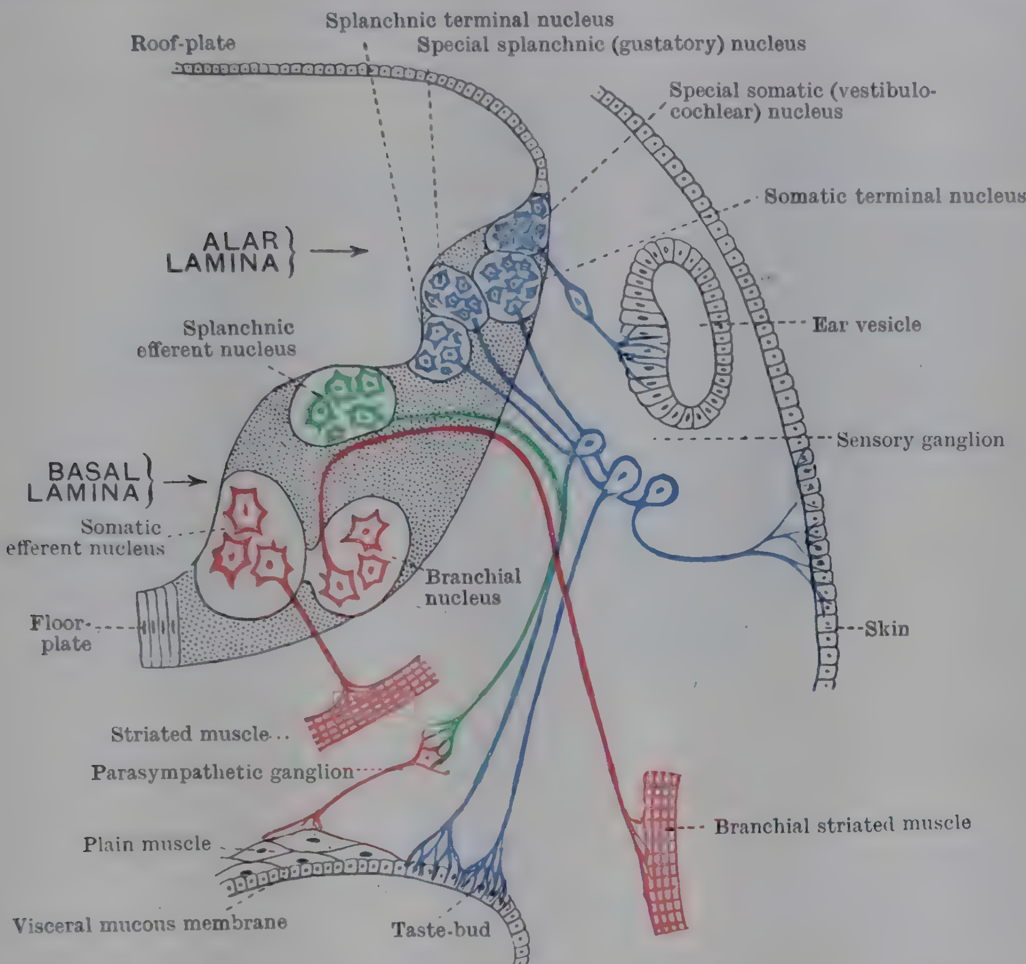

FIG. 911.—DIAGRAM OF COMPONENTS OF CRANIAL NERVES AND THEIR RELATION TO NUCLEI OF ORIGIN OR TERMINATION IN SECTION OF EMBRYONIC HIND-BRAIN.

Compare with components of spinal nerve in Fig. 910 and also with Fig. 730, p. 845.

first pharyngeal groove. That plate invaginates to form a flask-like auditory vesicle (otocyst) from the lining cells of which patches of neuro-epithelium are later differentiated. The vestibular and cochlear ganglia develop between the vesicle and the hind-brain in close association with the ganglion of the seventh nerve. Although the origin of the common mass is usually said to be from the neural crest, it is probable that some at least of the cells of the auditory ganglia are derived from the neuro-epithelium of the auditory vesicle. The ganglia, composed of bipolar cells, grow in direct proportion to the vestibular and cochlear outgrowths of this vesicle, and their central and peripheral fibres form the vestibular and cochlear nerves.

SOMATIC EFFERENT GROUP

The hypoglossal nerve and the three nerves to the muscles of the eyeball all arise from the somatic efferent cell-column in the basal lamina of the neural tube, and on that account, as well as by reason of the fact that they innervate somatic muscles, are usually considered as being in series with the anterior roots of the spinal nerves.

Though the primitive vertebrate head undoubtedly was segmental, little reliable evidence remains upon which to base a reconstruction of its segmentation, and various investigators have placed the number of the primitive cephalic segments between eight and nineteen. No distinct myotomes are visible in the head of the human embryo, but a study of the lower vertebrates leads to the conclusion that the premuscle mass from which the extrinsic ocular muscles are developed represents the first three cephalic myotomes. The first myotome forms the superior,

inferior, and medial recti and the inferior oblique, supplied by the oculomotor nerve; the second myotome forms the superior oblique, supplied by the trochlear nerve; and the third forms the lateral rectus, supplied by the abducent (see Fig. 478, p. 554).

Similar studies tend to show that the intrinsic muscles of the tongue are derived from the last three cephalic myotomes. Between those two sets of persisting myotomes (ocular and lingual) there is a gap which probably represents three or more myotomes which have disappeared.

III. Oculomotor Nerve.—This nerve arises from neuroblasts in the basal lamina of the mid-brain. The fibres emerge in small bundles from the anterior surface of the lamina and converge to form the trunk of the nerve, which runs to the premuscle mass from which the extrinsic muscles of the eye (with the exception of the superior oblique and lateral rectus) are formed.

IV. Trochlear Nerve.—The neuroblasts from which this nerve arises lie just caudal to and in line with the nucleus of the third nerve. Instead of leaving the basal lamina by its anterior

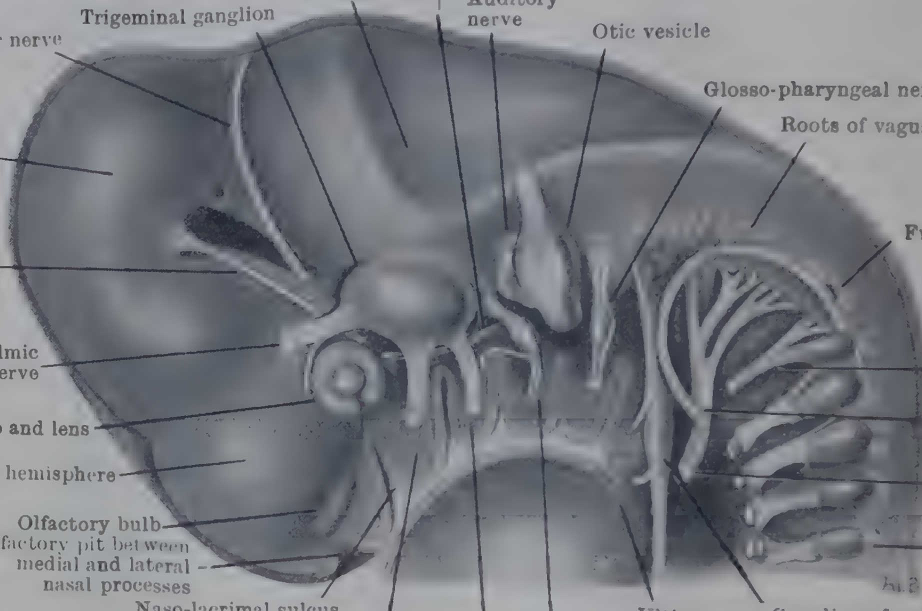

Fig. 912.—Developmental Arrangement of the Cranial Nerves. (After Streeter, 1908.)

surface, however, the fibres grow backwards, curve round the neural canal (aqueduct), and, after crossing behind it, emerge on the opposite side at the junction of the mid-brain and hind-brain.

VI. Abducent Nerve.—The nucleus of origin lies in the basal lamina of the hind-brain under the floor of the fourth ventricle. The fibres emerge at a point caudal to the future pons and run to the rudiment of the lateral rectus muscle.

XII. Hypoglossal Nerve.—The twelfth is a compound nerve representing the fused efferent nerves of three, or possibly more, precervical neural segments. Its fibres take origin from neuroblasts in the somatic efferent cell-column and emerge from the walls of the basal lamina in several groups; they then converge anteriorly to form the trunk of the nerve and grow forwards to end in the muscle-rudiment of the tongue. The occasional presence of a ganglion (Froriep, 1882) on the hypoglossal nerve (human and other mammalian embryos and some adult mammals) suggests that this nerve has carried sensory fibres earlier in phylogeny. The presence of sensory components in the adult human hypoglossal has been disputed; but Pearson (1945) has described sensory-type ganglion-cells in the intra-medullary part of the nerve in human fœtal and adult material, and Tarkhan & Abou-el-Naga (1947) claim to have demonstrated the presence of afferent fibres in the dog.

Branchial and Splanchnic (Afferent and Efferent) Group

The nerves of this group are essentially related to the **pharyngeal arches** (see p. 66). In the embryo each of these arches contains a muscle-plate which differs from the myotomes in that it is developed from splanchnic mesoderm but resembles the myotomes in producing striated muscle. Associated with each arch is a nerve which contains both afferent and efferent fibres, and runs along the upper or cephalic border of the arch; that nerve sends a small branch (*pretrematic*) round the dorsal end of the pharyngeal pouch to run along the lower, or caudal, border of the arch in front of the one from which it arises. The nerve of the first or mandibular arch is the mandibular division of the trigeminal nerve; the nerve of the second arch is the

facial, and that of the third is the glosso-pharyngeal; the nerves of the remaining arches are fused to form the vagus and accessory nerves.

The nerve of each arch supplies branchial efferent fibres to the muscle-plate; and it has a ganglion on its root from which afferent (general splanchnic afferent) fibres pass to the pharyngeal mucosa on the inner surface of the arch and the pharyngeal pouch in front of it.

Furthermore, in connexion with the branchial system there are in the human embryo vestiges of a series of sense organs which have been lost by the higher vertebrates. They are small areas of modified ectoderm which are found at the dorsal end of each external pharyngeal groove or branchial cleft and are known as epibranchial **placodes**. During the fifth week of embryonic development the placodes are in contact with the ganglia of the facial, glosso-pharyngeal, and vagus nerves—and contribute cells to the formation of these ganglia.

Whilst the nerves of the splanchnic group typically do not possess somatic afferent fibres, the trigeminal, in conformity with the large part taken by the first arch in the formation of the face, receives a preponderance of that type of fibre. In reality, however, the trigeminal is a double nerve, and the present tendency is to regard its efferent (branchial) part as a separate nerve (the masticator); and the remainder as a somatic afferent nerve. The vagus nerve also contains a limited number of somatic afferent fibres which supply the skin around the persistent dorsal part of the first pharyngeal groove—that is, the external auditory meatus.

V. Trigeminal Nerve.—The trigeminal ganglion arises very early from the neural crest at the extreme cranial end of the hind-brain. Central processes from its cells form the afferent root of the nerve, and, reaching the hind-brain at the level of the pontine flexure, divide to run up and down in the alar plate, where the descending fibres form the spinal tract of the fifth nerve. The peripheral fibres separate into three large divisions which grow out into the three processes that take part in the formation of the face (the fronto-nasal, maxillary, and mandibular processes) and form the three divisions of the fully developed nerve.

The efferent fibres arise from the branchial efferent column of the basal lamina, where the cell-bodies form a dorsal nucleus opposite the point at which the afferent fibres enter the brain. The efferent fibres emerge as a distinct trunk in the embryo, and, after coursing along the medial side of the trigeminal ganglion, run to the muscle-plate of the first arch, which later forms the muscles of mastication.

VII. Facial Nerve.—The facial is composed mainly of efferent fibres which arise from a nucleus in the branchial efferent column of the basal lamina. Growing out from that nucleus they emerge from the hind-brain just medial to the auditory ganglion and run to the muscle-plate of the second or hyoid arch from which the platysma group of muscles is later developed. At first the fibres run directly from their nucleus of origin to the lateral surface of the hind-brain, passing above the nucleus of the abducent nerve. Later, however, the facial nucleus shifts downwards (caudally) and ventro-laterally towards the afferent nuclei of the solitary tract and the spinal tract of the trigeminal nerve, following the general law of neurobiotaxis that the chief dendrite and body of a neuron tend to move towards the source of the majority of their afferent impulses (p. 890). General splanchnic efferent fibres (parasympathetic) also leave the brain in the seventh nerve.

The afferent fibres are developed from the ganglion of the facial nerve, which is derived from the neural crest and lies in close association with the ganglia of the auditory nerve. It is probable that certain cells are also contributed to this ganglion by the epibranchial placode of the first pharyngeal groove. The central fibres enter the alar lamina and form, together with fibres from the glosso-pharyngeal nerve, the solitary tract. Pearson (1947) suggests that some central fibres also run to the descending root of the trigeminal nerve and a few possibly to the mesencephalic tract of the same nerve. The peripheral fibres run in front of the pharyngeal groove and form the chorda tympani and greater superficial petrosal nerves, which represent the pretrematic branch of the facial nerve.

IX. Glosso-Pharyngeal Nerve.—The efferent fibres arise from the nucleus ambiguus, which is a common nucleus of origin for the efferent fibres of the glosso-pharyngeal, vagus, and accessory nerves and lies in the branchial efferent column in line with the efferent nuclei of the fifth and seventh nerves. Emerging from the hind-brain they grow out ventrally to meet the muscle-plate of the third arch, and eventually supply the pharyngeal muscles derived from that element. General splanchnic efferent fibres (parasympathetic) also leave the brain in the ninth nerve.

The afferent fibres, which form the larger part of the nerve, are derived from two ganglia—the superior ganglion, developed from the neural crest, and the inferior ganglion, formed in part from the neural crest and in part from an epibranchial placode with which it is in contact. Centrally the fibres enter the alar lamina and join fibres from the facial and vagus to form the solitary tract. Most of the peripheral fibres from the ganglia run ventrally to enter the third arch, passing, as a lingual branch, to that part of the tongue which is later developed from it. Some of the peripheral fibres, however, form a pretrematic branch in front of the second pharyngeal pouch, and, as the tympanic nerve, supply the structures derived from the dorsal extremity of the first and second pouches (tympanum, etc., see p. 67).

X. Vagus.—The vagus is a composite nerve representing, with the accessory, the union of the nerves of all the pharyngeal arches behind the third. Its afferent fibres, therefore, grow out from several root-ganglia developed from the neural crest. The superior ganglion is the most cephalic of those; the others are vestigial and are called accessory ganglia. The ganglion inferior, like the inferior ganglion of the glosso-pharyngeal, is developed in contact with an epibranchial placode, and in all probability receives cells from that source as well as from the neural crest. The central fibres grow towards the alar lamina, and, after entering it, turn downwards

to form, in conjunction with fibres from the facial and glosso-pharyngeal nerves, the solitary tract. The peripheral fibres grow downward to form the bulk of the vagus nerve.

The efferent fibres arise from two nuclei in the basal lamina—the nucleus ambiguus in the branchial efferent column, and a dorsal efferent nucleus which lies in the general splanchnic efferent column. The fibres from these two sources emerge laterally in two separate bundles and join the afferent fibres to form the trunk of the nerve. Those from the nucleus ambiguus grow out to the muscle-plates of the fourth and succeeding arches, from which the laryngeal and part of the pharyngeal muscles are developed. The fibres from the dorsal nucleus run to the parasympathetic plexuses of the vagus.

XI. Accessory Nerve.—This nerve is closely associated with the vagus; both embryologically and morphologically it may be regarded as the caudal part of the vagus complex which has become specialized because of a new rôle assumed by the branchial muscles which it supplies, these muscles (sterno-mastoid and trapezius) having been pressed into service as muscles of the limb-girdle.

The efferent fibres, of which alone it is composed, arise from two sources. The larger number grow out from cell-groups which are developed in the lateral grey column of the upper four or more cervical segments of the spinal cord (branchial efferent column) in series with the nucleus ambiguus of the tenth. Emerging from the cord laterally, these fibres run upwards along the line of the neural crest as the spinal accessory trunk to join the vagus. Leaving this nerve after a short course, however, they run to their destination. A few fibres of the accessory nerve arise from cells in the dorsal motor nucleus of the vagus and, after pursuing a short course with the accessory proper, rejoin the vagus and are distributed to its plexuses.

SPINAL NERVES

The spinal nerves are characterized by being attached to the spinal cord and by passing from the vertebral canal through the intervertebral foramina.

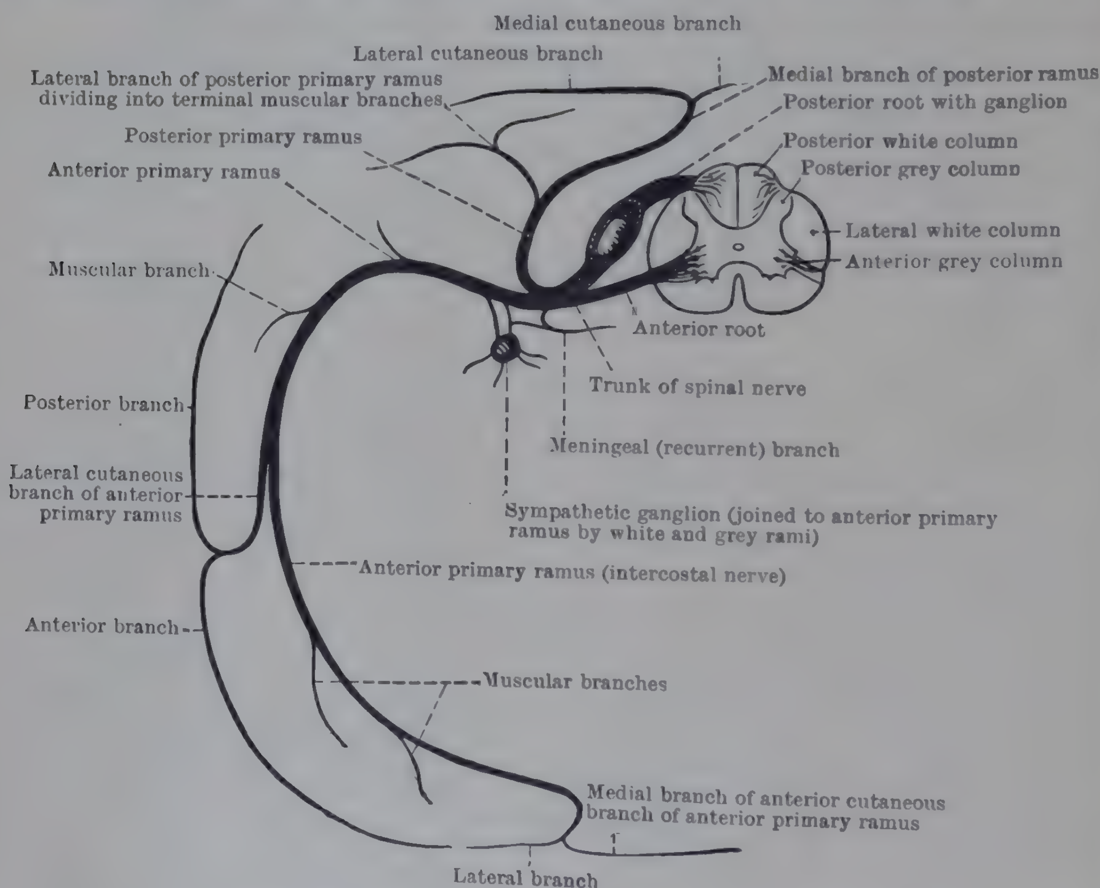

FIG. 913.—DIAGRAM OF ORIGIN AND DISTRIBUTION OF TYPICAL SPINAL NERVE.

Note that the medial branch of the posterior primary ramus is represented as distributed to skin, whilst the lateral branch terminates at a deeper level in muscle. Both branches, however, supply muscles; and in the lower half of the body it is the lateral branch that supplies the skin.

There are usually thirty-one pairs, which are grouped as cervical, thoracic, lumbar, sacral, and coccygeal, in relation to the vertebræ between which they emerge. There are eight cervical nerves, the first passing out of the vertebral canal between the occipital bone and the atlas, and the last appearing between the seventh cervical and first thoracic vertebræ; the other cervical nerves are numbered in corre-

spondence with the vertebræ *above* which they emerge from the canal. There are twelve thoracic, five lumbar, five sacral nerves, and one coccygeal nerve, all appearing *below* the corresponding vertebræ.

The thirty-first nerve is occasionally absent; and there are sometimes one or two additional pairs of minute filaments below the thirty-first, which, however, do not emerge from the vertebral canal. They are the vestigial caudal nerves.

The size of the spinal nerves varies. The largest are those which take part in the formation of the great nerve-trunks of the limbs (lower cervical and first thoracic, and lower lumbar and upper sacral nerves); and of these the nerves destined for the lower limbs are the larger. The coccygeal nerve is the smallest of the spinal nerves; the thoracic nerves (except the first) are more slender than the limb nerves; and the cervical nerves diminish in size from below upwards.

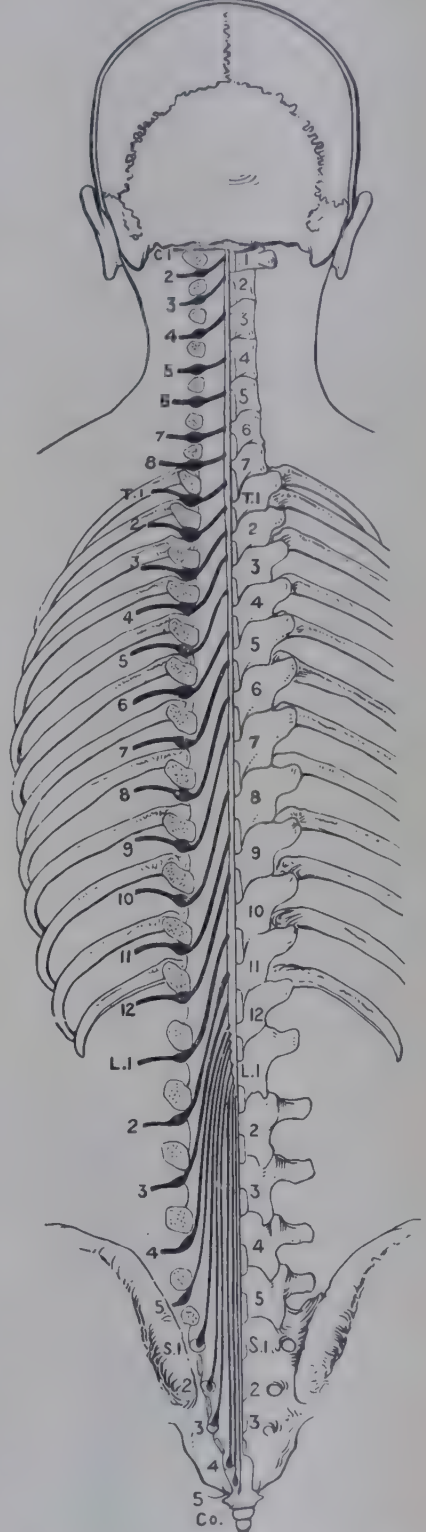

Fig. 914.—Diagram of Origin of Spinal Nerves, showing Position of Roots and Ganglia in Relation to Vertebral Column. The nerves are shown as thick black lines on the left side.

Origin of Spinal Nerves.—Each nerve is attached to the spinal cord by two roots, one of which is ganglionic and the other not; they are called respectively **posterior** (dorsal or afferent) and **anterior** (ventral or efferent).

The **posterior root** is larger than the anterior root; it contains a larger number of radicular fibres, and the individual fibres are of larger size than in the anterior root. It has a vertical linear attachment to the postero-lateral sulcus of the spinal cord. The fibres of contiguous posterior roots are in close relation, and, in some instances, overlap. As the radicles of the posterior root pass away from the spinal cord, they form two bundles, both of which become connected with the proximal end of a **spinal ganglion.** From the distal end of the ganglion the posterior root proceeds to its junction with the anterior root in the intervertebral foramen.

The **spinal ganglia** are found on the posterior roots of all the spinal nerves. (In the case of the first cervical nerve, the posterior root, with its ganglion, is not infrequently reduced or absent.) They occupy the intervertebral foramina, except (1) the ganglia of the sacral and coccygeal nerves, which lie *within* the vertebral canal, and (2) the ganglia of the first and second cervical nerves, which lie upon the vertebral arches of the atlas and axis respectively. With the exception of the coccygeal ganglia they are outside the dura mater, but are invested by a prolongation of that membrane. The ganglia are of ovoid form, bifurcated in some cases at their proximal ends. They consist of unipolar nerve-cells, whose axons, after a very short course, divide into central (root) fibres and peripheral (trunk) fibres. The central fibres form the portion of the root which enters the spinal cord; the peripheral fibres are continued in a lateral direction from the ganglion into the spinal nerve.

There is no adequate evidence to support the view that the dorsal roots contain efferent fibres; they are entirely afferent (Westbrook & Tower, 1940).

Aberrant Spinal Ganglia.—Between the spinal ganglion and the spinal cord small collections of cells are occasionally found on the posterior roots, either as scattered cells or distinct ganglia. They are most frequently met with on the posterior roots of the lumbar and sacral nerves.

The **anterior root** is smaller than the posterior root and has no ganglion. It arises from the anterior surface of the spinal cord (*anterior root-zone*) by means of scattered bundles of nerve-fibres, which occupy a greater horizontal area and are more irregular in their arrangement than the fibres of the posterior root. The rootlets sometimes overlap, and are not infrequently connected with neighbouring radicular fibres above and below.

The posterior and anterior roots proceed laterally in the vertebral canal from their attachment to the spinal cord towards the intervertebral foramina, where they unite to form the spinal nerve. The direction of the roots of the first two nerves is upwards and laterally; the roots of the remaining nerves course obliquely downwards and laterally, the obliquity gradually increasing until the course of the lower lumbar, the sacral and coccygeal nerve-roots is vertically downwards in the vertebral canal. This increasing obliquity of the roots is due to the fact that the spinal cord extends down only as far as the lower border of the first lumbar vertebra, and results in the length of the roots being steadily augmented from cervical to sacral region (Fig. 914). The collection of nerve-roots which occupies the lower part of the canal, below the first lumbar vertebra, and comprises all the nerve-roots below those of the first lumbar nerve, is designated the **cauda equina.** They arise from the lumbar enlargement and the conus medullaris, and surround the filum terminale of the spinal cord.

Within the vertebral canal the nerve-roots are in relation with the **meninges** of the spinal cord, and the anterior are separated from the posterior by the ligamentum denticulatum, and, in the neck, by the spinal part of the accessory nerve also. Each receives on leaving the cord an investment of pia which becomes continuous with the arachnoid where the roots pierce the dura. The two roots are thereafter enclosed in a single tubular sheath of dura mater, in which the spinal ganglion is included. The spinal nerve thus ensheathed occupies the intervertebral foramen (except the first two cervical and the sacral and coccygeal nerves). In the region of the intervertebral foramen the nerve is in relation to the postero-lateral aspect of the intervertebral disc; protrusion or herniation of the nucleus pulposus may compress the adjacent nerve and induce sensory and motor symptoms.

Primary Rami of Spinal Nerve.—After emerging from the intervertebral foramen the nerve immediately divides into two main branches, named the **posterior and anterior primary rami**. Just before its division each nerve gives off a minute **meningeal branch**, which re-enters the vertebral canal after effecting a junction with a branch from the sympathetic trunk, and is distributed to the membranes and vessels of the spinal cord.

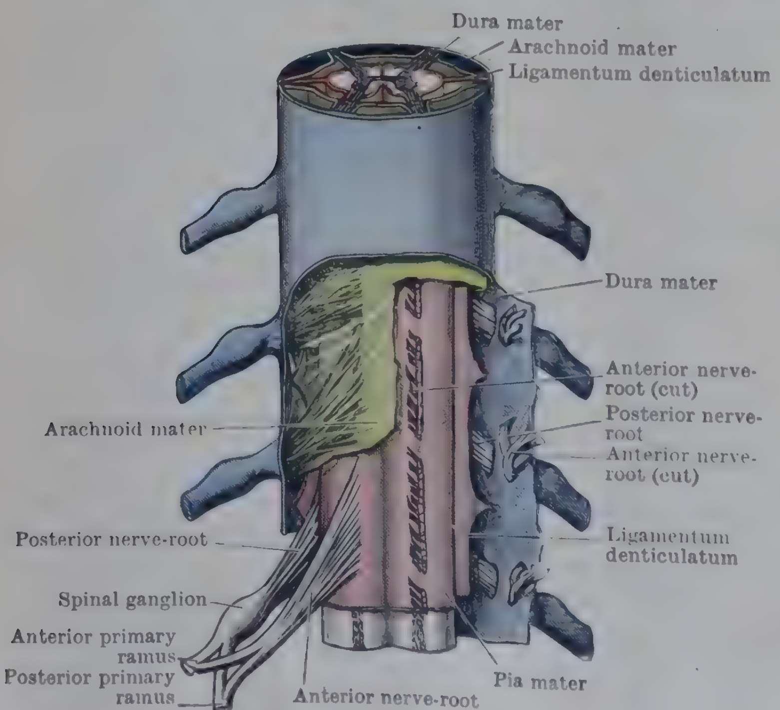

FIG. 915.—MODE OF ORIGIN OF SPINAL NERVES, SHOWN IN RELATION TO MEMBRANES OF SPINAL CORD.

The **posterior** and **anterior primary rami** of the spinal nerves are mainly somatic in their distribution, and are responsible for the innervation of the skeletal muscles and of the skin and fascia of trunk and limbs.

The primary rami of the nerves contain fibres from both posterior and anterior roots. Indeed, each root can be seen, on removal of its sheath, to divide into two portions, of which one portion enters into the formation of the posterior primary ramus, the other into the

formation of the anterior primary ramus. The posterior primary rami, with the exception of the first two, are smaller than the anterior primary rami. They are responsible for the innervation of the skin, fascia, ligaments, and axial muscles of the back. They do not supply the muscles of the limbs, although in their cutaneous distribution they are prolonged on to the back of the head, the shoulder, and the gluteal region. They form two small plexuses—the **posterior cervical** and the **posterior sacral plexuses**. The anterior primary rami are, with the exception of the first two cervical nerves, much larger than the posterior primary rami. They supply the sides and anterior parts of the body, the limbs, and the perineum. For the most part they have a complicated arrangement. The thoracic or intercostal nerves alone have a simple mode of distribution; the other nerves give rise to the **plexuses—cervical, brachial, lumbar, sacral**, and **coccygeal**.

White Rami Communicantes.—From the anterior primary rami of certain nerves (first thoracic to second or third lumbar inclusive) a series of fine nerves arises which serves to connect the spinal with the sympathetic system. These **white rami communicantes**, through the medium of the gangliated trunk of the sympathetic, have a wide distribution to blood-vessels, viscera, certain glands, and other structures.

A second stream of nerves called **pelvic splanchnic nerves** (parasympathetic), associated with the second and third or third and fourth sacral nerves, connects these spinal nerves with the pelvic plexuses of the autonomic system (pp. 1125 and 1143).

Distribution of Spinal Nerves.—Although the distribution, like the origin of the spinal nerves, presents primarily and essentially a segmental arrangement, that is masked, and in some instances obliterated, by developmental changes in the parts supplied. In no region can an isolated nerve be traced to a complete segment. The nearest approach to a complete girdle of innervation is found in the thoracic region, in such a nerve as the sixth thoracic nerve. Yet even such a nerve is not distributed to any part entirely alone. In its *cutaneous distribution* it supplies a distinctly segmental area of skin, from the median plane posteriorly to the median plane anteriorly; yet at the same time the adjacent nerves overstep, so to speak, the boundaries of the area and assist in its cutaneous nerve supply. Each segmental area will then have its own proper nerve, but it will have also the overlapping innervation of the segmental nerves immediately above and below. The trunk and the limbs may, with the above qualification, be mapped out into segmentally supplied strips of skin called **dermatomes**; these are arranged with some considerable regularity in the trunk where the segmental pattern has not been greatly altered in development. In the limbs, however, distortion of the segmental areas has resulted from the growth of the limb-buds, and the dermatomes (Figs. 929 and 942) no longer show the simplicity they exhibit in the trunk (see M.R.C. War Memo. No. 7, 1942). It must be clearly understood that to denervate a dermatome would necessitate the section of its own nerve and also of those of the immediately adjacent dermatomes above and below. (See Head, 1893; Foerster, 1933; and Keegan & Garrett, 1948.)

In "shingles" [*cingulum* = a girdle] or *herpes zoster*, the cutaneous distribution of a thoracic nerve may be marked out, partially or completely, by a characteristic vesicular eruption which is due to a specific kind of inflammation of the spinal ganglion. Herpes may occur also in the cutaneous areas of distribution of the fifth and seventh cranial nerves (p. 1033).

The *muscular distribution*, also, of a spinal nerve is segmental; the anterior primary ramus supplies the intercostal muscles of the space in which it lies; but in its course it forms communications with adjacent nerves. The posterior primary ramus supplies axial muscles of the back; not, however, in an obviously segmental manner, on account of the fusion of the segmental myotomes in the formation of complex longitudinal muscles, which are together supplied by the series of muscular branches derived from the posterior primary rami of contiguous nerves. In other regions still greater changes of structure are accompanied by deviations from a segmental type of distribution, causing the foundation of the nerve-plexuses by which the trunk and limbs are innervated.

When describing the distribution of nerves, it is important to bear in mind that the descriptions "muscular" and "cutaneous" applied to branches may be misleading. Muscular branches contain afferent as well as efferent fibres, and so-called cutaneous branches are invariably distributed to the neighbouring subcutaneous fascia as well as

skin. In certain regions—for example, the digits—they supply filaments to joints also. Further, efferent fibres of the sympathetic nervous system accompany both muscular and cutaneous nerves.

POSTERIOR PRIMARY RAMI OF SPINAL NERVES

The **posterior primary rami** of the spinal nerves innervate skin, fascia, and muscles: the skin of the trunk posteriorly, the back of the head, the shoulder and the gluteal region; and the longitudinal muscles of the back, but not the muscles of the limbs.

Each posterior ramus divides as a rule into two parts—a **medial** and a **lateral branch** (Fig. 913, p. 1050). In the upper half of the body the medial branches generally supply the cutaneous fibres, while the lateral trunks are purely muscular nerves. In the lower part of the body the opposite is the case: the lateral branches provide the cutaneous nerves and the medial branches are distributed entirely to muscles. The cutaneous nerves have a different course in the two cases. In the upper half of the back they course backwards deep to and among the muscles to within a short distance of the spines of the vertebræ, close to which they become superficial. They then extend laterally in the superficial fascia. In the lower half of the back the cutaneous nerves are directed downwards and laterally among the muscles, and become superficial at a greater distance from the median plane. In both regions the nerves pursue a sinuous course to the surface, and the lower series emerge and become superficial a considerable distance below the level of their origin. There are considerable individual differences in the origin, course, and distribution of the several nerves.

CERVICAL NERVES

First Cervical Nerve.—The posterior root of this nerve may be small or even absent. Its *posterior primary ramus* is larger than the anterior ramus; it does not divide into medial or lateral branches, and it does not directly supply any cutaneous branch.

Passing backwards, in the space between the occipital bone and the posterior arch of the atlas, the nerve enters the suboccipital triangle, and is placed below and behind the vertebral artery, and under cover of the semispinalis capitis muscle. It supplies the following branches:—

(*a*) **Muscular branches** to the semispinalis capitis, rectus capitis posterior major and minor, and obliquus capitis superior and inferior.

(*b*) A **communicating branch** descends to join the second cervical nerve.

The communicating branch may arise in common with the nerve to the obliquus inferior and reach the second cervical nerve by piercing or passing superficial or deep to that muscle; or it may accompany the nerve to the semispinalis capitis and communicate with the greater occipital nerve, under or over that muscle.

Second Cervical Nerve.—The *posterior primary ramus* of this nerve is larger than the anterior primary ramus. It passes backwards between the atlas and axis, in the interval between the obliquus inferior and the semispinalis cervicis muscles, and under cover of the semispinalis capitis muscle. In that situation the nerve gives off several small muscular and communicating branches. The main trunk, after piercing the semispinalis capitis and trapezius muscles, accompanies the occipital artery to the scalp as the **greater occipital nerve**. This is the chief cutaneous nerve for the posterior part of the scalp. It enters the superficial fascia at the level of the superior nuchal line of the occipital bone and about an inch from the external occipital protuberance. Ramifying over the surface, it supplies the skin and subcutaneous tissues of the scalp as far as the vertex. It *communicates* on the scalp with the following nerves: great auricular, lesser occipital, posterior auricular, and third occipital. At the vertex it reaches the area of cutaneous supply of the ophthalmic division of the fifth cranial nerve.

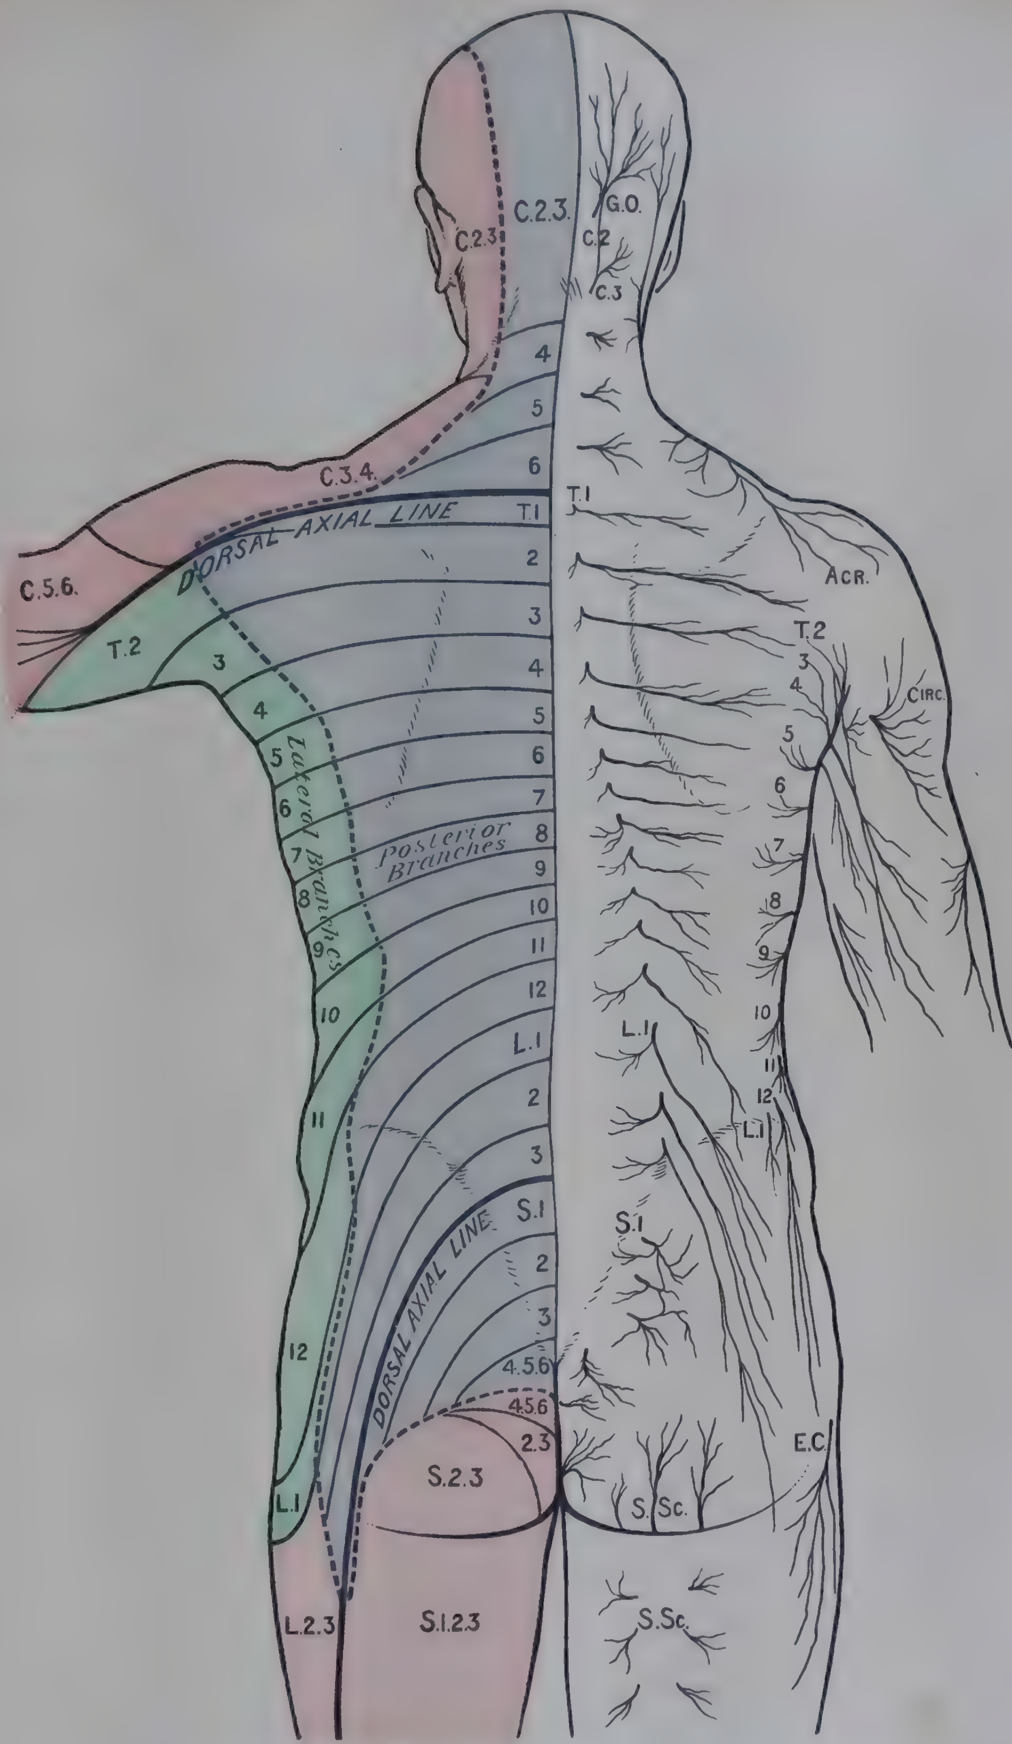

FIG. 916.—DISTRIBUTION OF CUTANEOUS NERVES ON THE BACK OF THE TRUNK.

On the right side of the figure the distribution of the several named nerves is represented.

G.O. (C.2), Greater occipital; C.3, Third occipital; T.1, L.1, S.1 *et seq.*, Posterior primary rami of thoracic, first three lumbar, and sacral nerves; Acr., Supraclavicular branches from cervical plexus; T.2-12. Lateral branches of thoracic nerves; Circ. Cutaneous branches of circumflex nerve; L.1, Lateral cutaneous branch of ilio-hypogastric nerve; E.C., Lateral cutaneous nerve of thigh; S.Sc., Posterior cutaneous nerve of thigh.

On the left side a schematic representation is given of the segmental areas (dermatomes) supplied by the above nerves, the numerals indicating the spinal origin of the branches of distribution to each area. For the lower part of the trunk and upper part of the thigh, cf. Figs. 942 and 945, based on more recent clinical data.

The **muscular branches** of the second cervical nerve are destined for the semispinalis capitis, obliquus inferior, semispinalis cervicis, and multifidus.

Associated with the posterior primary ramus is the **posterior cervical plexus**. Descending over the posterior arch of the atlas is a branch from the first cervical nerve which forms a loop or network with a branch of the second nerve. From that loop twigs are supplied to

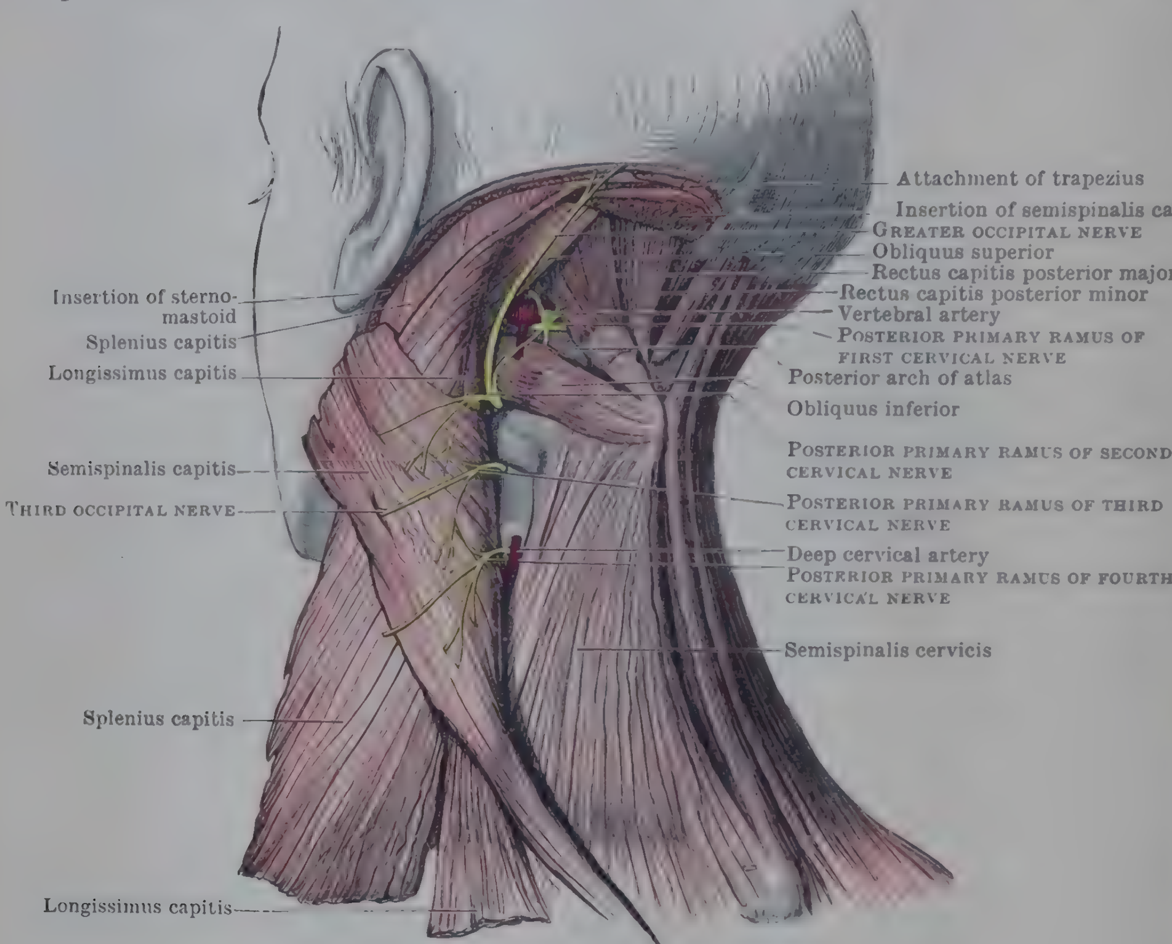

FIG. 917.—POSTERIOR CERVICAL PLEXUS.

the surrounding muscles. A similar loop is formed by a communication between the posterior primary rami of the second and third nerves, from which also muscles are supplied. Occasionally an additional loop is formed between the posterior primary rami of the third and fourth nerves.

Third Cervical Nerve.—This *posterior primary ramus* is much smaller than that of the second nerve. Near its origin it forms a loop of communication with the second, and it may give off a similar communicating branch to the fourth nerve. The main trunk divides into a medial, cutaneous branch, and a lateral, muscular, branch. The lateral branch enters contiguous muscles; the medial branch passes backwards and medially and becomes superficial as the **third occipital nerve** close to the median plane of the neck. It supplies fine branches to the skin and fascia of the neck and scalp, and it communicates with the greater occipital nerve.

The **posterior primary rami** of the **fourth, fifth, and sixth cervical nerves** are still smaller. Deep to the semispinalis capitis each divides into a lateral (muscular) and a medial (cutaneous) branch. The muscular branches supply neighbouring muscles; the cutaneous branches are small nerves which pass backwards and become superficial close to the median plane. They supply the skin of the back of the neck. The sixth is the smallest, and the cutaneous branches of the fifth and sixth nerves may be absent altogether. In certain cases the fourth nerve forms, with the third, a loop of communication from which muscles are supplied.

Seventh and Eighth Cervical Nerves.—These are the smallest of the posterior primary rami of the cervical nerves. They give off ordinarily no cutaneous branches, and they end in the deep muscles of the back. There is occasionally a small cutaneous offset from the eighth nerve.

THORACIC NERVES

The *posterior primary ramus* of each thoracic nerve divides into a **medial** and a **lateral branch.** The medial branches of the upper six or seven thoracic nerves are distributed chiefly as *cutaneous* nerves—their muscular twigs being very small—while the lateral branches are *muscular* in their distribution; in the case of the lower five or six thoracic nerves the opposite is the case. In all of them the muscular branches innervate the longitudinal muscles of the back. The distribution of the cutaneous branches is therefore different in the upper and lower part of the back. The **medial cutaneous branches** of the *upper six* or *seven* thoracic nerves innervate the skin and fascia of the scapular region; after a sinuous, backward course among the dorsal muscles, they reach the surface near the spines of the vertebræ and are directed laterally and almost horizontally over the trapezius muscle. The first is small; the second is very large and reaches the acromion. The rest diminish in size from above downwards, and become more and more oblique in direction. The **lateral cutaneous branches** of the *lower five* or *six* thoracic nerves are directed from their origin obliquely downwards and laterally among the parts of the sacro-spinalis muscle. Becoming cutaneous after piercing the latissimus dorsi at some distance from the median plane, they supply the skin and fascia of the back in the lower part of the chest and loin, the lowest nerves (eleventh and twelfth) passing over the iliac crest into the gluteal region. The lower nerves often divide into two branches before or after they emerge from the latissimus dorsi muscle. Owing to the obliquity of their course, each of those cutaneous branches supplies an area of skin which lies at an increasingly lower level than does the posterior primary ramus from which the branch arises, thus accounting for the change in the disposition of the dermatomes, compared with the more horizontal arrangement in the upper thoracic region (Fig. 916).

LUMBAR NERVES

The *posterior primary rami* of the **first three lumbar nerves** divide into medial and lateral branches in the same way as the lower thoracic nerves. The medial branches are muscular and innervate the deep muscles of the back. The lateral branches are chiefly cutaneous. They are directed obliquely downwards and laterally among the fibres of the sacro-spinalis and become superficial by piercing the lumbar fascia just above the iliac crest and a short distance in front of the posterior superior iliac spine. They are then directed downwards in the superficial fascia of the gluteal region, and supply a lengthy strip of skin, extending from the median plane above the iliac crest to a point distal to and behind the greater trochanter of the femur. There may be only two cutaneous branches, derived from the first two lumbar nerves.

The *posterior primary rami* of the **fourth and fifth lumbar nerves** (like those of the last two cervical nerves) usually supply only muscular branches to the longitudinal muscles of the back. The fifth nerve in many cases sends a branch to form a loop of connexion with the posterior primary ramus of the first sacral nerve, contributing to the posterior sacral plexus.

SACRAL AND COCCYGEAL NERVES

The *posterior primary rami* of the sacral nerves issue from the posterior sacral foramina. As in the case of the thoracic and lumbar nerves, the upper sacral nerves differ from the lower in their distribution.

The *posterior primary rami* of the **first three sacral nerves** supply medial muscular branches for the multifidus and lateral cutaneous branches which pierce the fibres of the sacro-tuberous ligament and the gluteus maximus muscle, and supply the skin and fascia over the back of the sacrum and contiguous part of the gluteal region, giving rise to the posterior sacral plexus.

The **posterior sacral plexus** consists, like the posterior cervical plexus, of loops or plexiform communications over the back of the sacrum between the posterior primary rami

of the first three sacral nerves, to which are frequently joined branches of the last lumbar nerve and the fourth and even the fifth sacral nerve. From those loops branches proceed to supply the multifidus muscle; others pierce the sacro-tuberous ligament and form secondary loops deep to the gluteus maximus muscle. From the secondary loops two or more cutaneous branches arise, which, after traversing the muscle, supply the skin and fascia over the sacrum and medial part of the gluteal region.

The *posterior primary rami* of the **fourth and fifth sacral nerves** do not divide into medial and lateral branches. They unite together to form a loop which is joined by the minute *posterior primary ramus* of the **coccygeal nerve.** The union of the three constitutes a nerve which, after perforating the sacro-tuberous ligament, is distributed to the skin and fascia in the neighbourhood of the coccyx. It supplies no muscles. This nerve is the representative of the **superior caudal trunk** of tailed animals.

Morphology of Posterior Primary Rami

1. Muscular Distribution.—In their muscular distribution they are strictly limited to the longitudinal muscles of the back: namely, those associated with the axial skeleton alone.

2. Cutaneous Distribution.—Their cutaneous distribution presents two points of interest.

A. In the first place, while the skin of the back is supplied in a fairly regular segmental manner by the several nerves, certain of them fail to reach the surface at all. The absence of a cutaneous branch from the first cervical nerve may be due either to the absence of a perfect posterior root, or to its communication with the second nerve. The other nerves which do not usually supply the skin are the last two, three, or four cervical, and the fourth and fifth lumbar nerves. Those nerves are placed in the centre of regions in which the upper and lower limbs are developed. They are minute nerves, while the corresponding anterior primary rami are among the largest of the spinal nerves. Thus opposite the centre of each limb posteriorly there is a hiatus in the segmental distribution of the posterior primary rami of the spinal nerves to the skin of the shoulder and gluteal region, attributable to the formation of the limbs and the extension into them of the greater part of the nerves of the region. The gap, in the case of the upper limb, begins at the level of the vertebra prominens; in the case of the lower limb it commences at the level of the posterior superior iliac spine. It can be continued on to each limb as a hypothetical area (the **dorsal axial line**) which indicates the area of contact (and overlapping) of cutaneous nerves not in strictly numerical sequence. Thus, in the region of the shoulder, the sixth (or fifth) cervical nerve innervates an area of skin adjoining that supplied by the eighth cervical or first thoracic nerve; in the gluteal region the third lumbar nerve supplies an area contiguous with that supplied by the fifth lumbar or first sacral nerve (Fig. 916).

B. The cutaneous branches of the posterior primary rami of the spinal nerves differ from the muscular branches in respect of their penetration into regions beyond those supplied by their motor roots. The cutaneous branches, in regions where outgrowths or extensions from the trunk have occurred, follow those extensions; and, in consequence, supply skin covering parts which do not belong to segments represented by the nerves in question. Thus the second and third cervical nerves (greater and third occipital) are drawn upwards so as to supply the posterior part of the *scalp*; the upper thoracic nerves are drawn laterally over the *scapular region*; the upper lumbar and sacral nerves supply the skin of the *gluteal region*; and the lower lumbar and coccygeal nerves form a rudimentary *caudal nerve.*

3. Plexuses.—The plexuses formed by the posterior primary rami of the upper cervical and upper sacral nerves are the simplest met with in the human body. The posterior cervical plexus is one from which muscular branches are supplied; the posterior sacral plexus is mainly concerned with cutaneous offsets.

ANTERIOR PRIMARY RAMI OF SPINAL NERVES

The **anterior primary rami** of the spinal nerves are, with the exception of the first two cervical nerves, much larger than the posterior primary rami. Composed of elements of both posterior and anterior roots, each nerve separates from the posterior primary ramus on emerging from the intervertebral foramen, and, proceeding laterally, is distributed to structures on the lateral and anterior aspects of the body—including the limbs.

Each nerve is joined near its origin by a **grey ramus communicans** from the corresponding sympathetic trunk; and in the case of the thoracic and certain lumbar nerves the anterior primary ramus gives off a delicate bundle of fibres which forms the **white ramus communicans** to the sympathetic trunk. From two of the sacral nerves white rami (belonging to the parasympathetic) pass to the pelvic plexuses of the autonomic nervous system; those rami form the *pelvic splanchnic*

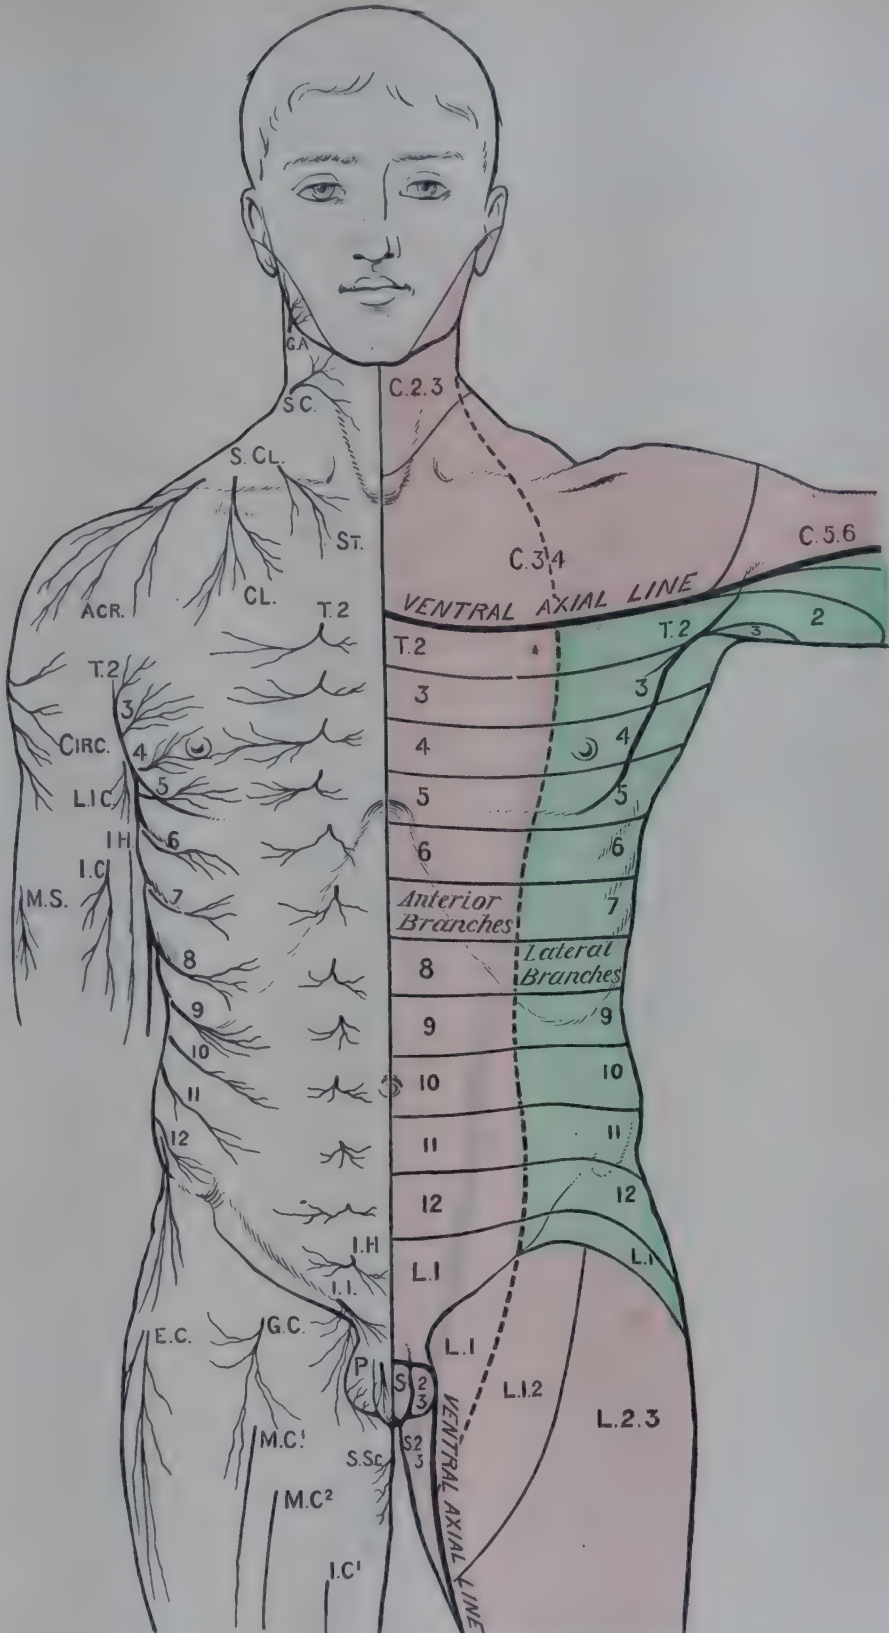

Fig. 918.—Distribution of Cutaneous Nerves on the Front of the Trunk.

On the left side of the figure the distribution of the several named nerves is represented.

G.A., Great auricular nerve; S.C., anterior cutaneous nerve of the neck; S.Cl., Supraclavicular nerves:—Acr., Lateral; Cl., Intermediate; St., Medial. T.2-12, Lateral and anterior branches of thoracic nerves; I.H. (below) Ilio-hypogastric nerve; I.I., Ilio-inguinal nerve; Circ., Cutaneous branch of circumflex nerve; L.I.C., Medial cutaneous nerve of the arm; I.H. (above) Intercosto-brachial; I.C., Medial cutaneous nerve of the forearm; M.S., Cutaneous branch of radial nerve; E.C., Lateral cutaneous nerve of thigh; G.C., Femoral branch of genito-femoral nerve; M.C.[1], [2], Branches of intermediate cutaneous nerve of thigh; I.C.[1], Branch of medial cutaneous nerve of thigh; P., Branches of pudendal nerve; S.Sc., Branches of posterior cutaneous nerve of the thigh.

On the right side a schematic representation is given of the segmental areas (dermatomes) supplied by the above nerves, the numerals indicating the spinal origin of the branches of distribution to each area. For the lower part of the trunk and upper part of the thigh, cf. Fig. 942, based on more recent clinical data.

nerve on each side as they extend towards the plexuses. That part of a spinal nerve which is distributed to the skeletal musculature and skin of the body-wall and limbs may be termed **somatic** ; the small white ramus communicans, innervating structures in the splanchnic area as well as blood-vessels and sweat-glands in the body-wall and limbs, may be termed the **visceral** or **splanchnic** part of a spinal nerve.

The anterior primary rami of the spinal nerves are distributed in a regular segmental manner only in certain cases. Except in the case of the thoracic nerves, the anterior primary rami combine to form **plexuses**—cervical, brachial, and lumbar, sacral and coccygeal—and their arrangement and distribution is exceedingly complex.

An **intercostal nerve,** such as the fifth or sixth, may be regarded as a type to illustrate the mode of distribution of the anterior primary rami of the spinal nerves (Fig. 913, p. 1050). It occupies an intercostal space; near its origin it possesses *grey* and *white rami communicantes*; it courses through the interval between the innermost and internal intercostal muscles and occupies the subcostal groove of the upper rib bounding the space; it supplies branches to those muscles and gives off, when it reaches the side of the chest, a large *lateral cutaneous branch*, which, after supplying small muscular branches, pierces the overlying intercostal muscles and is distributed to an area of skin and fascia over the lateral part of the trunk contiguous dorsally with a similar area innervated by the cutaneous branches of the posterior primary ramus of the same nerve. The lateral branch generally divides into a smaller *posterior* and a larger *anterior branch* as it pierces the muscles clothing the wall of the chest. The main trunk of the nerve, having given off its lateral branch, then pursues its course obliquely forwards to the side of the sternum, where, after piercing the pectoral muscles, it terminates superficially as the anterior cutaneous branch. A *collateral branch* of the main nerve is commonly present and runs close to the lower rib of the space concerned (Davies, Gladstone & Stibbe, 1932). It may arise quite far back in the space and continue as a separate trunk to the anterior end of the space and there become cutaneous, or it may rejoin the main nerve in its course round the chest-wall. The *anterior cutaneous branch* supplies an area of skin and fascia continuous with that

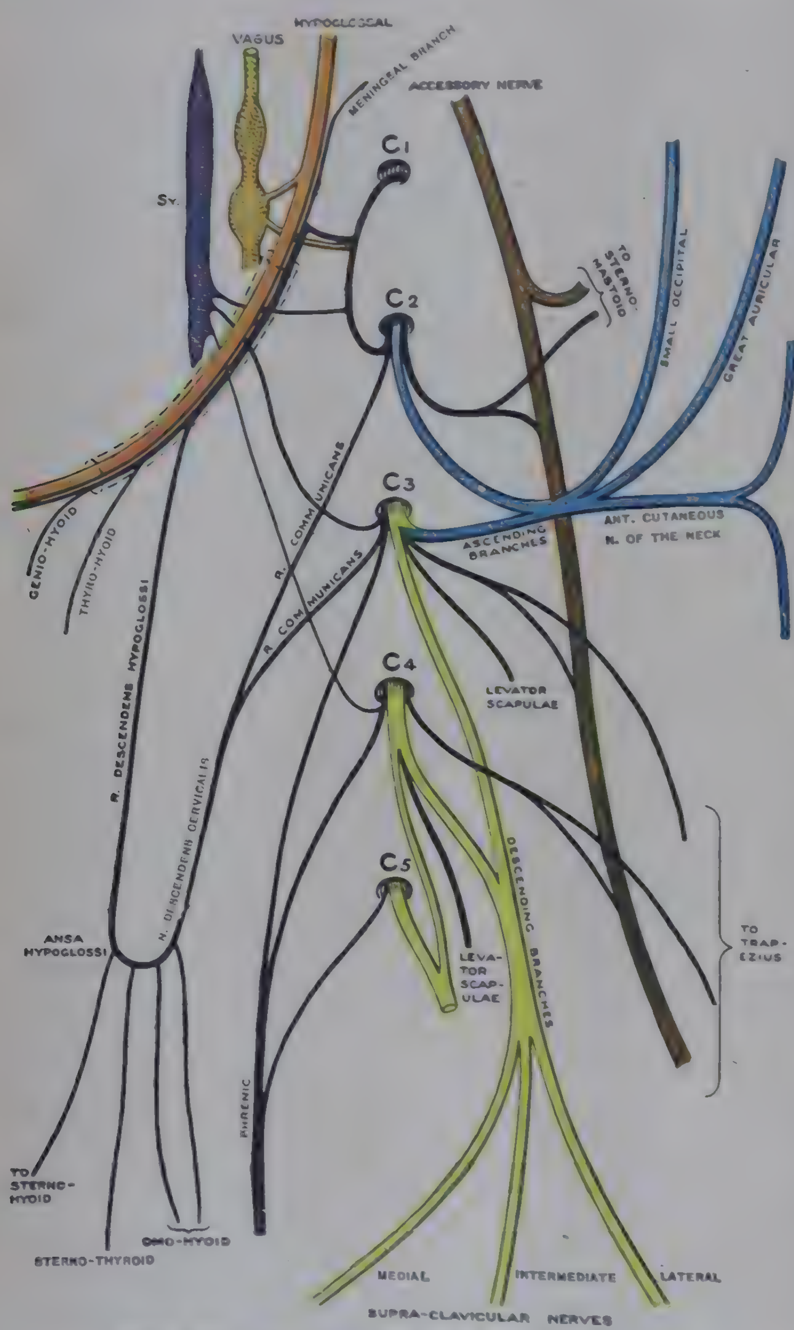

FIG. 919.—DIAGRAM OF LEFT CERVICAL PLEXUS.

supplied by the anterior part of the lateral branch of the same nerve. Such a nerve thus supplies, by means of its lateral and anterior branches, an area of skin which (with the area supplied by the cutaneous branch of its posterior primary ramus) forms a continuous and uninterrupted belt (*i.e.*, a dermatome), extending from the median plane behind to the median plane in front. The lateral and anterior branches of the nerve innervate in their course the intercostal and other muscles, to be mentioned in detail later.

CERVICAL NERVES

The *anterior primary rami* of the cervical nerves, together with parts of the first and second thoracic nerves, are distributed to the head, neck, and upper limb. The first four cervical nerves, by means of the **cervical plexus**, innervate the neck; the last four cervical nerves, together with a large part of the first thoracic nerve, through the **brachial plexus**, supply the upper limb. The second thoracic nerve may contribute to this plexus, and always assists in the innervation of the arm.

The *anterior primary ramus* of the **first cervical nerve** emerges from the vertebral canal by passing over the posterior arch of the atlas deep to the vertebral artery; it curves forwards round the lateral side of the upper articular process of that vertebra, lying medial to the vertebral artery, and, after passing between the rectus capitis lateralis and rectus capitis anterior, it descends in front of the transverse process of the atlas to form a loop with the ascending branch of the second cervical nerve. A large part of its fibres joins the hypoglossal nerve (*vide infra*).

The *anterior primary ramus* of the **second cervical nerve** passes between the vertebral arches of the first two vertebræ, behind the upper articular process of the axis. It curves forwards on the lateral side of the vertebral artery and divides into an ascending portion, which unites with the first cervical nerve and also contributes fibres to the hypoglossal nerve, and a descending part, which joins the third cervical nerve and takes part in the cervical plexus.

CERVICAL PLEXUS

The *anterior primary rami* of the first four cervical nerves are concerned in forming the **cervical plexus.** Each nerve emerges from the vertebral canal posterior to the vertebral artery. Each is joined on its emergence from the intervertebral foramen at the side of the vertebral column by one or more **grey rami communicantes** from the superior cervical ganglion of the sympathetic trunk. In the neck the cervical nerves are concealed at their origins by the sterno-mastoid muscle; in front lies the longus capitis muscle, and behind are the scalenus medius, and (behind the first nerve) the rectus capitis lateralis. The cervical plexus is constituted by the combination of the four nerves in an irregular series of loops under cover of the sterno-mastoid muscle and overlapped by the internal jugular vein.

From the loops of the plexus the branches of distribution arise, as (*a*) **cutaneous branches** to the head, neck, and shoulder; (*b*) **muscular branches** to muscles of the neck and to the diaphragm; and (*c*) **communicating branches** to the vagus, accessory, hypoglossal, and sympathetic nerves (Figs. 919, 922).

For convenience of description, the nerves derived from the plexus may be classified as follows:—

I. Superficial (Cutaneous) Branches—

A. **Ascending Branches** (C. 2, 3).
Lesser occipital,
Great auricular,
Anterior cutaneous of the neck.

B. **Descending (supraclavicular) Branches** (C. 3, 4).
Medial supraclavicular,
Intermediate supraclavicular,
Lateral supraclavicular.

II. Deep (Muscular and Communicating) Branches—

A. Lateral Branches.

1. Muscular branches to
   Sterno-mastoid (C. 2),
   Trapezius (C. 3, 4),
   Levator scapulæ (C. 3, 4),
   Scaleni (medius and posterior) (C. 3, 4).
2. Communicating branches to
   Accessory nerve (C. 2, 3, 4).

B. Medial Branches.

1. Muscular to
   Prevertebral muscles (C. 1, 2, 3, 4),
   Infrahyoid muscles (C. 1, 2, 3) (ansa hypoglossi),
   Diaphragm (C. 3, 4, 5) (phrenic nerve).
2. Communicating branches to
   Vagus nerve (C. 1, 2),
   Hypoglossal nerve (C. 1, 2),
   Ansa hypoglossi (C. 2, 3),
   Sympathetic (C. 1, 2, 3, 4).

The second, third, and fourth cervical nerves are the chief nerves engaged in forming the plexus.

Superficial Cutaneous Branches.—These nerves, six in number, are entirely cutaneous. They radiate from the plexus, and appear in the posterior triangle of the neck a little above the mid-point of the posterior border of the sterno-mastoid muscle. They are divisible into two series—(1) the **ascending**: lesser occipital, great auricular, and the anterior cutaneous nerve of the neck; (2) **descending** (supraclavicular): lateral, intermediate and medial.

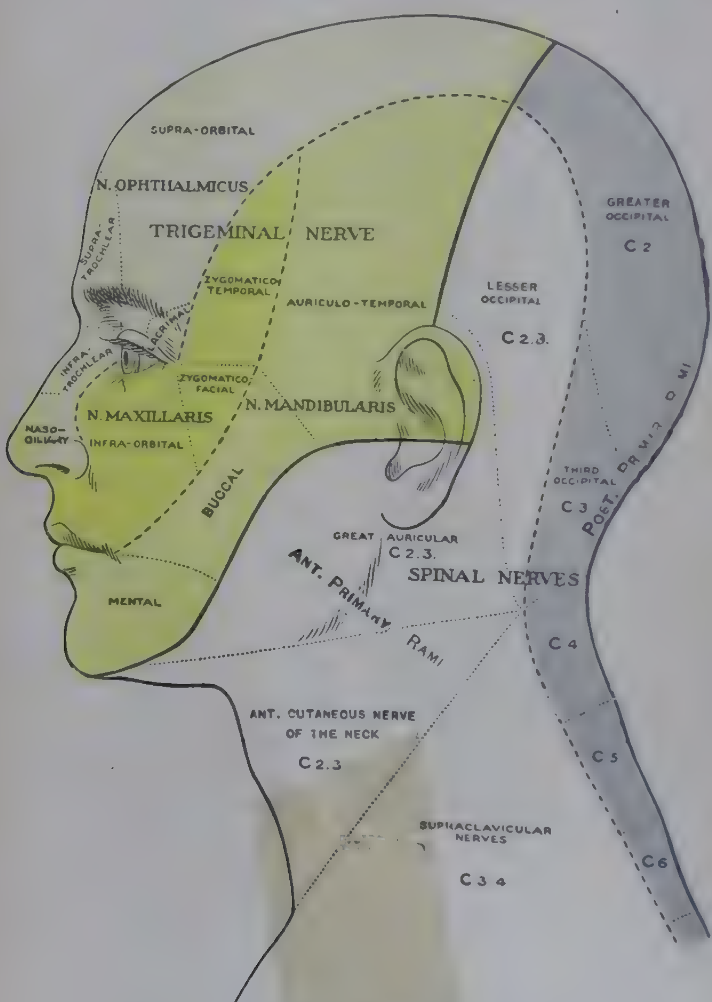

FIG. 920.—DISTRIBUTION OF CUTANEOUS NERVES TO HEAD AND NECK.

Ascending Branches.—The **lesser occipital nerve** is variable in size and is sometimes double. Its origin is from the second and third cervical nerves (more rarely from the second only). It extends backwards under cover of the sterno-mastoid, and then upwards along its posterior border. Piercing the deep fascia near the apex of the posterior triangle, it divides into branches for the supply of the skin and fascia of the upper part of the neck, the cranial surface of the auricle and part of the scalp adjoining. The nerve communicates on the scalp with the greater occipital and great auricular nerves, and with the posterior auricular branch of the facial nerve.

The **great auricular nerve** is the largest of the cutaneous branches. It arises from the second and third cervical nerves (or, more rarely, from the third alone). Winding round the posterior border of the sterno-mastoid muscle, it proceeds upwards and forwards towards the front of the auricle. In its course it crosses the sterno-mastoid muscle obliquely and is covered by the platysma muscle. Before arriving at the auricle it subdivides into three groups of branches. The posterior ascend over the mastoid process and supply the skin and fascia of the scalp immediately behind the auricle, communicating with the lesser occipital

and posterior auricular nerves. The middle ones ascend to the auricle and supply its lower part on both surfaces; their communications are similar to those of the posterior branches. The anterior pass over the angle of the mandible and through the substance of the parotid gland to supply the skin and fascia of the face over the inferior part of the masseter muscle and the parotid gland. They communicate with branches of the facial nerve in the parotid gland.

The **anterior cutaneous nerve of the neck** arises from the second and third cervical

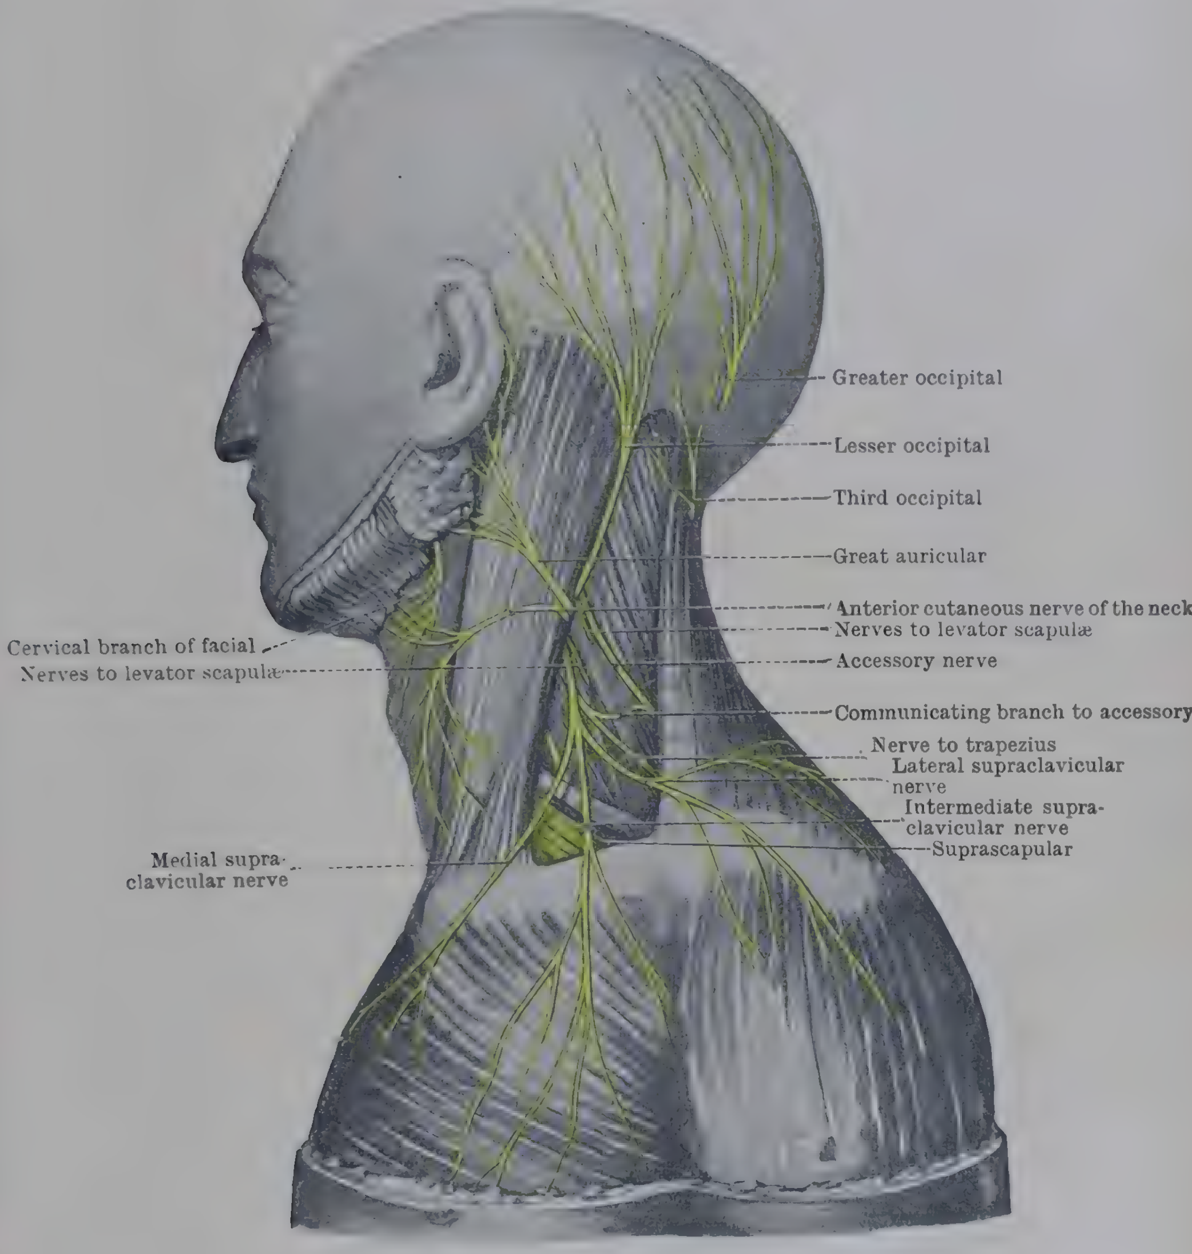

FIG. 921.—NERVES OF SIDE OF NECK.

nerves. It winds round the posterior border of the sterno-mastoid muscle, and crosses the muscle to reach the anterior triangle, under cover of the platysma muscle and the external jugular vein. It divides near the anterior edge of the sterno-mastoid muscle into superior and inferior branches which are distributed through the platysma to the skin and fascia covering the anterior triangle of the neck. The upper branches communicate freely, under cover of the platysma, with the cervical branch of the facial nerve.

Descending (Supraclavicular) Branches.—By the union of two roots derived from the third and fourth cervical nerves a considerable trunk is formed which emerges from under cover of the sterno-mastoid muscle and extends obliquely downwards through the inferior part of the posterior triangle of the neck. It subdivides into radiating branches—**medial, intermediate,** and **lateral**—which pierce the deep fascia of the neck above the clavicle, and are distributed to the skin and fascia

of the inferior part of the side of the neck, to the front of the chest, and the shoulder. The **medial branches** are the smallest. They pass over the medial part of the clavicle, and supply the skin and fascia of the neck and chest as far down as the angle of the sternum. Twigs of supply are given also to the sterno-clavicular joint. The **intermediate branches** pass over the intermediate third of the clavicle, deep to the platysma, and can be traced as low as the third rib. These branches may groove the clavicle, and one of them may even pierce it. The **lateral branches** pass over or through the insertion of the trapezius muscle and over the lateral third of the clavicle to the shoulder, where they supply the skin and fascia as far down as the distal third of the deltoid muscle. Occasionally one of these branches pierces the clavicle. Small twigs assist in the supply of the acromio-clavicular joint.

Deep Branches.—The deep branches of the cervical plexus are separated into a **lateral** and a **medial set**. Deep to the sterno-mastoid muscle, the lateral branches are directed laterally towards the posterior triangle; the medial branches pass medially towards the anterior triangle.

The **lateral branches** consist of muscular and communicating nerves, which for the most part lie in the posterior triangle.

The **muscular branches** are the following: (1) To the *sterno-mastoid*, from the second cervical nerve; it enters the muscle on its deep surface and communicates with the accessory nerve. (2) To the *trapezius*, from the third and fourth cervical nerves; these branches cross the posterior triangle and end in the trapezius, after communicating with the accessory nerve, both in the posterior triangle, and under cover of the muscle. (3) To the *levator scapulæ*, from the third and fourth cervical nerves; two independent branches enter the lateral surface of the muscle in the posterior triangle. (4) To the *scaleni* (medius and posterior), from the third and fourth cervical nerves.

The **communicating branches** are three in number. They join the accessory nerve in three situations: (*a*) A branch from the second cervical nerve to the sterno-mastoid joins the accessory nerve *under cover of that muscle.* (*b*) Branches to the trapezius from the third and fourth nerves are connected with the accessory nerve *in the posterior triangle.* (*c*) Branches from the same nerves join the accessory *under cover of the trapezius muscle.*

The **medial branches** of the plexus also comprise muscular and communicating branches. The anterior ramus of the first cervical nerve assists in the formation of this series of nerves, forming a slender loop with part of the second nerve in front of the transverse process of the atlas.

Communicating Branches.—(*a*) *With the sympathetic.*—A grey ramus communicans passes to each of the first four cervical nerves, near its origin, from the superior cervical ganglion or from the trunk below the ganglion. (*b*) *With the vagus nerve.*—The inferior ganglion of the vagus may be connected by a slender nerve with the loop between the first two cervical nerves. That communication is not constant. (*c*) *With the hypoglossal.*—An important communication occurs between the hypoglossal nerve and the loop between the first and second cervical nerves (Figs. 909, 919). A branch from the loop joins the hypoglossal just beyond its exit from the skull; some cervical fibres are then carried upwards along the hypoglossal to the cranium (*meningeal branch*), but the main group of cervical fibres descends with the hypoglossal and subsequently leaves it as three branches—the **descending branch** (ramus descendens), and the **branches to the thyro-hyoid** and **genio-hyoid muscles**. It is probable that no part of the hypoglossal nerve itself is concerned in the formation of those three branches. The descending branch of the hypoglossal descends in front of the internal and common carotid arteries, and is joined under cover of the sterno-thyroid muscle by the **nervus descendens cervicalis** which winds obliquely round the internal jugular vein to form the **ansa hypoglossi**, from which the infrahyoid muscles, except the thyro-hyoid, are innervated. (The "descending branch of the hypoglossal", in some cases, arises from the vagus nerve.)

Muscular Branches.—The muscles supplied by the medial branches of the plexus are the prevertebral muscles, the genio-hyoid and the infrahyoid muscles, and the diaphragm.

(*a*) **Prevertebral Muscles.**—(1) From the loop between the first and second cervical nerves a small branch arises for the supply of the rectus capitis lateralis, longus capitis, and the rectus capitis anterior. (2) From the second, third, and fourth nerves small branches supply the intertransverse, longus cervicis, and longus capitis muscles. (3) From the third and fourth nerves a branch arises for the supply of the scaleni (medius and posterior).

(*b*) **Genio-Hyoid and Infrahyoid Muscles.**—The **nervus descendens cervicalis** is formed in front of the internal jugular vein by the union of two slender trunks from the second and third cervical nerves. It forms a loop of communication in front of the carotid sheath with the descending branch of the hypoglossal nerve (derived ultimately from the first two cervical nerves). The loop of communication is called the **ansa hypoglossi.** It is often plexiform; and from it branches are given to the sterno-hyoid and sterno-thyroid muscles and both bellies of the omo-hyoid muscle. The nerve to the sterno-hyoid muscle is often continued behind the sternum, to join, in the thorax, with the phrenic nerve or the cardiac plexus.

The thyro-hyoid and genio-hyoid muscles are supplied by branches of the hypoglossal nerve, but the fibres concerned are derived from the loop between the first two cervical nerves.

The anterior muscles in immediate relation to the median plane of the neck, between the chin and the sternum, are thus continuously supplied by the first three cervical nerves. The hypoglossal is the source of supply to the intrinsic muscles of the tongue, and it is improbable that it contributes any fibres to the above-named muscles.

(*c*) **Diaphragm.**—The phrenic nerve supplies the diaphragm.

Phrenic Nerve

The **phrenic nerve** is derived mainly from the **fourth cervical nerve**, reinforced by roots from the third (either directly or through the nerve to the sterno-hyoid) and fifth (either directly or through the nerve to the subclavius muscle). It runs downwards in the neck upon the scalenus anterior muscle postero-lateral to the internal jugular vein; at the root of the neck it passes between the subclavian artery and vein, enters the thorax and traverses the mediastinum to reach the diaphragm, lying in the middle mediastinum between the pericardium and pleura and anterior to the root of the lung. In its course it presents certain differences on the two sides. In the neck, on the left side, it crosses the first part of the subclavian artery; on the right side it crosses the second part. On both sides after crossing the subclavian artery the nerve deviates medially and crosses in front of the internal mammary artery; occasionally on the left side the nerve may run behind that artery. In the superior mediastinum, on the left side, it lies between the left subclavian and carotid arteries, and crosses lateral to the vagus nerve and the aortic arch. On the right side it accompanies the innominate vein and superior vena cava, and has no direct relationship with the vagus nerve. The right nerve sends fibres along the inferior vena cava through the hiatus venæ cavæ. Reaching the diaphragm the nerve separates into numerous branches for the supply of the muscle; some enter its thoracic surface (subpleural branches), but most of the fibres supply it after piercing the muscle (subperitoneal branches). It is apparent, from clinical observations, that the nerve contains some afferent fibres as well as motor.

The **branches of the phrenic nerve** are:—(1) Muscular (to the diaphragm); (2) pleural (to mediastinal and diaphragmatic pleura); (3) pericardial; (4) abdominal (to diaphragmatic peritoneum and probably, through the phrenic and hepatic plexuses, to the inferior vena cava and the liver).

Of interest to the surgeon, particularly with reference to the operation of avulsion of the phrenic, is the occasional presence of an *accessory phrenic nerve.* It arises from the fifth or fifth and sixth cervical nerves and, after descending for a variable distance, joins the main nerve in the lower part of the neck or in the thorax. The accessory phrenic nerve not uncommonly arises from the nerve to the subclavius muscle.

Communications of Phrenic Nerve.—(1) As stated in the previous paragraph, the phrenic nerve may communicate with the nerve to the subclavius muscle, and with the fifth and sixth cervical nerves. (2) It may communicate with the *ansa hypoglossi*, or a branch from it (the nerve to the sterno-hyoid). (3) It frequently communicates with the cervical part of the sympathetic. (4) It communicates with the cœliac plexus by a junction on the abdominal surface of the diaphragm with the *phrenic plexus* on the phrenic artery, in which a small *phrenic ganglion* is found on the right side. From the junction branches are given off to the inferior vena cava and hepatic plexus.

Morphology of Cervical Plexus

The characteristic feature of the cervical plexus is the combination of parts of adjacent nerves into compound nerve-trunks by the formation of series of loops. The result of the formation of

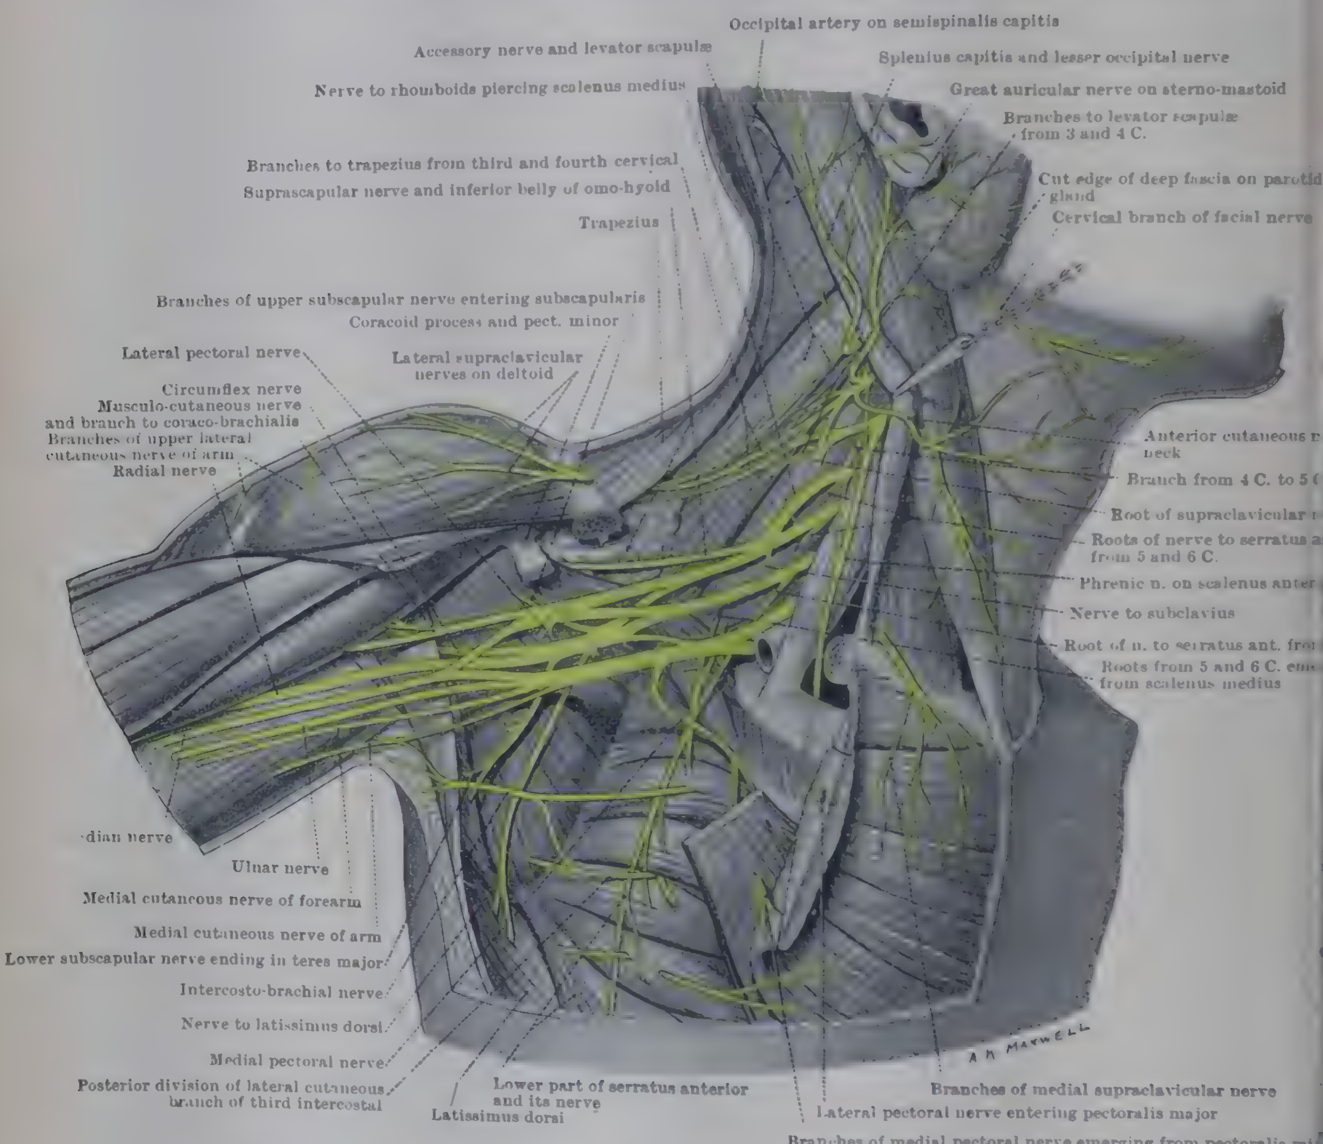

Fig. 922.—Posterior Triangle and Axilla, showing Cervical and Brachial Plexuses and Origin of their Principal Branches.

these loops is that parts (particularly cutaneous areas) are supplied by branches of more than one spinal nerve.

A. **Cutaneous Distribution.**—By the combinations of the nerves into loops the discrimination of the elements in the upper cervical nerves, corresponding to the lateral and anterior branches of a typical intercostal nerve, is made a matter of some difficulty. The second, third, and fourth nerves, through the cervical plexus, supply an area of skin extending laterally from the side of the head to the shoulder; anteriorly from the face to the level of the third rib. The higher nerves supply the upper region (second and third); the lower nerves supply the lower region (third and fourth). It is not possible to compare the individual nerves strictly with the lateral and anterior branches of an intercostal nerve. A line drawn from the auricle to the middle of the clavicle separates, however, a lateral from an anterior cutaneous area; and certain of the cutaneous nerves fall naturally into one of these two categories. The nerves homologous with the anterior continuations of the anterior branches of intercostal nerves are the anterior

cutaneous nerve of the neck and the medial branches of the supraclavicular series; those homologous with lateral branches are the lesser occipital and lateral supraclavicular branches. The great auricular and intermediate supraclavicular branches are mixed nerves, comprising elements belonging to both sets.

B. **Muscular Distribution.**—The nerves from the cervical plexus that supply muscles are simpler in their arrangement. They are not generally in the form of loops, and they are easily separated into lateral and medial series. The lateral nerves comprise the branches to the rectus capitis lateralis, sterno-mastoid, trapezius, levator scapulæ. The nerves in the medial series are those to the longus capitis, rectus capitis anterior, the hyoid muscles, and the diaphragm.

It is noteworthy that the last-named muscles—genio-hyoid, thyro-hyoid, sterno-hyoid, omohyoid, sterno-thyroid, and diaphragm—are continuously supplied by branches from the first five cervical nerves: the higher muscles by the higher nerves; the lower muscles by the lower nerves.

BRACHIAL PLEXUS

The **brachial plexus** is formed by the anterior primary rami of the fifth, sixth, seventh and eighth cervical nerves, along with the greater part of that of the first thoracic nerve. More often than not a slender branch of the fourth cervical nerve

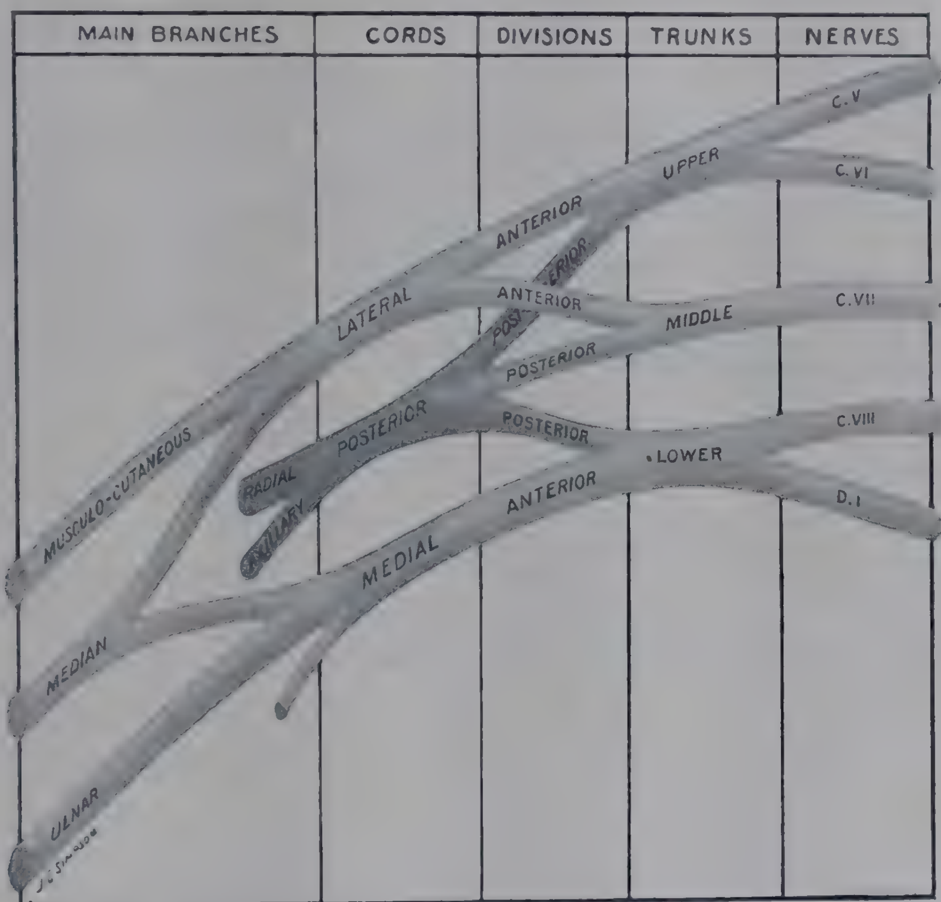

FIG. 923.—SCHEME TO SHOW STAGES OF FORMATION OF BRACHIAL PLEXUS.

is also engaged; and the second thoracic nerve always contributes to the innervation of the arm through the intercosto-brachial nerve. Frequently it contributes also directly to the plexus by an intrathoracic communication with the first thoracic nerve.

Position of the Plexus.—The nerves that contribute to the brachial plexus appear in the posterior triangle of the neck between the scalenus anterior and scalenus medius muscles in series with the nerves that form the cervical plexus (Fig. 922). In the triangle the plexus is covered by the skin, platysma, supraclavicular nerves, and the deep fascia, and is crossed by the nerve to the subclavius muscle, external jugular vein, inferior belly of the omo-hyoid muscle, and the transverse cervical artery, which vessel sometimes passes between its branches. At the root of the neck the plexus passes behind the clavicle, subclavius muscle, and suprascapular vessels, and it lies above and behind the third part of the subclavian artery. In the axilla its cords and branches surround the axillary artery.

Constitution of Brachial Plexus.—Whilst liable to some variation in the sequence of separation and junction of its individual parts, in a typical plexus four stages may always be identified:—

(1) The undivided anterior primary rami of the nerves.
(2) The formation of three trunks.
(3) The separation of each trunk into an anterior and a posterior division.
(4) The union of the divisions to form three cords from which the principal nerves of distribution originate.

(1) The undivided **nerves** or **roots of the plexus** have only a very short independent course at the side of the neck whilst passing between the scalene muscles.

(2) Immediately after entering the posterior triangle, there are formed three **trunks** in order from above downwards: the *upper trunk* is formed by the union of the fifth and sixth nerves; the *middle trunk* is always formed by the seventh

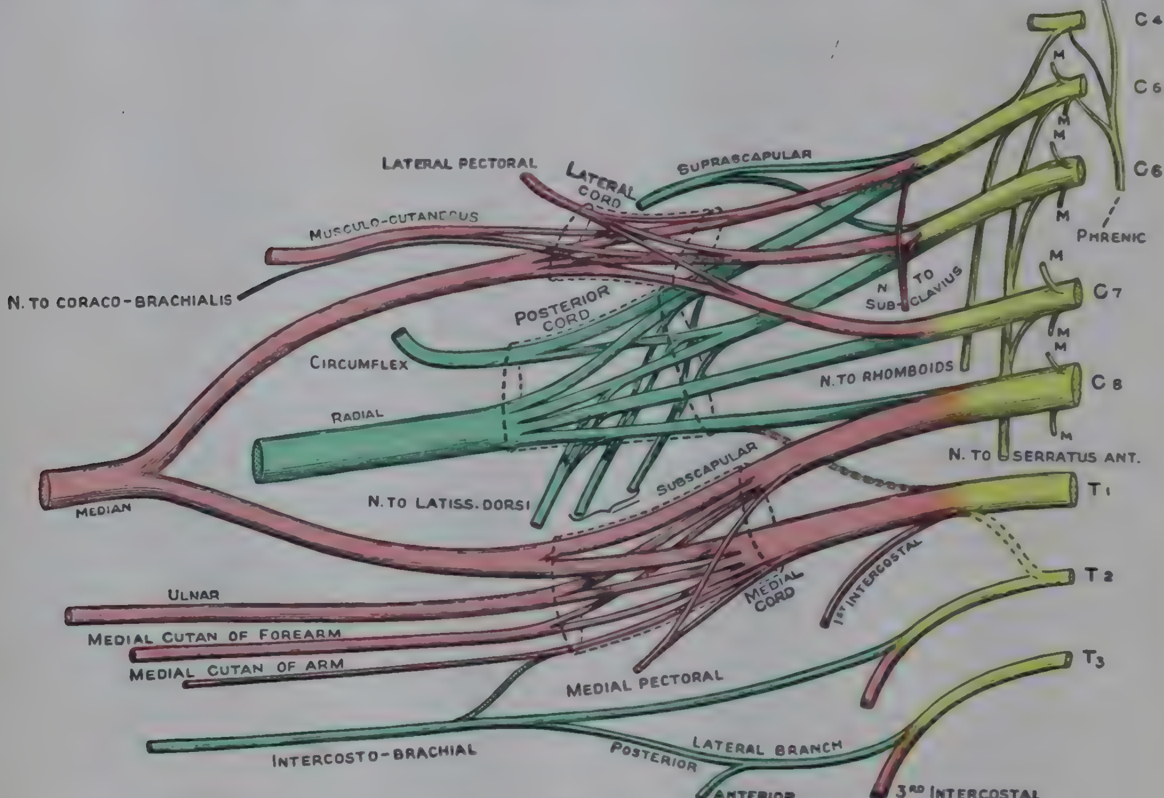

FIG. 924.—DIAGRAM OF BRACHIAL PLEXUS, SHOWING THE ORIGINS OF ITS BRANCHES.

nerve alone; and the *lower trunk*, by the union of the eighth cervical and first thoracic nerves. The lower trunk often grooves the upper surface of the first rib behind the groove for the subclavian artery.

(3) Each trunk divides into anterior and posterior **divisions**, which represent corresponding separation of the nerves; sometimes the nerves themselves divide before or during the formation of the trunks, making identification of those two stages difficult. The anterior and posterior divisions of the fifth, sixth, and seventh nerves are nearly equal in size; the posterior division of the eighth cervical nerve is much smaller; and that of the first thoracic nerve is minute and may not be present at all. The division is of morphological significance, since it indicates the separation of the nerve-fibres destined for the supply of the originally ventral parts of the limb from those which supply the dorsal parts.

(4) The **cords** of the plexus are formed by combinations of the anterior and posterior divisions. They are three in number, and lie in relation to the axillary artery. The *lateral cord* is formed by union of the anterior divisions of the upper and middle trunks, or of the fifth, sixth, and seventh nerves, and lies on the lateral side of the axillary artery. The *medial cord* is formed by the anterior division of the lower trunk, containing the corresponding division of the eighth nerve with the part of the first thoracic nerve; it lies on

the medial side of the axillary artery. The *posterior cord* is made up of the posterior divisions of all three trunks, that is, of the fifth, sixth, seventh, and eighth cervical and first thoracic nerves; it lies behind the axillary artery. The first thoracic nerve generally contributes a small branch to the posterior cord (Harris, 1939).

The **nerves of distribution** for the shoulder and arm are derived from the cords, and receive in that way various contributions from the constituent spinal nerves. *From the lateral cord* arise the lateral pectoral and musculo-cutaneous nerves, and the lateral root of the median nerve. *From the medial cord* arise the medial pectoral nerve, the medial cutaneous nerves of the arm and forearm, the ulnar nerve, and the medial root of the median nerve. *From the posterior cord* arise the two subscapular nerves, the nerve to the latissimus dorsi, the circumflex nerve, and the radial nerve.

It is to be remembered that, although derived from a cord formed by a certain set of spinal nerves, any given nerve does not necessarily contain fibres from all the constituent nerves; *e.g.*, the musculo-cutaneous and the circumflex nerves, from the lateral and posterior cords respectively, are ultimately derived only from the fifth and sixth cervical nerves. In other words, the cords are merely collections of nerves of distribution bound together in a common sheath in their passage through the axilla. It may be pointed out also that it is impossible in nearly all cases to dissect out and trace the fibres of a given spinal nerve through the plexus to their ultimate distribution, owing to the complex manner in which the nerve bundles interlace with one another.

Communications with Sympathetic.—The lower four cervical nerves communicate with the cervical portion of the sympathetic by means of **grey rami communicantes.** Commonly two branches arise from the middle cervical ganglion; they join the anterior primary rami of the fifth and sixth nerves. Two or more from the inferior cervical ganglion join the seventh and eighth nerves. They reach the nerves either by piercing the prevertebral muscles or by passing beneath the medial border of the scalenus anterior muscle. The sympathetic plexus associated with the vertebral artery gives branches (post-ganglionic fibres) to the fourth, fifth, and sixth cervical nerves.

Variations are found (1) in the number of nerves that take part in the formation of the plexus; and (2) in the pattern formed by the union and division of its constituent parts. (1) As regards the former, Kerr (1918), on an examination of 175 plexuses, forms three groups: (*a*) a part of the fourth nerve joins the plexus in nearly two-thirds; (*b*) no contribution is received from the fourth nerve. but all the fifth joins the plexus in one-third; (*c*) a part only of the fifth enters the plexus in about 7 per cent. At the lower end of the plexus there is an intrathoracic communication between the second and first thoracic nerves in one-third or more. These figures indicate a possible higher or lower position (prefixation or postfixation) of the plexus relative to the vertebral column, though it is evidently subject to very slight variation. The presence of a cervical rib may coincide with little or no change in the relation of the nerves. (2) Variations in the pattern of the plexuses are due to (*a*) the stage of either trunk-, divisional or even cord-formation being absent in one or other part of the plexus, prior to a succeeding stage; in all such cases, however, there is no alteration in the typical nerve-source of the ultimate terminal branches; (*b*) in very few cases the lateral or the medial cord may receive fibres from nerves below the seventh or above the eighth respectively—that is, a new element is introduced into their composition. (For further details concerning the brachial plexus see Herringham (1886), Harris (1904, 1939) and Wood Jones (1910).)

Branches of Brachial Plexus

It is customary to separate artificially the nerves of distribution of the brachial plexus into two sets: (1) supraclavicular and (2) infraclavicular, a topographical division which is, to some extent, affected by the alteration in position of the bone in raising or lowering the shoulder.

The point of junction of the three posterior divisions of the trunks to form the posterior cord has been found fairly constantly situated 6·75 cm., or $2\frac{3}{4}$ inches, horizontally lateralwards, from the lateral border of the common carotid artery at the root of the neck, the arm being fully abducted; a vertical line passing through this point separates the trunks from the cords (Linell, 1921).

Clinically it is important to realize the position of origin of the nerves relative to the different stages of formation of the plexus. (*a*) The nerves to the prevertebral muscles, the communication with the phrenic, the nerves to the rhomboids and serratus anterior arise from the *anterior primary rami* of the nerves involved in the plexus. (*b*) The suprascapular and the nerve to the subclavius

arise at the level of formation of the *trunks*. (*c*) The pectoral and subscapular nerves, the nerve to the latissimus dorsi, and the medial cutaneous nerves of the arm and forearm arise from the *cords*, prior to their ultimate division into the nerves of distribution for the upper limb. (*d*) All the rest are terminal branches.

Supraclavicular Branches.—The nerves derived from the plexus above the level of the clavicle are, like the main trunks, divisible into two series: **anterior branches**, arising from the front of the plexus; **posterior branches**, arising from the back of the plexus (Fig. 924).

(a) Arising from the Primary Rami.

Anterior Branches

1. Nerves to scalenus anterior and longus cervicis.
2. Communicating nerve to join the phrenic nerve.

Posterior Branches

1. Nerves to scalenus medius and scalenus posterior.
2. Nerve to the rhomboids.
3. Nerve to serratus anterior.

(b) Arising from the Trunks.

3. Nerve to the subclavius muscle.
4. Suprascapular nerve.

The **muscular twigs** to the anterior scalene and longus cervicis muscles arise from the lower four cervical nerves as they emerge from the intervertebral foramina.

The **communicating branch to the phrenic nerve** arises usually from the fifth cervical nerve at the lateral border of the anterior scalene muscle. It is sometimes absent, and occasionally an additional root is present from the sixth cervical nerve. In some instances the nerve is replaced by a branch which springs from the nerve to the subclavius, and passes medially behind the sterno-mastoid muscle to join the phrenic at the inlet of the thorax.

The **nerve to the subclavius** is a slender nerve which arises from the front of the upper trunk of the plexus, and usually receives fibres from the fourth, fifth, and sixth cervical nerves. It descends in the posterior triangle of the neck anterior to the third part of the subclavian artery. It often communicates with the phrenic nerve (see *accessory phrenic nerve*, p. 1065).

The **branches to the scalenus medius and scalenus posterior** are small, and arise from the lower four cervical nerves as they emerge from the intervertebral foramina.

The **nerve to the rhomboids** arises from the back of the fifth cervical nerve as it emerges from the intervertebral foramen. It appears in the posterior triangle of the neck, after piercing the scalenus medius muscle, and it passes downwards, under cover of the levator scapulæ and rhomboid muscles, and along the medial border of the scapula, to be distributed to the levator scapulæ, rhomboideus minor, and rhomboideus major muscles. It occasionally pierces the levator scapulæ.

The **nerve to the serratus anterior** arises by three roots, of which the middle one is usually the largest, from the back of the fifth, sixth, and seventh nerves as they emerge from the intervertebral foramina. The upper two roots pierce the scalenus medius and unite into one stem which is joined by the contribution from the seventh cervical nerve which passes in front of that muscle. The nerve descends in the neck behind the cords of the brachial plexus and enters the axilla between the superior edge of the serratus anterior muscle and the axillary artery. It continues downwards on the axillary surface of the serratus, to the slips of which it is distributed.

There is a more or less definite relation between the roots of the nerve and the parts of the serratus muscle. The upper part of the muscle is innervated by the fifth nerve alone; the middle part by the fifth and sixth, or the sixth alone; the lower part by the sixth and seventh, or the seventh nerve alone.

The **suprascapular nerve** arises from the back of the upper trunk of the plexus, receiving fibres from the fourth, fifth, and sixth cervical nerves. It occupies a position above the cords of the brachial plexus, and courses downwards and

laterally parallel to them towards the superior border of the scapula, where it passes through the suprascapular notch to the dorsum of the scapula. After supplying the supraspinatus muscle it passes through the spino-glenoid notch in company with the suprascapular artery and terminates in the infraspinatus muscle. It also supplies articular branches to the shoulder joint.

Infraclavicular Branches.—The so-called infraclavicular branches of the brachial plexus all arise from the *cords* of the plexus and are distributed to the chest, shoulder, upper arm, and forearm. According to their origin they are divisible into two sets—an **anterior set,** derived from the lateral and medial cords, and a **posterior set,** derived from the posterior cord. In their distribution the same arrangement is maintained. The anterior nerves of distribution, springing from the lateral and medial cords, supply the chest and the front of the limb; the posterior nerves, springing from the posterior cord, supply the shoulder and the back of the limb.

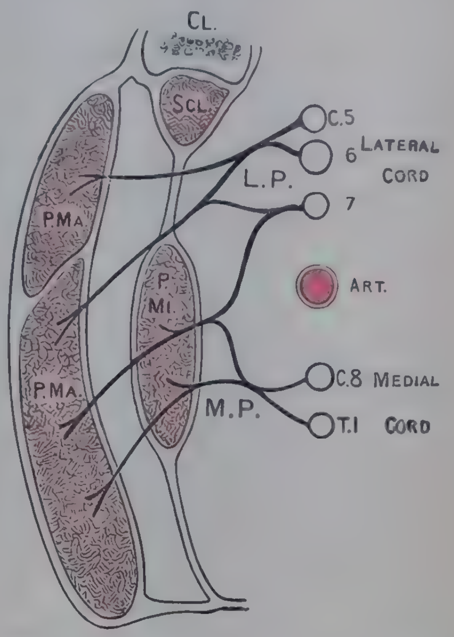

FIG. 925.—DIAGRAM OF THE ORIGIN AND DISTRIBUTION OF THE NERVES TO THE PECTORAL MUSCLES.

(c) and (d) Arising from the Cords.

Anterior Branches

From the Lateral Cord

Lateral pectoral,
Median (lateral root).
Musculo-cutaneous.

From the Medial Cord

Medial pectoral.
Median (medial root).
Ulnar.
Medial cutaneous nerve of arm.
Medial cutaneous nerve of forearm.

Posterior Branches

Circumflex nerve.
Radial nerve.
Two subscapular nerves.
Nerve to latissimus dorsi.

PECTORAL NERVES

The **pectoral nerves** are two in number, lateral and medial. The **lateral pectoral nerve** arises from the anterior divisions of the fifth, sixth, and seventh cervical nerves just before they form the lateral cord of the plexus. The **medial pectoral nerve** arises from the medial cord of the plexus immediately after its formation, receiving fibres from the eighth cervical and first thoracic nerves. Both course downwards and forwards, one on each side of the axillary artery, and a loop of communication is formed between them in front of the artery. They are distributed to the pectoralis major and minor muscles (Fig. 925).

The nerves are distributed to the pectoral muscles in the following way. Two sets of branches from the lateral pectoral nerve pierce the clavi-pectoral fascia. The superior branches supply the *clavicular part* of the pectoralis major; the inferior branches are distributed to the superior fibres of the *sterno-costal portion* of the muscle. The superior branches come from the fifth and sixth cervical nerves; the inferior branches, from the fifth, sixth, and seventh nerves. The *pectoralis minor* is pierced by two sets of nerves—the superior set is derived from the loop of communication between the two pectoral nerves over the axillary artery; the inferior set is derived from the medial pectoral nerve alone. The two sets supply the *pectoralis minor* muscle, and, after piercing it, supply the *sterno-costal part* of the pectoralis major. The inferior set, in many cases, sends its branches to the pectoralis major round the infero-lateral border of the pectoralis minor, and they may supply the *axillary arches*, if present. The two branches

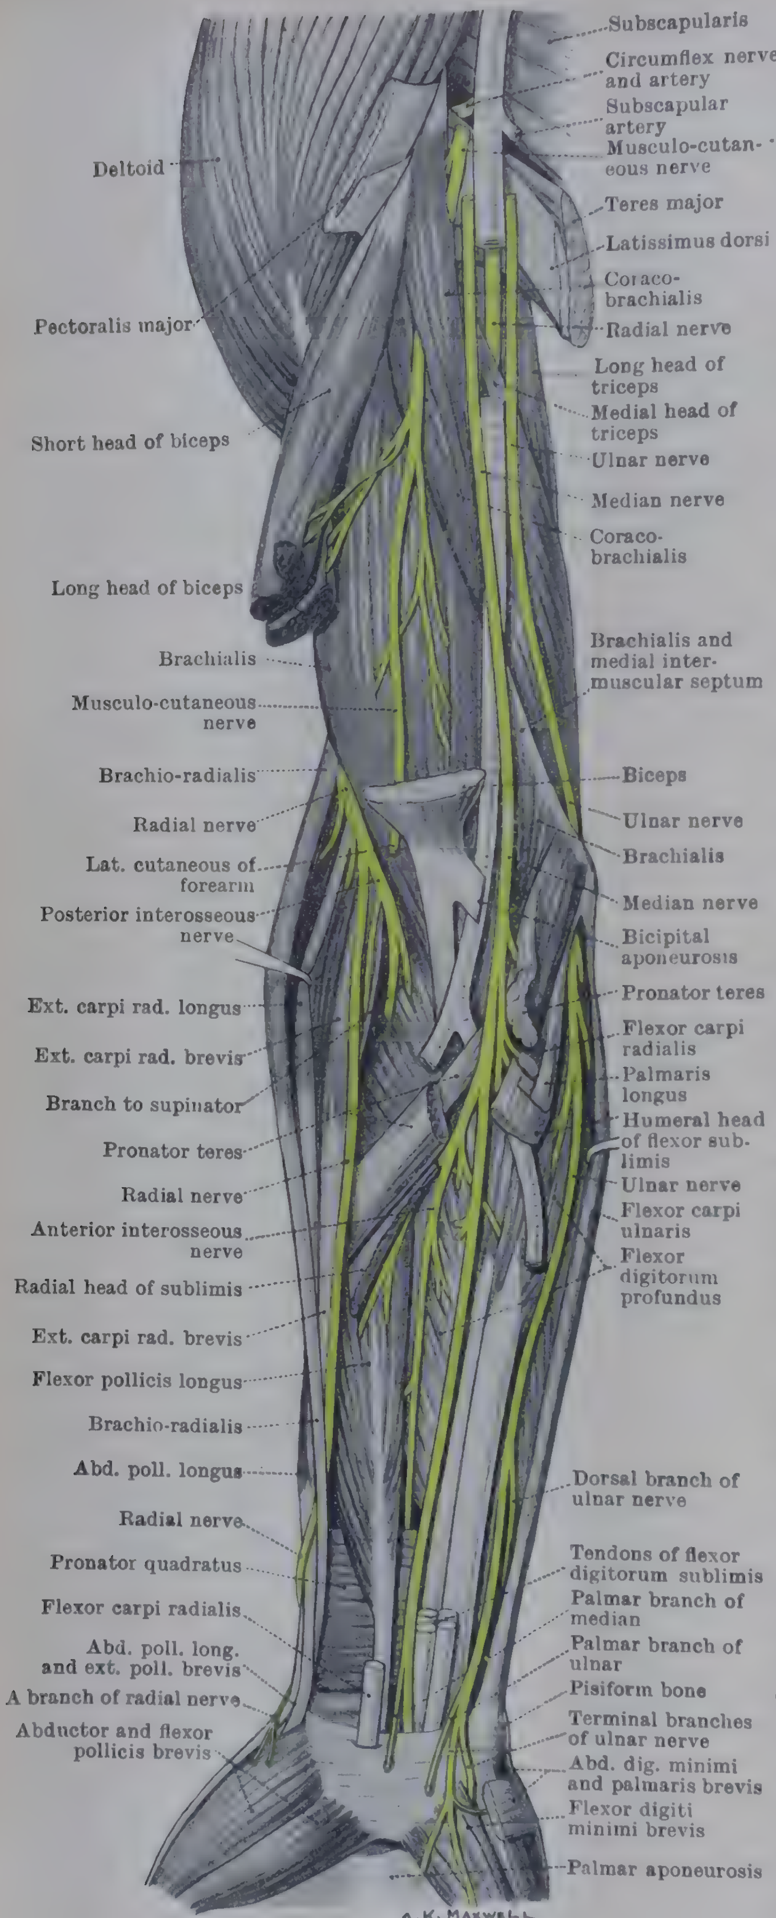

FIG. 926.—DEEPER NERVES OF FRONT OF UPPER ARM AND FOREARM.

of the superior set are derived from the seventh and eighth cervical and first thoracic nerves; those of the inferior set from the eighth cervical and first thoracic nerves. The pectoral muscles are thus both supplied by the two pectoral nerves. The clavicular fibres of the pectoralis major are innervated by the fifth and sixth nerves; the sterno-costal fibres, from above downwards, by the fifth, sixth, seventh, and eighth cervical and first thoracic nerves; and the pectoralis minor is supplied by the seventh and eighth cervical and first thoracic nerves.

MUSCULO-CUTANEOUS NERVE

The **musculo-cutaneous nerve** takes origin from the lateral cord of the plexus, from the fifth and sixth cervical nerves, and also from the fourth in over half the number of cases (Fig. 924). The **nerve to the coraco-brachialis muscle**, arising from the seventh or sixth and seventh nerves, is usually incorporated with it. After the musculo-cutaneous nerve separates from the lateral root of the median nerve, it lies at first between the coraco-brachialis muscle and the axillary artery. It then passes between the two parts of the coraco-brachialis, and runs between the biceps and brachialis muscles, to the bend of the elbow. It pierces the deep fascia over the front of the elbow, between the biceps and brachio-radialis (Fig. 926), and terminates as the *lateral cutaneous nerve of the forearm.* Whilst behind the biceps it may send a communicating branch to the median nerve.

The branches of the nerve are muscular and cutaneous. The **muscular branches** are supplied to the two heads of the biceps and the brachialis, as the nerve lies between the muscles, and to the coraco-

brachialis. The nerve to the coraco-brachialis (usually incorporated with the trunk of the musculo-cutaneous nerve) has an independent origin from the seventh or sixth and seventh nerves (possibly the fifth also). The **lateral cutaneous nerve of the forearm** divides into anterior and posterior branches. The **anterior branch** descends along the front of the lateral aspect of the forearm to the wrist, and supplies an area of skin and fascia extending medially to the middle line of the front of the forearm, and distally to the ball of the thumb. It usually communicates, proximal to the wrist, with the radial nerve, and supplies branches to the radial artery. The **posterior branch** passes backwards and downwards over the extensor muscles and supplies the skin and fascia over a variable extent on the lateral aspect of the forearm posteriorly. It communicates with the cutaneous branches of the radial nerve, and it sometimes extends on to the dorsum of the hand, supplying the skin and fascia over the first metacarpal bone.

In addition to the above branches, the musculo-cutaneous nerve supplies in many cases the following small twigs in the arm: (1) a medullary branch to the humerus; (2) a periosteal branch to the distal end of the humerus on its anterior surface; and (3) a branch to the brachial artery.

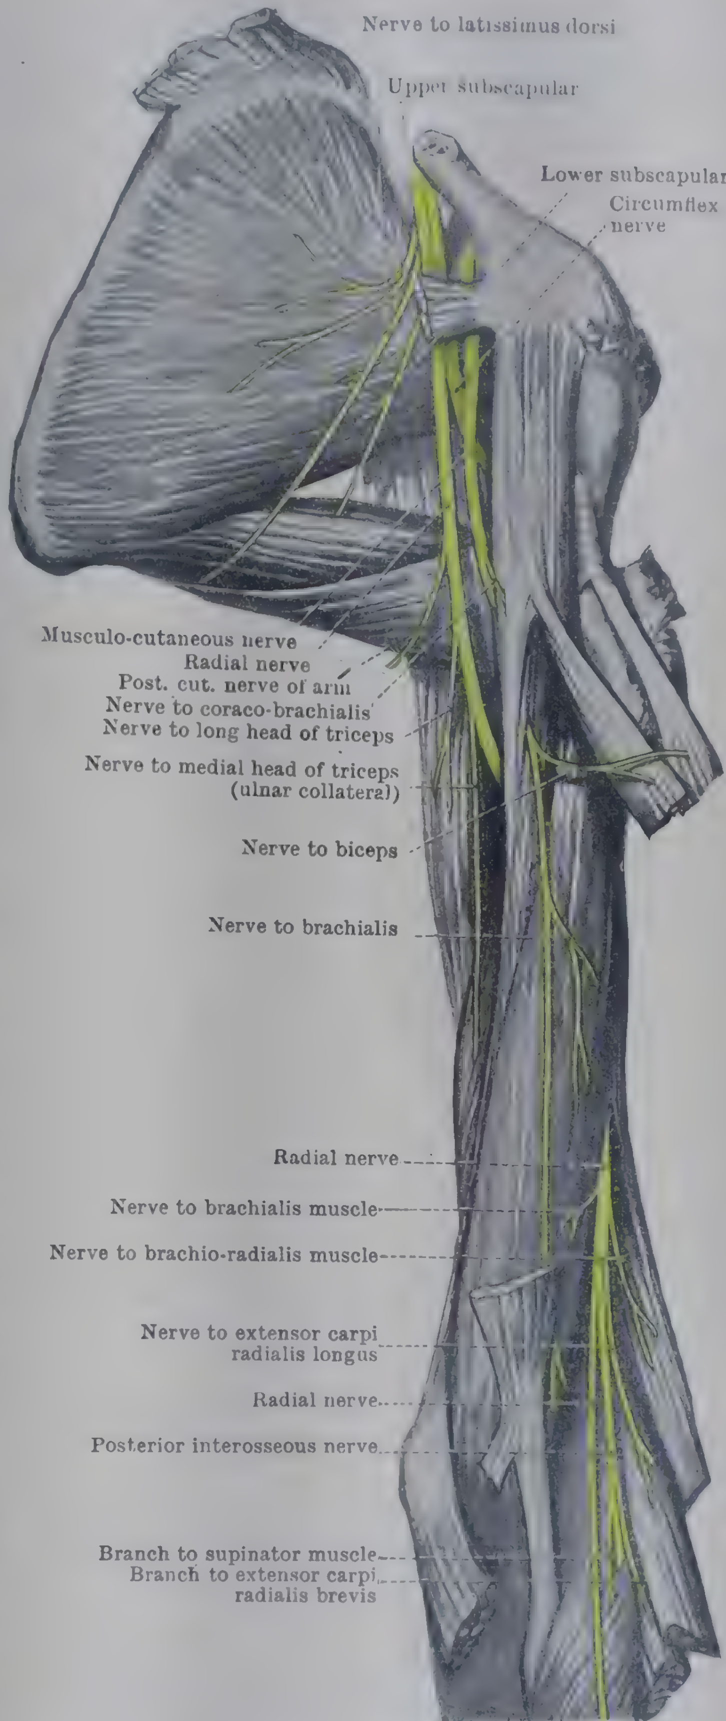

Fig. 927.—Deeper Nerves of Upper Arm.

The nerve to the brachialis usually enters the medial side of the muscle as in Fig. 926.

Median Nerve

The **median nerve** arises by two roots—one from the lateral cord of the brachial plexus, the other from the medial cord. The lateral root, from the (fifth), sixth, and seventh nerves, descends along the lateral side of the axillary artery; the medial root, from the eighth cervical and first thoracic nerves, crosses in front of the terminal part of the axillary artery or the beginning of the brachial artery, to join the lateral root in the proximal part of the upper arm. The trunk therefore receives fibres from all the main nerves that form the plexus. It descends along the lateral side of the brachial artery to the

level of the insertion of the coraco-brachialis, where it crosses the artery (usually in front). Thereafter it lies on the medial side of the artery (Figs. 926, 930) and in the hollow of the elbow it is behind the bicipital aponeurosis and the median cubital vein. It passes into the forearm between the two heads of the pronator teres muscle, separated from the ulnar artery by the ulnar head of that muscle, and extends downwards, along the middle of the forearm between the superficial and

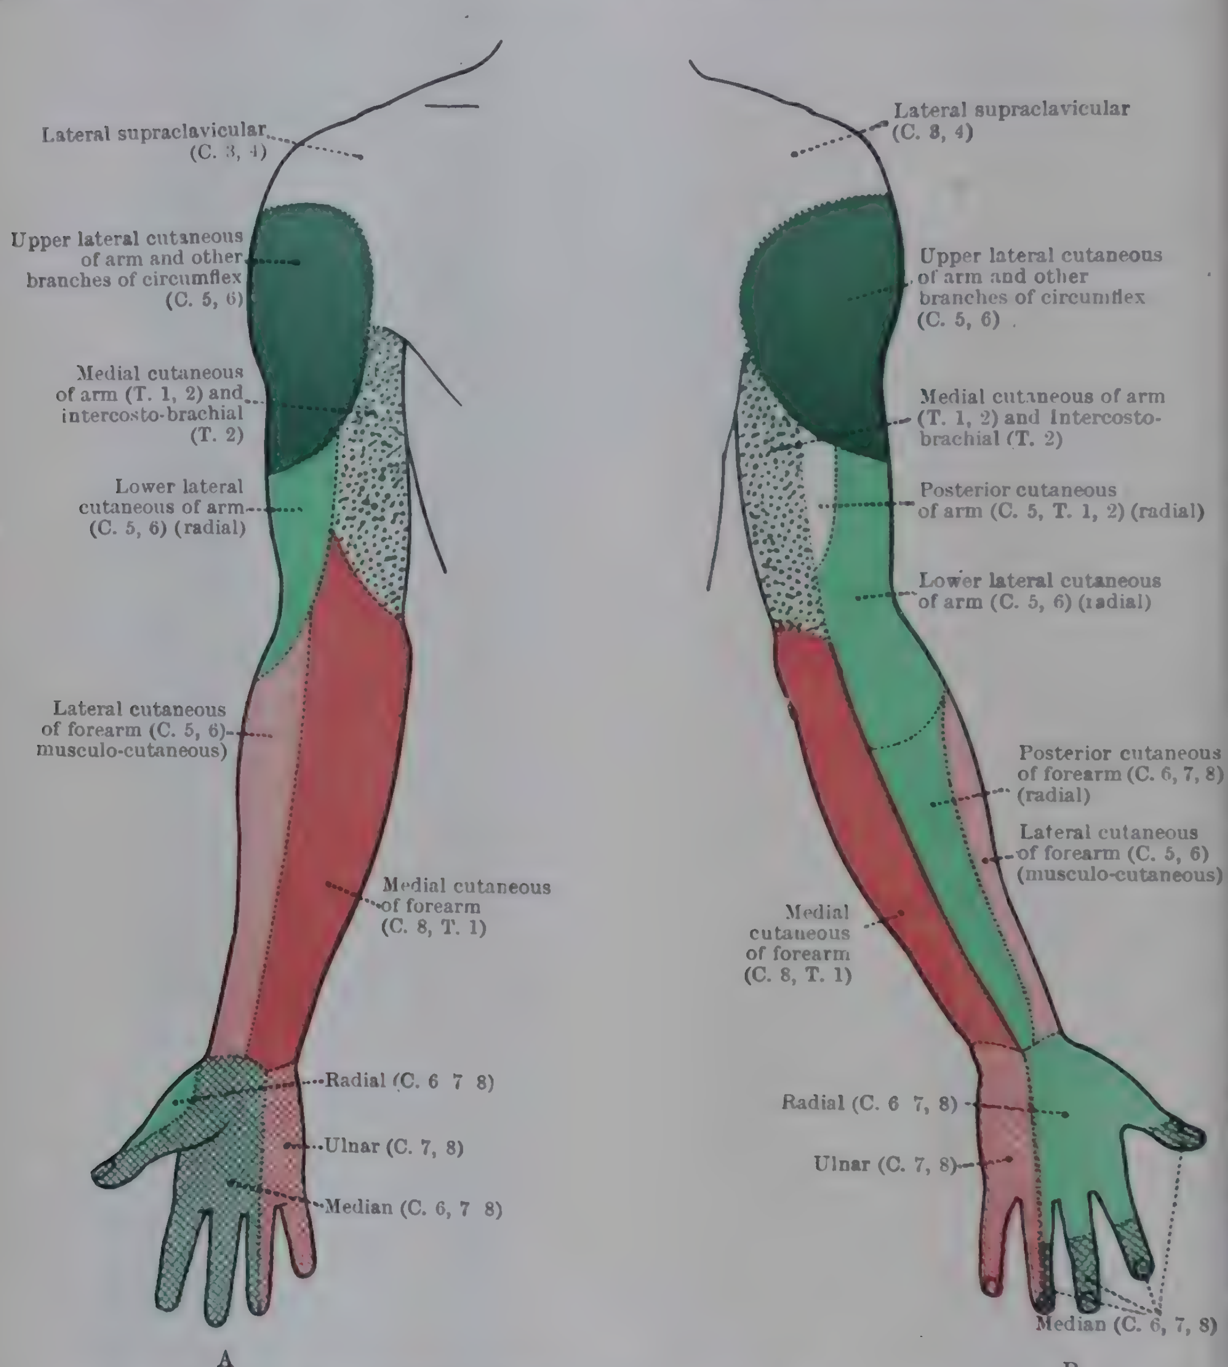

Fig. 928.—Distribution of Cutaneous Nerves: A, on the Front; B, on the Back of Upper Limb. The overlapping of nerve-areas, and of dermatomes in Fig. 929, is not shown (see p. 1053).

deep muscles. In its course in the forearm the nerve is closely bound to the deep surface of the flexor sublimis. As it approaches the wrist it becomes more superficial and enters the palm of the hand by passing deep to the flexor retinaculum in front of the tendons of the flexor digitorum sublimis. In the hand it spreads out at the distal border of the flexor retinaculum, under cover of the palmar aponeurosis and superficial palmar arch, and separates into its six terminal branches (Fig. 931). In the forearm a small artery accompanies it—the median branch of the anterior interosseous artery.

Branches.—The median nerve usually gives off no branches in the upper arm.

Branches in Forearm.—(1) **Articular Branches.**—Minute articular filaments

arise from the muscular branches and are distributed to the front of the elbow joint.

(2) **Muscular Branches.**—In the hollow of the elbow a bundle of nerves arises to be distributed to the following muscles: pronator teres, flexor carpi radialis, palmaris longus, flexor digitorum sublimis. Nerves are also generally traceable from that bundle to the upper fibres of the flexor pollicis longus and flexor digi-

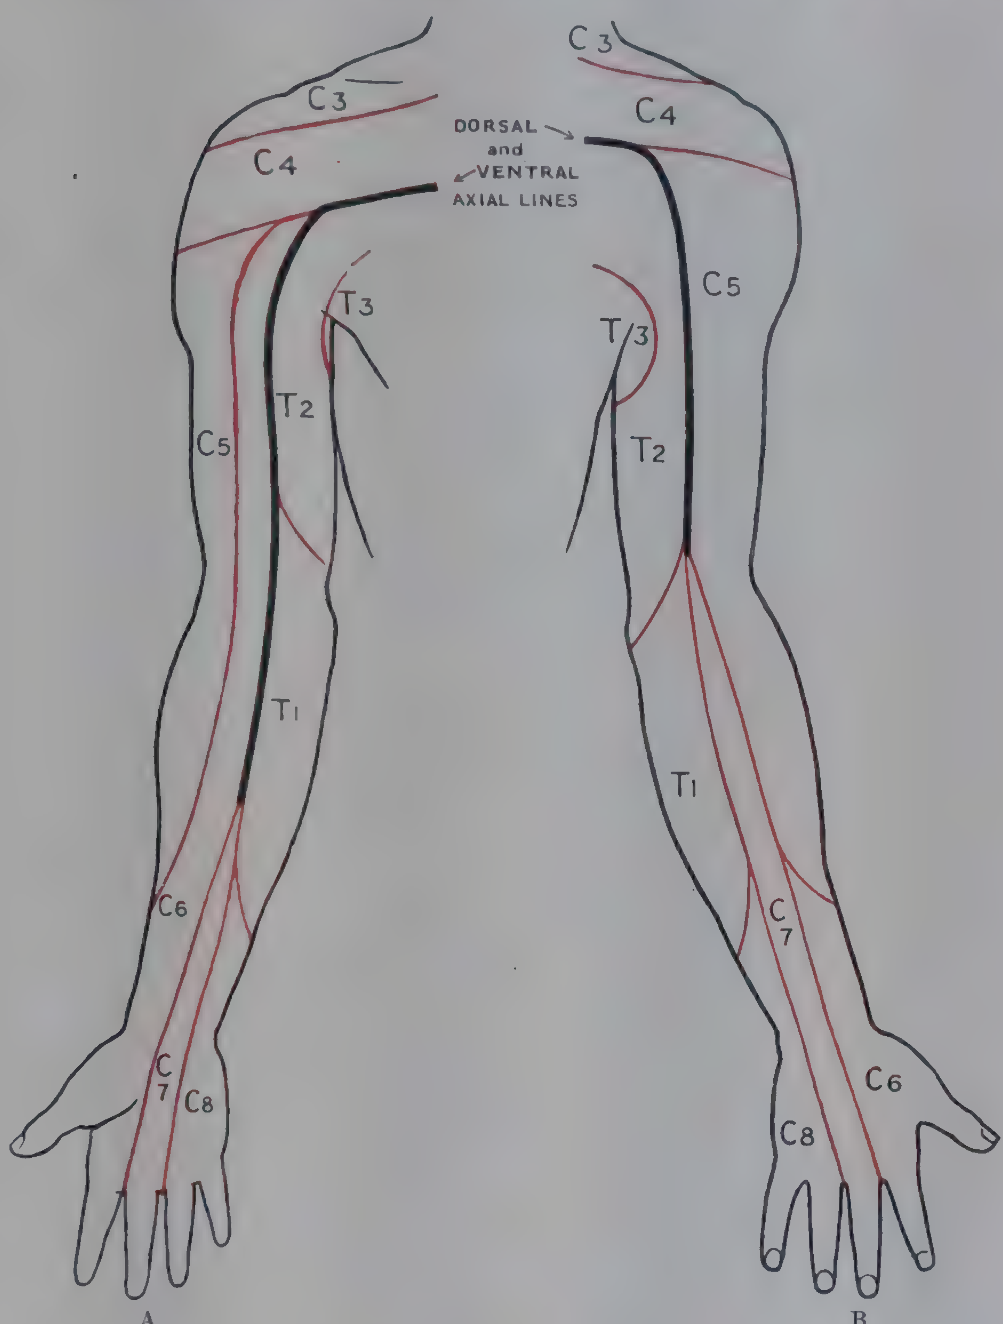

Fig. 929.—Dermatomes of Upper Limb, showing the Segmental Cutaneous Distribution of Spinal Nerves (C—T) on A, the Front, and B, the Back of the Limb (after Head, 1893 and Foerster, 1933). See p. 1053 for definition of "dermatome" and p. 1114 for more particular reference to the segmental innervation of the upper limb.

torum profundus. A separate branch to the index belly of the sublimis often leaves the nerve in the lower half of the forearm. The nerve to the pronator teres, which is the first given off, often arises independently in the hollow of the elbow but seldom proximal to the joint.

(3) The **anterior interosseous nerve** arises from the posterior surface of the median nerve in the cubital fossa. It extends downwards on the front of the interosseous membrane along with the anterior interosseous artery, passes behind the pronator quadratus muscle, and terminates by supplying articular filaments to the radio-carpal and intercarpal joints. In its course the nerve supplies muscular branches to the flexor pollicis longus, the lateral half of the flexor digitorum pro-

fundus, and the pronator quadratus, minute medullary branches to the radius and ulna, and twigs to the periosteum and interosseous membrane.

(4) **Palmar Cutaneous Branch.**—In the distal third of the forearm a small cutaneous branch arises which pierces the deep fascia and crosses the flexor retinaculum to reach the palm of the hand. It supplies a small piece of the skin and fascia of the palm and communicates with a similar branch of the ulnar nerve. It is not always present.

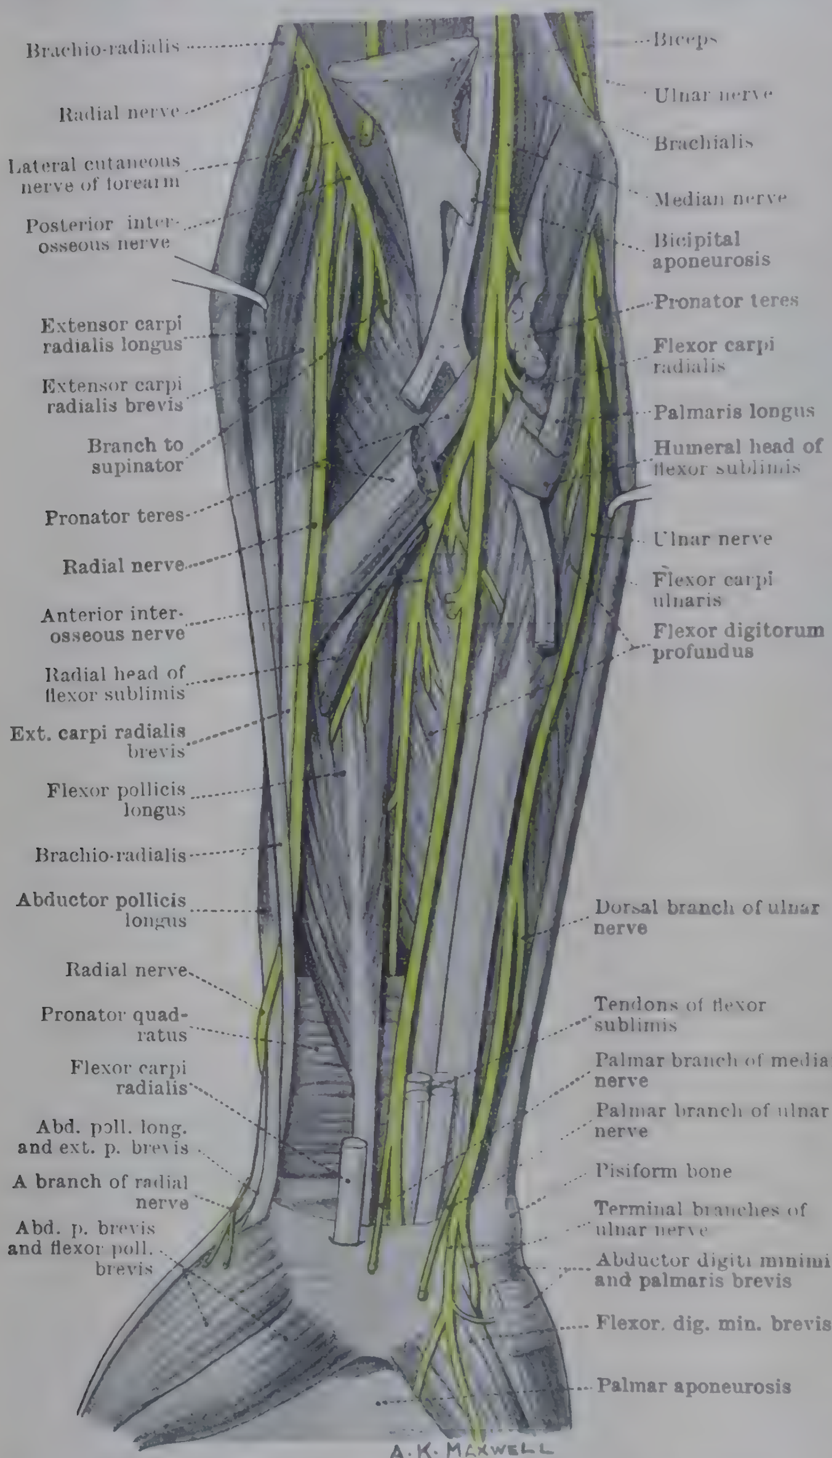

FIG. 930.—MEDIAN, ULNAR, AND RADIAL NERVES IN FOREARM.

Branches in Hand.—In the hand the median nerve gives off its terminal branches (Fig. 931). They are muscular, cutaneous, articular, and vascular.

The main **muscular branch** arises just distal to the flexor retinaculum and passes to the base of the thenar eminence; entering the ball of the thumb superficially on the medial side, it supplies branches to the abductor pollicis brevis, opponens pollicis, and the flexor pollicis brevis.

The **cutaneous branches** (*palmar digital nerves*) are five in number. Three separate branches supply the two sides of the thumb and the lateral side of the index finger. The two remaining branches divide, at the clefts between the second and third and the third and fourth fingers, into branches which supply the adjacent sides of the second and third and the third and fourth fingers. From the nerves which supply the lateral side of the index finger and the contiguous sides of the index and middle fingers, fine muscular branches arise for the lateral two lumbrical muscles. The cutaneous branches of the median nerve are placed in the palm between the superficial palmar arch and the flexor tendons. They become superficial at the roots of the fingers between the slips of the palmar aponeurosis, or, in the case of the nerves to the thumb and lateral side of the index finger, at the lateral edge of the palmar aponeurosis. In the fingers they are placed in front of the digital arteries, and are distributed to the sides and palmar surfaces of the fingers. These palmar branches, as in the case of the ulnar nerve, are beset with numerous lamellated corpuscles. Each nerve supplies one or more *dorsal branches*, distributed to the skin and fascia on the

back of the distal phalanx of the thumb and the distal two phalanges of the first two and a half fingers.

Articular branches can be traced to the interphalangeal joints, and usually also to the metacarpo-phalangeal joints of the thumb and index and middle fingers. Numerous **vascular** branches are distributed to the neighbouring arteries by the palmar cutaneous nerve and its branches.

Communications.—(1) The median nerve sometimes receives a communicating branch from the musculo-cutaneous nerve in the upper arm. (2) It communicates in some cases, in the proximal part of the forearm, with the ulnar nerve behind the flexor muscles. (3) It communicates by means of its cutaneous branches with the ulnar nerve in the palm of the hand.

Ulnar Nerve

The **ulnar nerve** arises from the medial cord of the brachial plexus, and contains fibres from the eighth cervical and first thoracic nerves (Fig. 924). In over half the number of cases it has also a root from the lateral cord of the plexus or from the lateral root of the median nerve (seventh cervical nerve). This additional root is subject to great variation in size. In the axilla the ulnar nerve lies between the axillary artery and vein, and behind the medial cutaneous nerve of the forearm; in the proximal half of the upper arm it lies on the medial side of the brachial artery anterior to the triceps muscle. In the distal half of the upper arm it separates from the brachial artery, pierces the medial intermuscular septum and descends in front of the medial head of the triceps in company with the ulnar collateral artery to reach the interval between the medial epicondyle of the humerus and the olecranon. It is there protected by an aponeurotic arch between the epicondyle and the olecranon. It enters the forearm between the humeral and ulnar origins of the flexor carpi ulnaris lying deeply on the coronoid process, and then descends between the flexor carpi ulnaris and flexor digitorum profundus. In the distal half of the forearm it becomes comparatively superficial, lying on the medial side of the ulnar artery (to which it furnishes branches) overlapped by the tendon of the flexor carpi ulnaris (Fig. 930). Just proximal to the flexor retinaculum it pierces the deep fascia in company with the artery, and passes on to the front of the retinaculum at the lateral side of the pisiform bone, where it divides, under cover of the palmaris brevis muscle, into its two terminal branches—superficial and deep.

Branches.—The ulnar nerve usually gives off no branches until it reaches the forearm.

In **the forearm** it gives off articular, muscular, and cutaneous branches.

The **articular branch** is distributed to the elbow joint and arises as the nerve passes behind the medial epicondyle of the humerus.

The **muscular branches** arise as soon as the nerve enters the forearm. They are distributed to the muscles between which the nerve lies—the flexor carpi ulnaris and the medial half of the flexor digitorum profundus. The flexor carpi ulnaris usually receives, just below the elbow joint, two branches, one each to its olecranon and condylar heads; the latter head may receive a secondary supply at a lower level, and a fourth branch to the muscle may be found. Only in exceptional cases does one of the branches arise proximal to the elbow joint (Linell, 1921).

The **cutaneous branches** are two in number—palmar and dorsal.

The **palmar cutaneous branch** is variable in size and position. It pierces the deep fascia in the distal third of the forearm and passes to the medial part of the palm of the hand, to the skin and fascia over which it is distributed. It gives branches to the ulnar artery, and often communicates with the medial cutaneous nerve of the forearm and the palmar cutaneous branch of the median nerve.

The **dorsal branch of the ulnar** is much larger. It arises from the ulnar nerve at a variable point in the middle third of the forearm; and, directed obliquely downwards and backwards, under cover of the tendon of the flexor carpi ulnaris and in contact with the ulna, it becomes cutaneous on the medial side of the forearm in its distal fourth. At the medial side of the wrist it lies on the triquetrum where it may be rolled against that bone in palpation. It then passes on to the back of the hand, and, after giving off branches to the skin and fascia of the

usually innervation.

dorsum of the wrist and hand which communicate with the radial nerve, it terminates in ~~three~~ 2 *dorsal digital nerves* to supply the little finger, ~~the ring finger~~, ~~and~~ half of the ~~middle finger in~~ ring the following way: one branch courses along the ulnar side of the dorsum of the hand and supplies the little finger as far as the root of the nail; another branch divides at the cleft between the little and ring fingers to supply their adjacent sides to the same extent; a third branch bifurcates at the cleft between the ring and middle fingers, and supplies their adjacent sides, but only as far as the

Rarely 2½ fingers common 1½ f.

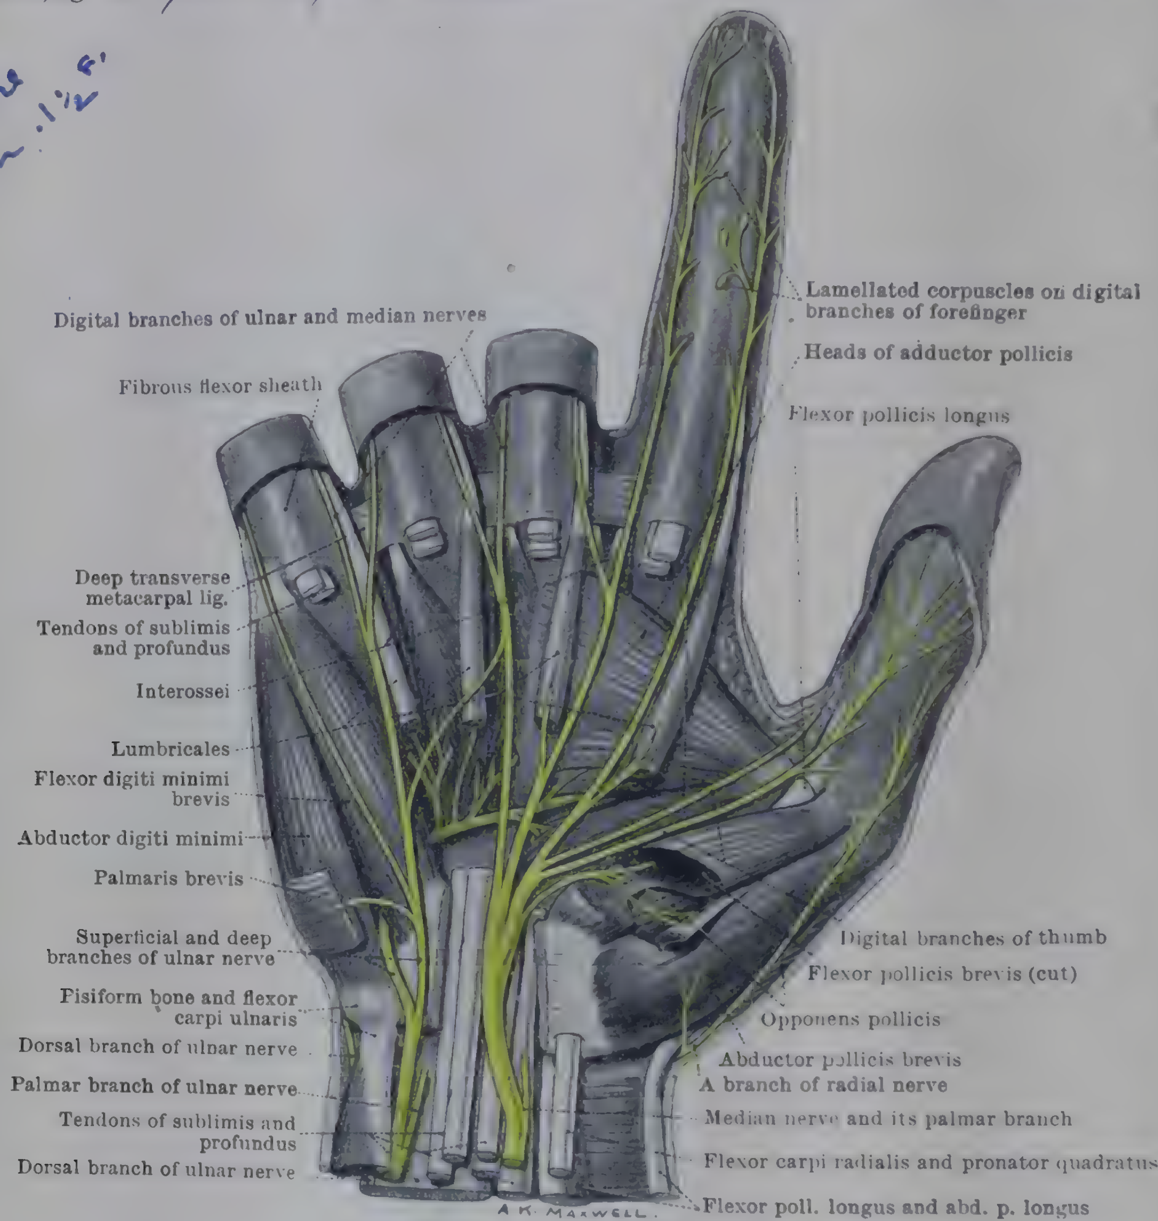

Fig. 931.—Median and Ulnar Nerves in Hand.

level of the proximal interphalangeal joints, the distal part of the surfaces being supplied by branches of the median overlapping from the palmar aspect. The last branch communicates with the radial nerve. The ulnar nerve sometimes supplies only the little finger and half of the ring finger on their dorsal surfaces.

In the palm the ulnar nerve supplies a small muscular branch to the palmaris brevis, and then divides into its terminal branches.

Terminal Branches.—The **superficial terminal branch** passes downwards deep to the palmar aponeurosis, and divides into a medial and a lateral branch. The medial branch proceeds along the medial border of the little finger, which it supplies on its palmar surface. The lateral branch becomes superficial at the cleft between the fourth and fifth digits, between the slips of the palmar aponeurosis, where it lies with the fourth lumbrical and the corresponding digital vessels in front of the deep transverse ligament of the palm. Here it divides into two branches (*palmar digital nerves*) which supply the adjacent sides of those fingers on their palmar surface. It communicates with the adjacent digital branch

of the median nerve, and it usually supplies the metacarpo-phalangeal and interphalangeal joints of the ring and little fingers. The digital nerves supply the neighbouring arteries also.

The ulnar nerve, therefore, usually supplies one and a half fingers on their palmar surfaces and two and a half fingers on their dorsal surfaces, the remaining digits being supplied by the median nerve on the palmar surface, and the radial nerve on the dorsal surface. The median nerve further extends on to the dorsal surface of the distal phalanx of the thumb and the distal two phalanges of the first two and a half fingers, so making up for the deficiency of the radial nerve in those regions. Clinical observations show this to be a much more common arrangement than the classical description of the distribution of the ulnar nerve to one and a half fingers on both their surfaces (Stopford, 1918).

The **deep terminal branch** is distributed mainly to muscles, but receives some fibres from afferent end-organs in the deep structures of the palm. It separates from the superficial branch and passes deeply (Fig. 931) between the flexor and abductor digiti minimi muscles; it supplies those muscles and the opponens digiti minimi, and, turning laterally round the hook of the hamate bone along the line of the deep palmar arch and under cover of the deep flexor tendons, it supplies branches to the following muscles: interossei, third and fourth lumbricals (on their deep surfaces), and the adductor pollicis (oblique and transverse heads). Vascular branches are given to the deeper vessels of the palm. The ulnar supply to the first dorsal interosseous muscle may be replaced in part, or even completely, by the median nerve (Brooks, 1888; Sunderland, 1946). (See also p. 508.)

Communications.—The ulnar nerve communicates (1), in some cases, with the median nerve in the forearm; (2) with the medial cutaneous nerve of the forearm, and sometimes with the median nerve, by its palmar branch; (3) with the cutaneous part of the median nerve in the palm, by means of its terminal cutaneous branches; (4) with the radial nerve on the dorsum of the hand by means of its dorsal branch.

Medial Cutaneous Nerve of Forearm

The **medial cutaneous nerve of the forearm** arises from the medial cord of the brachial plexus, and contains fibres of the eighth cervical and first thoracic nerves (Figs. 924 and 928). In the axilla and proximal half of the upper arm it lies superficial to the main artery. It becomes cutaneous by piercing the deep fascia about the middle of the upper arm on its medial side, and, accompanying the basilic vein through the distal half, it divides at the front of the elbow into its two terminal branches.

Branches.—In the upper arm, as soon as it becomes superficial, the nerve gives off a branch which supplies the skin and fascia of the distal half of the anterior surface of the upper arm on its medial side. At the elbow its two terminal branches—anterior and posterior—cross superficial or deep to the median cubital vein, and are distributed to the medial side of the forearm.

The **anterior branch** can be followed to the wrist and supplies the whole of the front of the forearm in the medial half. The **posterior branch** is not so large; it passes obliquely backwards and downwards over the origins of the pronator and flexor muscles, and it is distributed to the proximal two-thirds or three-fourths of the back of the forearm on the medial side.

Communication.—The medial cutaneous nerve of the forearm communicates with the ulnar nerve in the distal part of the forearm.

Medial Cutaneous Nerve of Arm

The **medial cutaneous nerve of the arm** arises from the medial cord of the brachial plexus, and ultimately from the first thoracic nerve (Fig. 924, p. 1068). It lies at first between the axillary artery and vein; and, after descending over, under, or even, in some cases, through the axillary vein, it perforates the deep fascia and is distributed to the skin and fascia of the upper arm for the proximal half or more on its medial side.

The nerve varies considerably in size. It may be absent, its place being taken by branches of the intercosto-brachial or by branches from the posterior cutaneous branch of the radial nerve. It generally bears a distinct relation in size to the intercosto-brachial, due to the fact that the size of the latter depends upon the size of the part of the second thoracic nerve connected

with the first in the thorax. If an intrathoracic connexion occurs between the first and second thoracic nerves, the intercosto-brachial may be deprived of a certain number of its fibres, which in that case reach the upper limb through the medial cutaneous nerve of the arm. When traced up to the plexus the medial cutaneous nerve of the arm is found to have an origin from the posterior part of the cord formed by the eighth cervical and first thoracic nerves, and usually receives fibres from the first thoracic nerve only. In cases where "*axillary arches*" are present they may be supplied by this nerve.

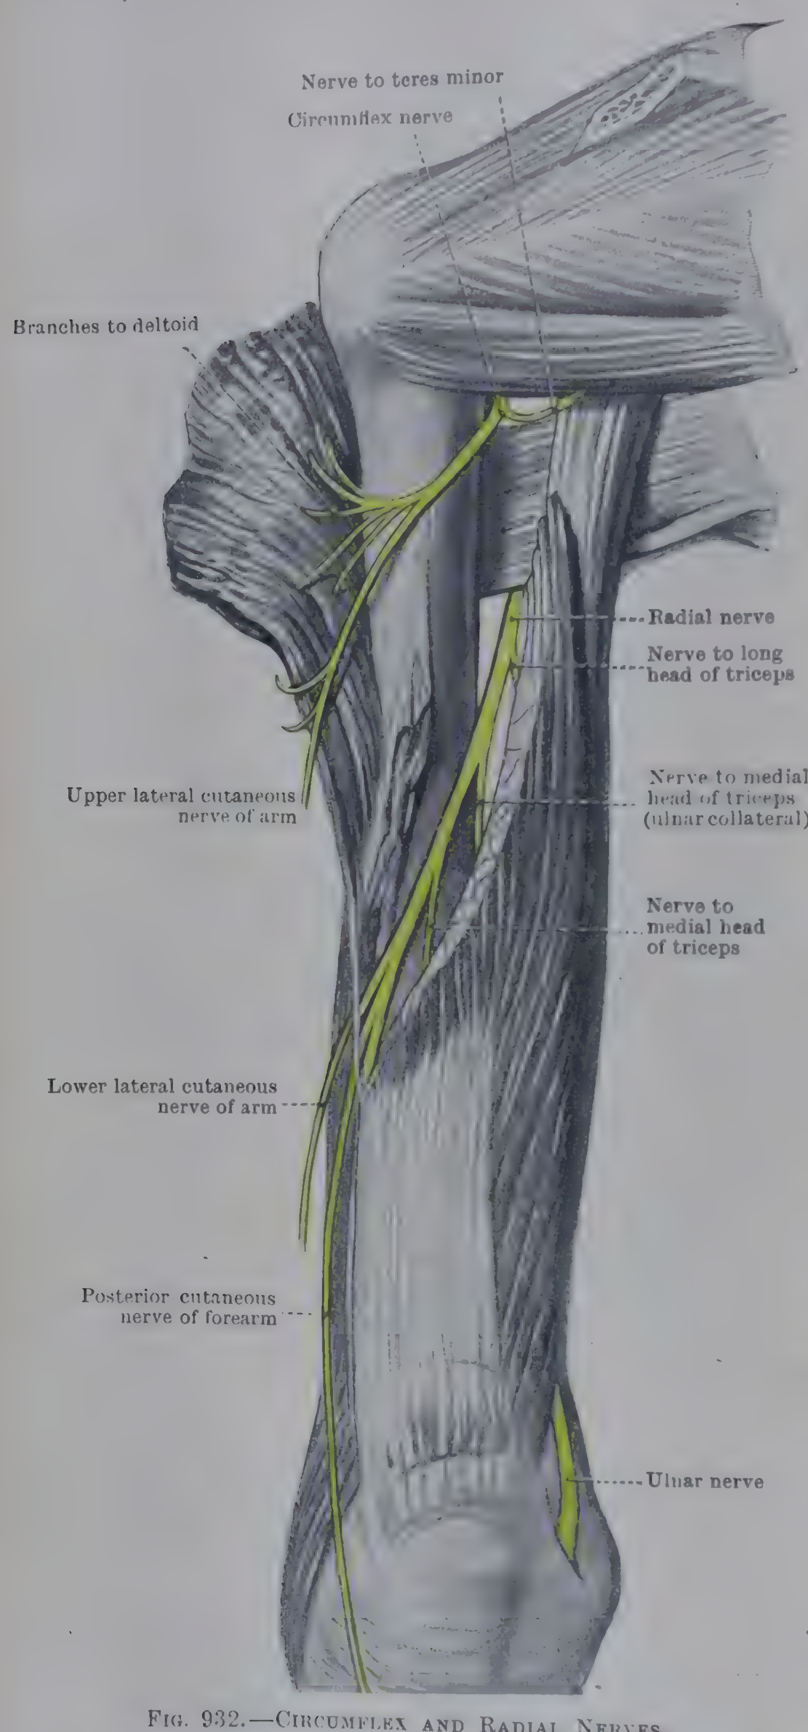

FIG. 932.—CIRCUMFLEX AND RADIAL NERVES.

CIRCUMFLEX NERVE

The **circumflex nerve** is a terminal branch of the posterior cord, and contains fibres of the fifth and sixth cervical nerves. At first it lies behind the axillary artery, but, at the lower border of the subscapularis, it leaves the axilla by passing backwards, in company with the posterior circumflex humeral artery, through a quadrilateral space bounded by the humerus, subscapularis, triceps (long head), and teres major and then divides into anterior and posterior branches. The anterior branch winds round the back of the surgical neck of the humerus from medial to lateral side in company with the artery and is distributed to the deltoid through its deep surface; a few filaments pierce the muscle and become cutaneous. The posterior branch supplies the teres minor, and, after giving a few twigs to the posterior part of the deltoid, curves round the posterior border of that muscle to become the *upper lateral cutaneous nerve of the arm* (Fig. 932).

Branches. — **Muscular branches** are supplied to the teres minor and deltoid muscles. It may give off the lower subscapular nerve. The nerve to the teres minor enters the lateral margin of the muscle; it has a pseudo-ganglionic thickening of fibrous tissue on its trunk.

Articular branches enter the lower part of the capsule of the shoulder joint.

A **cutaneous branch** of considerable size—*the upper lateral cutaneous nerve of*

the arm—becomes superficial at the posterior border of the deltoid muscle, and, passing obliquely downwards and forwards, supplies the skin and fascia over its lower half (Figs. 928, p. 1074, and 932).

Radial Nerve

The **radial nerve** appears to be the continuation into the upper limb of the posterior cord of the brachial plexus. It usually takes origin from all the nerves which form the posterior cord—the fifth, sixth, seventh, and eighth cervical and first thoracic nerves (Fig. 924, p. 1068). In some cases the first thoracic contributes no fibres, and often the fifth cervical nerve is excluded from it. It extends from the axilla, round the back of the humerus, to the bend of the elbow, where it passes into the forearm under cover of the brachio-radialis. After accompanying the radial artery in the middle third of the forearm, it passes backwards under the tendon of the brachio-radialis and becomes cutaneous by piercing the deep fascia on the lateral surface of the distal third of the forearm.

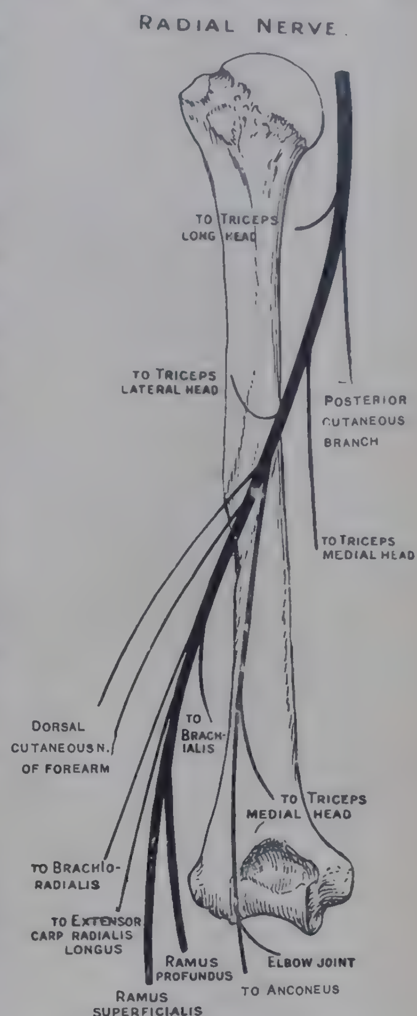

Fig. 933.—Diagram of Branches of Radial Nerve. *Ramus superficialis* = continuation of radial nerve ; *Ramus profundus* = posterior interosseous nerve.

In the axilla it lies behind the axillary artery, and in front of the subscapularis, teres major, and latissimus dorsi muscles.

In the upper arm it first lies to the medial side of the humerus, behind the brachial artery, and in front of the long head of the triceps. Leaving the front of the limb with the profunda brachii artery, it passes between the long and medial heads of triceps to reach the spiral groove. It extends laterally and downwards in the groove, accompanied by the artery, round the back of the humerus and under cover of the lateral head of the triceps. Reaching the distal third of the upper arm, it pierces the proximal part of the intermuscular septum at the lateral border of the triceps, and passes to the front of the lateral epicondyle of the humerus, where it is deeply placed in the interval between the brachio-radialis and the brachialis muscles. Under cover of the former muscle it gives off the posterior interosseous nerve and then descends into the forearm.

In the forearm it descends at first under the brachio-radialis and accompanies and supplies the radial artery in the middle third of the forearm. After passing backwards under the tendon of the brachio-radialis it pierces the deep fascia on the lateral surface of the forearm in the distal third. It is then distributed to the skin and fascia of the dorsum of the wrist, the lateral side and dorsum of the hand, and the dorsum of the thumb and lateral two and a half fingers (Fig. 928, p. 1074).

The **collateral branches** are in four sets, arising (*a*) on the medial side, (*b*) on the back, and (*c*) on the lateral side of the humerus (Fig. 933); and (*d*) in the forearm and hand.

I. **Branches which arise medial to Humerus.**—1. The **posterior cutaneous nerve of the arm**, arising in common with one of the following, or independently, pierces the fascia on the medial side of the limb near the axilla. It supplies the skin and fascia of the posterior surface of the upper arm in the proximal third, above and behind the area supplied by the medial cutaneous nerve of the arm and intercosto-brachial (Fig. 928). It varies in size inversely with the thickness of these two nerves.

2. The **muscular branches** supply the triceps and the anconeus. The triceps receives four distinct branches in the following order: (i) to the long head, arising from the nerve in the axilla; (ii) to the distal part of the medial head, arising near the lower border of the teres major, and sometimes termed the *ulnar collateral nerve*

because it accompanies the ulnar nerve in the middle third of the arm; (iii) to the lateral head, arising just distal to the last-mentioned branch; and (iv) the main supply to the medial head, arising from the nerve just prior to its entry into the spiral groove of the humerus. The last branch, after supplying the medial head of the triceps, passes through the muscle and behind the lateral epicondyle of the humerus to terminate in the anconeus muscle. All these branches arise above the spiral groove or just as the nerve enters it; the only branches of any consequence that arise in the groove are the lower lateral cutaneous nerve of the arm and the posterior cutaneous nerve of the forearm.

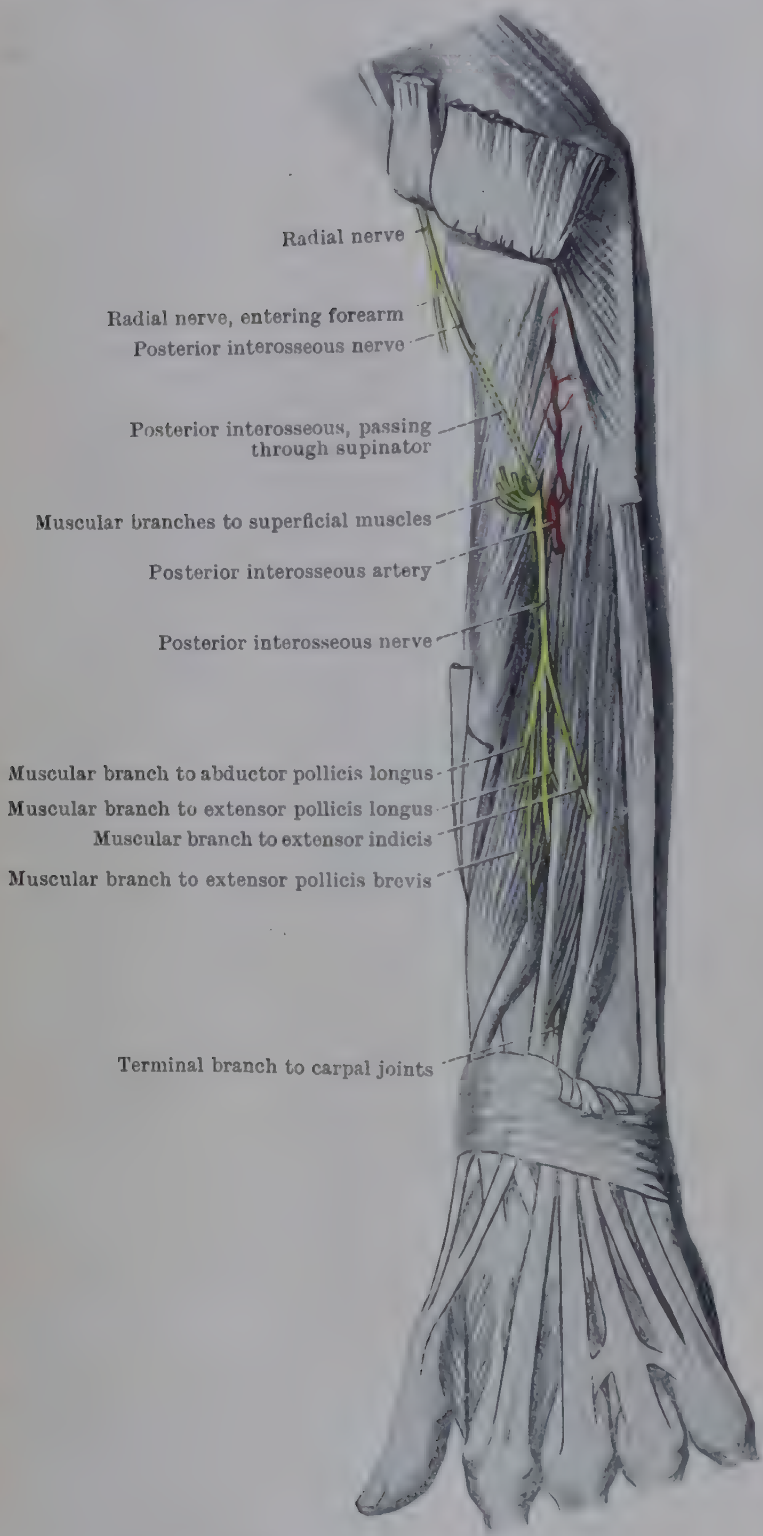

FIG. 934.—POSTERIOR INTEROSSEOUS NERVE.

II. **Branches which arise on Posterior Surface of Humerus.**—The **lower lateral cutaneous nerve of the arm** arises before the radial passes through the lateral intermuscular septum, and, piercing the deep fascia a little below the deltoid, it supplies the skin and fascia of the lateral surface and back of the distal third of the upper arm and a small portion of the back of the forearm. The **posterior cutaneous nerve of forearm** arises with the preceding or immediately below it, and pierces the deep fascia about an inch lower down; it descends into the back of the forearm, where it supplies the skin and fascia, medial to the area innervated by the musculo-cutaneous nerve (Fig. 928, p. 1074). The extent of this area is variable; sometimes it approaches or reaches the level of the wrist, whilst in others it extends on to the dorsum of the hand and supplements the supply from the terminal part of the radial nerve itself.

III. **Branches which arise at Lateral Side of Humerus.**—In the interval between the brachialis and brachio-radialis muscles, the radial nerve supplies **muscular branches** to the brachio-radialis (often double) and extensor carpi radialis longus. It may also provide the nerve to the extensor carpi radialis brevis. An inconstant branch is given to the brachialis, but it would appear from the negative results of electrical stimulation to be an afferent path.

IV. **Branches in Forearm and Hand.**—The only branches which arise from the radial nerve in this part of its course are: (1) some filaments

to the radial artery and (2) the terminal **dorsal digital nerves**. The terminal branches communicate on the ball of the thumb with the musculo-cutaneous nerve, and on the dorsum of the hand, with the dorsal branch of the ulnar nerve. The **dorsal digital nerves** are small, and are five in number. They supply a very variable extent of the dorsum of the hand and fingers. Two pass to the back of the thumb and reach the level of the interphalangeal joint, to which joint and the metacarpo-phalangeal they usually give filaments. One supplies the lateral side of the index finger as far as the second phalanx. The remaining two branches divide at the clefts between the second and third and third and fourth fingers and innervate the adjacent sides of these fingers as far as the middle phalanx. The rest of the skin and fascia of these digits is supplied by digital branches of the median nerve. The radial nerve may supply only the thumb and one and a half fingers, being replaced by branches from the ulnar nerve.

From clinical observations the last distribution would appear to be the more common, since in about 70 per cent of cases the radial has been found not to extend medially beyond the second metacarpal bone. The digital branches frequently give filaments to the metacarpo-phalangeal joints of the index, and more rarely to the same joint of the middle finger (Stopford, 1930).

Posterior Interosseous Nerve

The **posterior interosseous nerve** is entirely muscular and articular in its distribution. It arises under cover of the brachio-radialis muscle. Directed obliquely downwards and backwards, it reaches the back of the forearm after passing round the lateral side of the radius by piercing the fibres of the supinator muscle (Fig. 934). On the dorsal surface of the forearm it is placed in the proximal part of its course deep to the superficial extensor muscles, and superficial to the supinator and abductor pollicis longus, along with the posterior interosseous artery, to which it furnishes twigs. In the distal half of the forearm it passes deep to the extensor pollicis longus, and lies on the interosseous membrane. At the wrist it passes deep to the extensor tendons on to the back of the carpus, where it terminates in a gangliform enlargement of small size from which branches pass to the intercarpal joints. The nerve gives off the following branches:—

(1) Terminal **articular branches** to the intercarpal joints.

(2) **Muscular branches**, in its course through the forearm. On the lateral side of the radius, it supplies the extensor carpi radialis brevis and the supinator muscles before it enters the supinator. After emerging from that muscle, it gives branches to the extensor digitorum, extensor digiti minimi, and extensor carpi ulnaris, near their origins. At a more distal level it gives branches to the abductor pollicis longus, extensor pollicis longus and extensor pollicis brevis, and extensor indicis.

Subscapular Nerves

There are two subscapular nerves (Figs. 924 and 927)—upper and lower.

The **upper subscapular nerve** is often represented by two or three branches. It arises from the posterior cord of the plexus behind the axillary artery and contains fibres from the fifth and sixth cervical nerves (often from the fourth and seventh in addition). It passes downwards to supply the subscapularis muscle.

The **lower subscapular nerve** also arises behind the axillary artery from the posterior cord of the plexus (from the fifth and sixth cervical nerves) and it often arises in common with the circumflex nerve. It courses downwards behind the subscapular vessels to the teres major muscle, in which it ends. It supplies the lateral part of the subscapularis muscle and the teres major.

Nerve to Latissimus Dorsi

The **nerve to the latissimus dorsi** arises from the back of the posterior cord of the plexus, and receives fibres from the sixth, seventh, and eighth cervical nerves, or from the seventh and eighth nerves only. It is directed downwards and laterally between the two subscapular nerves, behind the axillary artery and over the posterior wall of the axilla, in company with the subscapular artery, to the latissimus dorsi muscle, which it supplies on its anterior (deep) surface.

THORACIC NERVES

The anterior primary rami of the **thoracic nerves** are twelve in number, each nerve emerging below the corresponding vertebra and rib. Eleven of the series are **intercostal**; the twelfth lies below the last rib and is called, therefore, the **subcostal** nerve. The first, second, third, and twelfth nerves present peculiarities in their course and distribution. The other thoracic nerves, as already stated, are simple, and may be regarded as types both in course and distribution.

The anterior primary ramus of the **first thoracic nerve** is the largest of the series. It emerges from the vertebral canal below the neck of the first rib, and divides in the first intercostal space into two very unequal parts. The *superior*

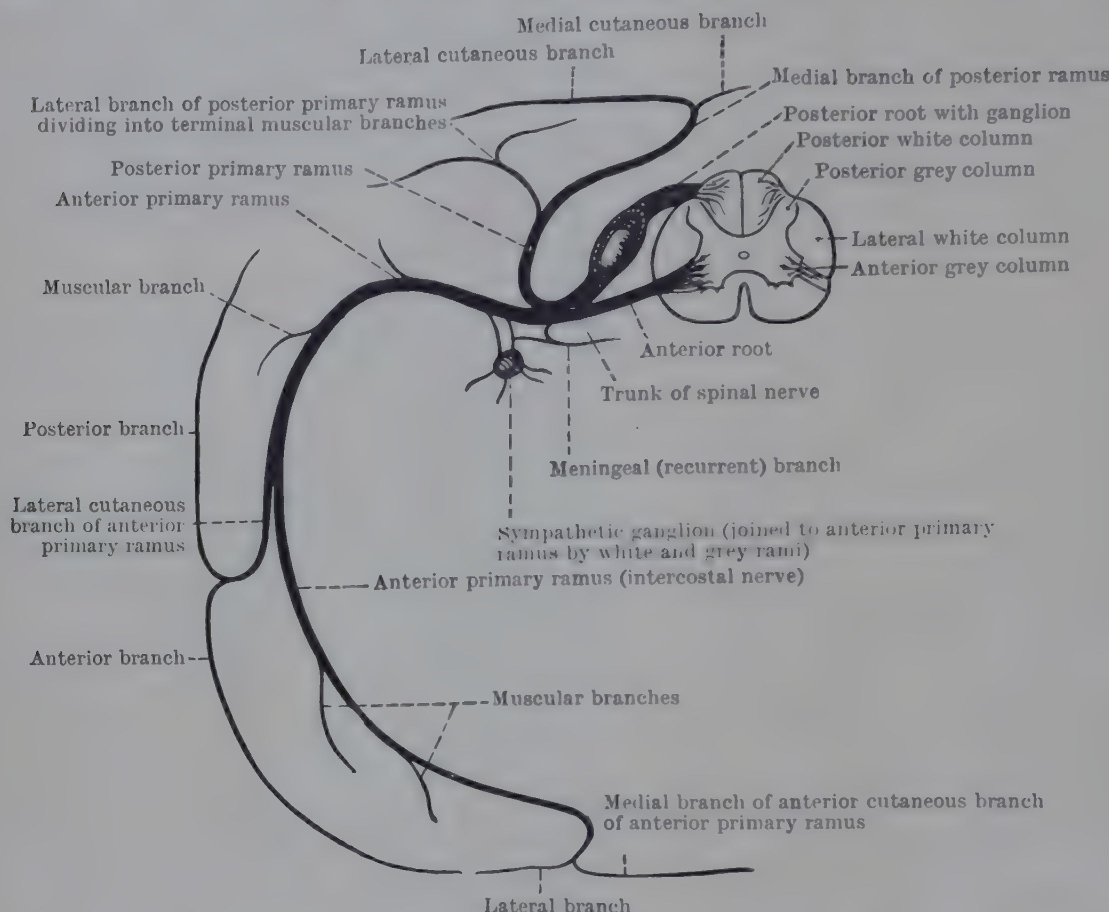

FIG. 935.—DIAGRAM OF ORIGIN AND DISTRIBUTION OF TYPICAL SPINAL NERVE.

Note that the medial branch of the posterior primary ramus is represented as distributed to skin, whilst the lateral branch terminates at a deeper level in muscle. Both branches, however, supply muscles; and in the lower half of the body it is the lateral branch that supplies the skin.

and larger part ascends obliquely across the neck of the first rib, lying lateral to the superior intercostal artery, and enters the neck behind the subclavian artery. It proceeds laterally across the scalenus medius muscle and enters into the formation of the brachial plexus, as already described.

The *inferior* or *intercostal part* of the nerve is much smaller. It courses forwards on the pleural surface of the first rib and enters the first intercostal space near the costal cartilage; it supplies the intercostal muscles. After crossing the internal mammary artery the nerve usually turns forward to terminate in the superficial fascia as the anterior cutaneous branch. A lateral cutaneous branch is inconstant: when present this branch may communicate with the intercosto-brachial nerve or, more rarely, with the medial cutaneous nerve of the arm.

Communications.—Besides its junction with the eighth cervical to enter the brachial plexus, the first thoracic nerve effects the following communications: (*a*) The inferior cervical or the first thoracic ganglion of the sympathetic sends a *grey ramus communicans* to join the nerve on its appearance in the thorax. (*b*) The second thoracic nerve in a majority of cases communicates with the first. That communication varies considerably in size and distribution. It may reinforce the intercostal branch of the nerve; it may

send one branch to the intercostal portion and another to the part of the nerve joining the brachial plexus; or it may consist of a nerve proceeding solely to join the brachial plexus by a junction in the first intercostal space with the part of the first thoracic nerve which is engaged in forming the plexus. Postganglionic sympathetic fibres from the second thoracic ganglion may reach the first thoracic nerve and the brachial plexus by way of this communication. (c) The first *white ramus communicans* in the thoracic region usually connects the first thoracic nerve with the first thoracic ganglion of the sympathetic trunk.

The **second intercostal nerve** is of large size, though much smaller than the first. It passes forwards, lying on the deep aspect of the second rib and covered by the parietal pleura. At a variable point, but usually well forwards, it passes between the innermost and internal intercostal muscles. At the level of the mid-axillary line it gives off a large lateral branch. It then continues its forward course either as a single trunk or as a main nerve in the upper part of

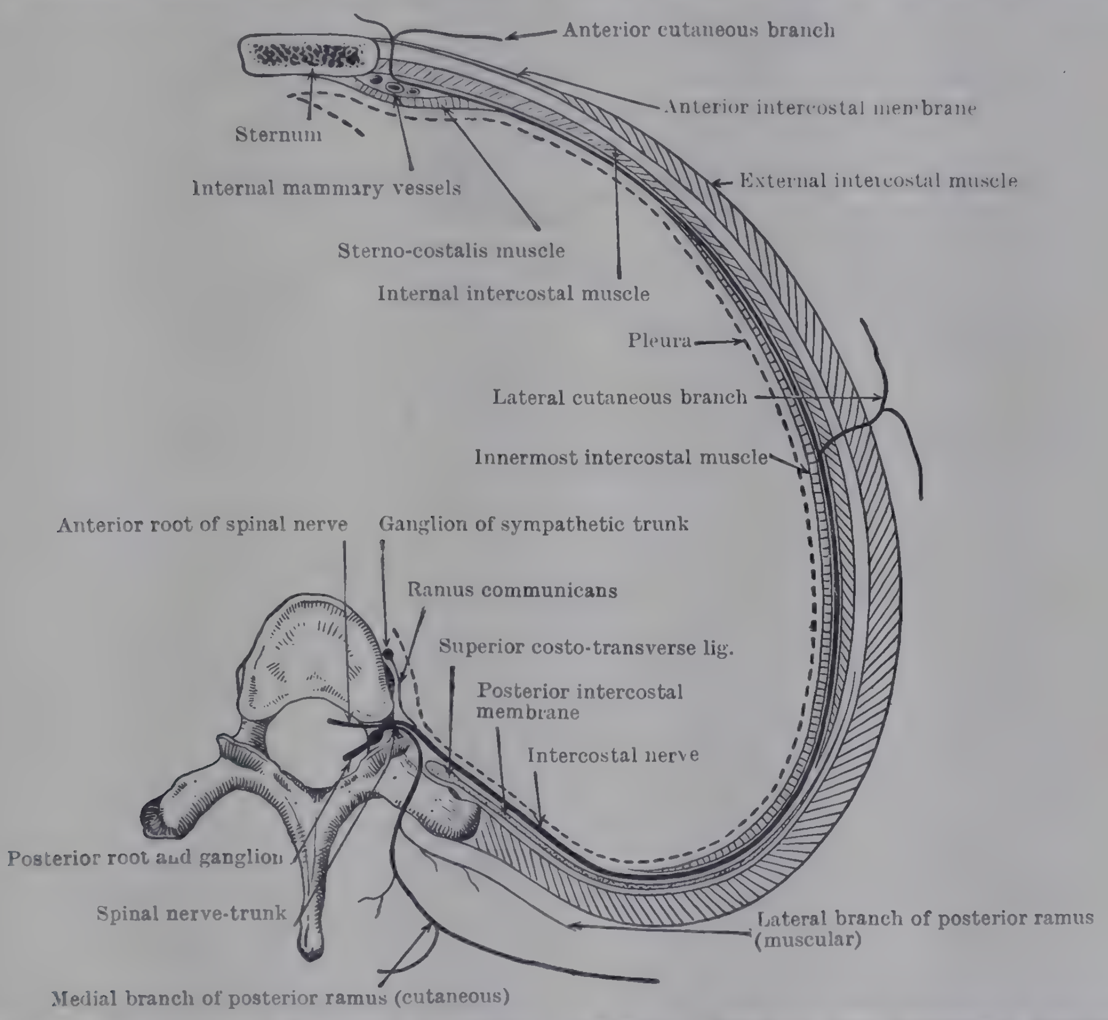

FIG. 936.—DIAGRAM TO SHOW RELATIONS OF TYPICAL INTERCOSTAL NERVE TO THE INTERCOSTAL MUSCLES AND MEMBRANES.

the space with a fine collateral nerve below (p. 1060); at the lateral border of the sternum, having crossed in front of the internal mammary artery, it passes forwards through the internal intercostal muscle, anterior intercostal membrane and pectoralis major, and ends in the front of the chest over the second intercostal space.

The nerve supplies the following branches:—

1. **Muscular branches** to the muscles of the second intercostal space.

2. **Cutaneous branches.** (*a*) Terminal **anterior cutaneous branches** to the skin and fascia over the second intercostal space (Fig. 918). (*b*) A large *lateral cutaneous branch* called the **intercosto-brachial nerve** (Figs. 922, 924). That nerve pierces the intercostal and serratus anterior muscles and crosses the axilla to reach the upper arm. It pierces the deep fascia just beyond the posterior fold of the axilla, and can be traced as far as the interval between the medial epicondyle of the humerus and the olecranon. It supplies an area of skin and fascia stretching across the axilla and along the posterior surface of

the upper arm on the medial side as far as the elbow (Fig. 928, p. 1074). It may supply the *axillary arches* when they are present.

The intercosto-brachial nerve varies in size. It may emerge through the first intercostal space; and it is often divisible into anterior and posterior branches, like the lateral cutaneous branch of an ordinary intercostal nerve.

Communications.—(1) The intercosto-brachial nerve communicates with two adjacent nerves. Either before or after piercing the deep fascia it is joined by the medial cutaneous nerve of the arm. It also communicates with the posterior part of the lateral cutaneous branch of the third intercostal nerve by means of the branches distributed to the floor and boundaries of the axilla. Sometimes it communicates with the lateral cutaneous branch of the first intercostal nerve. (2) Besides the branches referred to, the second thoracic nerve in many cases transmits a nerve to the brachial plexus which becomes incorporated with the first thoracic nerve after passing over the neck of the second rib. That branch is inconstant, as already mentioned (p. 1069). (3) Besides the communications effected by branches of the second thoracic nerve in its course, it receives a *grey ramus communicans* from the second thoracic ganglion of the sympathetic trunk; and it sends a *white ramus communicans* to the sympathetic.

The **third intercostal nerve** differs from a typical thoracic nerve only in one respect. Its **lateral cutaneous branch** divides in the usual way into anterior and posterior parts, of which the latter is carried to the upper arm and supplies an area of skin and fascia on the medial side near the root of the limb. It effects a junction with the intercosto-brachial nerve (Fig. 924, p. 1068).

The **fourth, fifth, and sixth intercostal nerves** have a course and distribution which are simple and typical. Except for the peculiarities above mentioned, the second and third intercostal nerves have a similar distribution.

At first each of these nerves lies in the posterior wall of the thorax between the ribs; then, entering the costal groove of the upper rib, it extends forwards between the innermost and the internal intercostal muscles, lying at a lower level than the intercostal vessels. Beyond the anterior limit of the innermost intercostal muscle the nerve lies in contact with the pleura and the endothoracic fascia, and farther forward passes in front of the sterno-costalis muscle and internal mammary artery. Thereafter, piercing the fibres of the internal intercostal muscle, the anterior intercostal membrane, and the pectoralis major, each nerve ends as an **anterior cutaneous branch,** which supplies the skin and fascia of the front of the chest over an area corresponding to the anterior part of the intercostal space to which it belongs (Fig. 936).

Branches.—Each intercostal nerve supplies, in addition to the terminal anterior cutaneous branches, *muscular branches* to the intercostal muscles, commonly a *collateral branch* (p. 1060) and a **lateral cutaneous branch,** which pierces the intercostal and serratus anterior muscles, and divides into anterior and posterior branches for the innervation of the skin and fascia over the side of the chest. Each area of skin thus innervated is continuous anteriorly with the area innervated by the anterior cutaneous branch of the same nerve, and posteriorly with the area supplied by its posterior ramus.

The upper six intercostal nerves supply the muscles of the first six intercostal spaces and the sterno-costalis (3, 4, 5, 6). The second, third, fourth, fifth, and sixth nerves supply the skin and fascia of the front of the chest: the second is immediately below the level of the sternal angle; the sixth is opposite the base of the xiphoid process. Their lateral branches supply branches to the intercostal muscles and the skin and fascia of the side of the chest, the second (intercosto-brachial) and the third, in part, being drawn out to the upper arm. The fourth supplies the nipple (Fig. 918). The upper six or seven intercostal nerves give numerous fine branches to the parietal pleura.

Communications.—Each of the intercostal nerves communicates with the sympathetic trunk and ganglia by two branches—a *white ramus communicans* to the corresponding sympathetic ganglion or the adjacent part of the sympathetic trunk; and a *grey ramus communicans* which passes to each nerve from the corresponding ganglion.

The **seventh, eighth, ninth, tenth, and eleventh intercostal nerves** differ from the preceding nerves only in regard to a part of their course and distribution. Each has the same course and communications as the preceding nerves

in the thoracic wall. In addition, these nerves have a further course and distribution in the abdominal wall. Each nerve traverses an intercostal space in the way described. At the anterior end of the space the nerve passes between the attachments of the diaphragm and the transversus abdominis muscle to the costal cartilages, and courses forwards in the abdominal wall between the transversus and obliquus internus muscles. The nerve then passes between the rectus abdominis muscle and the posterior wall of its sheath, where it divides into two branches. The larger passes medially behind the rectus, to which it sends a branch, and after breaking up in a plexiform manner gives off a cutaneous branch which pierces the muscle and the anterior wall of its sheath. The smaller division ends in the more lateral part of the rectus muscle.

Muscular Branches.—The lower intercostal nerves supply the intercostal muscles of the spaces in which they lie; and in the abdominal wall they innervate the transversus, obliquus internus and externus, and rectus abdominis. The branches arise from the main trunk as well as from its lateral and anterior branches. (The ninth, tenth, and eleventh nerves are described as assisting in the innervation of the diaphragm by communications with the phrenic nerve, but those fibres are probably afferent in function.)

Cutaneous Branches.—These are lateral and anterior. The **lateral cutaneous branches** divide into anterior and posterior parts, and, becoming superficial along the line of interdigitation of the obliquus externus muscle with the serratus anterior and latissimus dorsi, they are directed more obliquely downwards than the lateral branches of the higher intercostal nerves, and are distributed to the skin and fascia of the loin as far down as the iliac crest. The lateral branch of the eleventh nerve can be traced over the iliac crest into the gluteal region.

The **anterior cutaneous branches** are small. That of the seventh nerve innervates the skin and fascia at the level of the xiphoid process. The eighth and ninth appear between the xiphoid process and the umbilicus; the tenth nerve supplies the region of the umbilicus; and the eleventh, the area immediately below the umbilicus. The dermatomes are not placed horizontally, but tend to be drawn downwards anteriorly as the series is followed from the upper to the lower nerves.

The lower six intercostal nerves supply many fine branches to the parietal peritoneum and extra-peritoneal tissue.

The anterior primary ramus of the twelfth thoracic nerve is the **subcostal nerve**, and is peculiar in its course and distribution. It emerges below the last rib (Fig. 938), and passes laterally and downwards behind the upper part of the psoas muscle and sometimes behind the lowest part of the pleura. It enters the abdomen below the lateral arcuate ligament and crosses in front of the quadratus lumborum muscle. Behind the kidney it pierces the transversus abdominis muscle, and courses forwards in the interval between it and the obliquus internus. As it approaches the median line, it runs in front of the rectus muscle, and its terminal branches pierce the rectus sheath to become cutaneous about midway between the umbilicus and the pubis. The branches of the nerve are **muscular** to the transversus, obliqui, rectus, and pyramidalis muscles of the abdominal wall; and **cutaneous branches**, two in number—a terminal *anterior cutaneous branch*, which supplies the skin and fascia of the anterior abdominal wall midway between the umbilicus and the pubis, and a large *lateral cutaneous branch*, which, passing obliquely downwards through the lateral muscles of the abdominal wall, becomes superficial above the iliac crest, two inches behind the anterior superior spine. It supplies the skin and fascia of the gluteal region as far down as a point below and anterior to the greater trochanter of the femur (Figs. 916, 918).

The subcostal nerve often receives a **communicating branch** from the eleventh intercostal near its origin, and still more frequently it sends a fine branch to join the first lumbar nerve in the psoas muscle. It may communicate also with the ilio-hypogastric nerve as they lie near each other in the abdominal wall.

Intercommunications of the Thoracic Nerves.—It has been noted already that the dermatome supplied by the branches of each thoracic nerve is innervated also by the nerve above and below. Communications also take place between the branches that supply the intercostal muscles, whereby the muscles of a given space derive their innervation from more than one intercostal nerve.

LUMBAR, SACRAL, AND COCCYGEAL PLEXUSES

These plexuses are formed by the union of the anterior primary rami of the remaining spinal nerves (five lumbar, five sacral, and one coccygeal), and are united

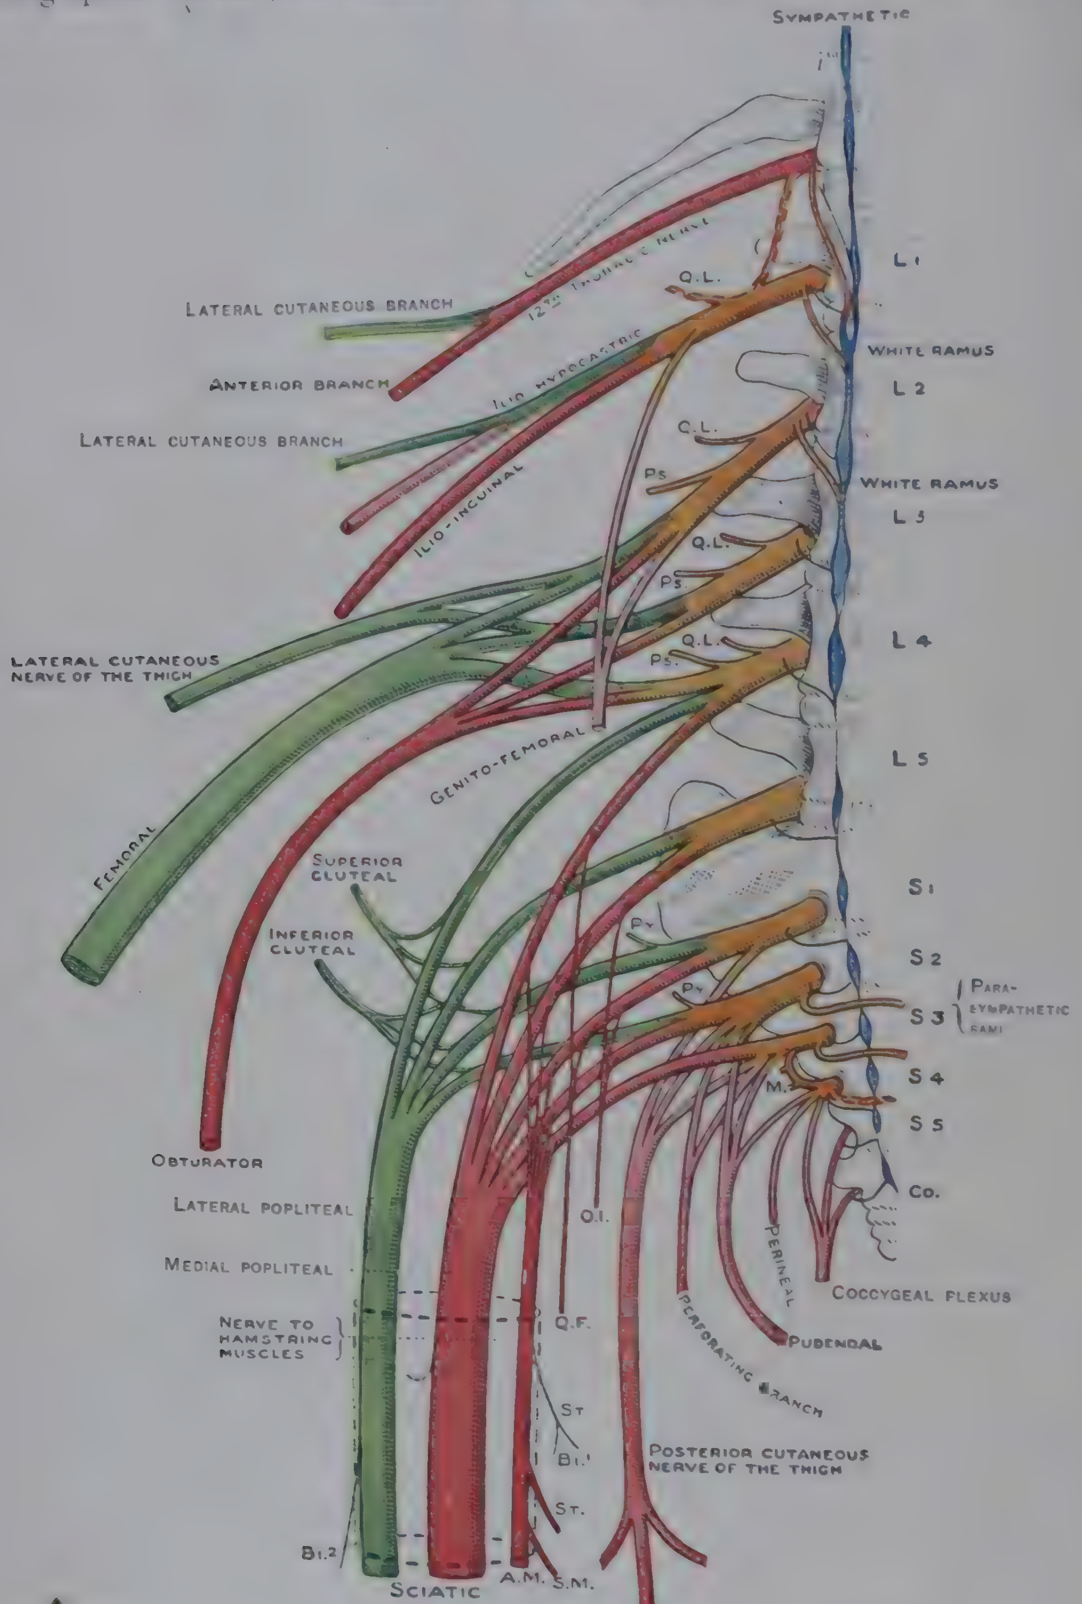

FIG. 937.—NERVES OF THE LUMBAR, SACRAL, AND COCCYGEAL PLEXUSES.

with one another—the lower lumbar nerves passing into the sacral plexus and the lower sacral into the coccygeal plexus. Frequently a fine communicating branch of the subcostal nerve joins the first lumbar nerve near its origin.

Of the nerves in question the first sacral is generally the largest in size, the nerves diminishing gradually above that nerve and rapidly below it. The nerves destined for the supply of the lower limb spring from the lumbar and sacral plexuses; in addition, nerves arise at their upper limit to be distributed to the trunk above the level of the limb; and near the lower limit nerves arise for the supply of the perineum.

Lumbar Plexus.—The lumbar plexus is formed by the anterior primary rami of the first four lumbar nerves, and is often joined by a branch from the twelfth thoracic nerve. It is limited below by the fourth lumbar nerve (*n. furcalis*), which enters also into the composition of the sacral plexus. The nerves of the lumbar plexus are formed in the loin, and supply that region as well as part of the lower limb.

Sacral Plexus.—The sacral plexus is formed by the anterior primary rami of the fourth and fifth lumbar and the upper four sacral nerves—the fourth sacral nerve dividing to take part in the coccygeal plexus also. The nerves of the sacral plexus are placed on the dorsal wall of the true pelvis, and are destined for the lower limb and the perineum.

Coccygeal Plexus.—The coccygeal plexus is formed by the anterior primary rami of the coccygeal and fifth sacral nerves and a portion of the fourth. It lies on the coccygeus muscle in the dorsal wall of the pelvis, and its branches are fine filaments to the coccygeus and levator ani and to the skin over the coccyx.

Communications with Autonomic System.—Each of the nerves has communications with the sympathetic trunk in the abdomen and pelvis by means of **grey rami communicantes.** From the lumbar and sacral ganglia, long, slender *grey rami communicantes* are directed backwards and laterally over the bodies of the vertebræ, and (in the lumbar region) behind the origins of the psoas muscle, to reach the spinal nerves. Those branches are irregular in their arrangement. A given nerve may receive branches from two ganglia, or one ganglion may send branches to two nerves. The grey rami are longer in the loin than in the pelvis, owing to the position of the sympathetic trunk.

Certain lumbar nerves are connected with the sympathetic by means of *white rami communicantes* also. From the first two lumbar nerves, and possibly in some cases also the third, white rami are directed forwards, either independently or incorporated with the corresponding grey rami, to join the upper part of the lumbar sympathetic trunk. The lower lumbar nerves and the sacral and coccygeal nerves are unprovided with white rami.

From the anterior primary rami of the second and third or third and fourth sacral nerves, parasympathetic fibres pass medially, and, crossing over (without joining) the sympathetic trunk, enter the pelvic plexuses of the autonomic system.

Variations in Position of Lumbar and Sacral Plexuses

These plexuses show a very considerable variability in position and constitution. Eisler (1891) records concomitant variations in 18 per cent. of the cases examined by him. The variations occur within wide limits. The lumbar plexus may begin at the eleventh or twelfth thoracic or first lumbar nerve. The last nerve in the sciatic cord may be either the second, the third, or the fourth sacral nerve. The position of the *nervus furcalis* is a guide to the arrangement of the plexus. It may be the third, third and fourth, fourth, fourth and fifth, or fifth lumbar nerves. The resulting variations are illustrated by the following extreme cases :—

	(1) *Prefixed Variety.*	(2) *Normal.*	(3) *Postfixed Variety*
Nervus furcalis	L. 3 and 4 (double).	L. 4.	L. 5.
Obturator	L. 1, 2, 3.	L 2, 3, 4.	L. 2, 3, 4, 5.
Femoral	T. 12, L. 1, 2, 3, 4.	L. 2, 3, 4	L. 2, 3, 4, 5.
Med. popliteal	L. 3, 4, 5, S. 1, 2.	L. 4, 5, S. 1, 2, 3.	L. 5, S. 1, 2, 3, 4.
Lat. popliteal	L. 3, 4, 5, S. 1.	L. 4, 5, S. 1, 2.	L. 5, S. 1, 2, 3.

The variations in the constitution of the lumbar and sacral plexuses which are most numerous are those due to the inclusion of nerves more caudally placed. Thus, out of twenty-two variations in the position of the *n. furcalis*, in nineteen Eisler found it to be the fifth lumbar nerve; in two cases only, the third lumbar nerve. There is further evidence that these variations in position are accompanied by variations in the vertebral column itself. Out of the twenty-two abnormal plexuses examined by Eisler, sixteen were coincident with abnormal arrangement of the associated vertebræ.

LUMBAR PLEXUS

The **lumbar plexus** is formed by the anterior primary rami of the first three lumbar nerves and a part of the fourth, with the addition, in half the number of

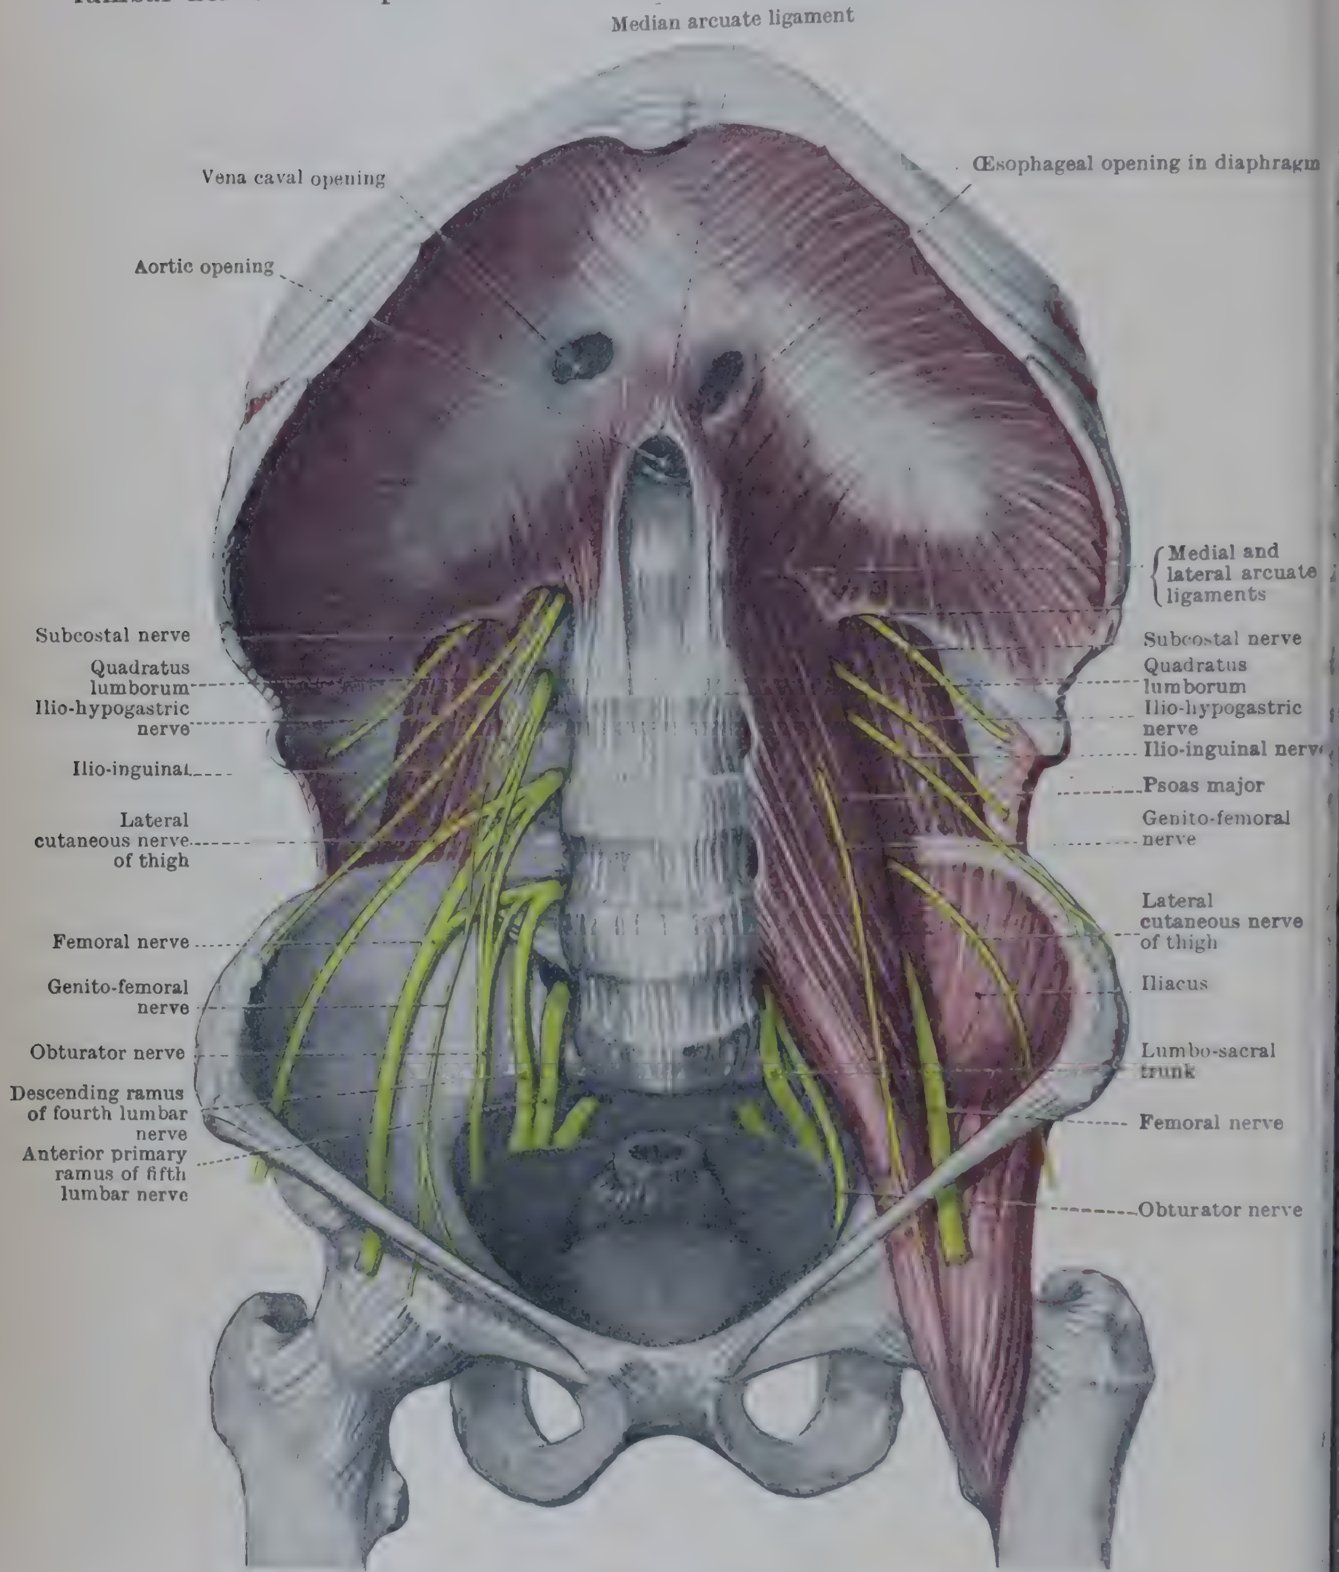

FIG. 938.—MUSCLES AND NERVES ON POSTERIOR ABDOMINAL WALL.

cases, of a small branch from the subcostal nerve. The nerves increase in size from above downwards (Fig. 938).

Position and Constitution.—The plexus is formed in the substance of the psoas major muscle, in front of the transverse processes of the lumbar vertebræ. The nerves, on emerging from the intervertebral foramina, are connected as above described with the sympathetic system, and then divide in the following manner in the substance of the psoas major muscle. The first and second nerves divide into superior and inferior branches. The superior branch of the first nerve (which may

be joined by the branch from the subcostal nerve) forms two nerves, the **ilio-hypogastric** and **ilio-inguinal**. The inferior branch of the first joins the superior branch of the second nerve, to form the **genito-femoral nerve**. The inferior branch of the second nerve, the whole of the third, and that part of the fourth nerve engaged in the constitution of the plexus divide each into two unequal parts—smaller *anterior* and larger *posterior parts*. The anterior portions combine together to form the **obturator nerve**; the root from the second nerve is not always present. The posterior portions of the same nerves combine together to form the **femoral nerve**. From the back of the posterior parts of the second and third nerves the **lateral cutaneous nerve of the thigh** arises. The nerves also provide, near their origins, irregular **muscular branches** for the psoas and quadratus lumborum muscles. The following is a list of the nerves which spring from the lumbar plexus, together with their origins:—

(1) Muscular branches to the quadratus lumborum (L. 1-4) and psoas (L. 2, 3) muscles.
(2) Ilio-hypogastric (? T. 12, L. 1).
(3) Ilio-inguinal (? T. 12, L. 1).
(4) Genito-femoral (L. 1, 2).
(5) Lateral cutaneous (L. 2, 3).
(6) Obturator (L. 2, 3, 4).
(7) Femoral (L. 2, 3, 4).

Muscular Branches.—The nerves to the **quadratus lumborum muscle** arise independently from the first three or four lumbar nerves (and sometimes also from the subcostal nerve). The nerves to the **psoas major** arise from the second and third lumbar nerves, with additions, in some cases, from the first or fourth. They are often associated in their origin with the nerve to the iliacus from the femoral nerve. The **psoas minor**, when present, is innervated by the first or the second lumbar nerve.

The ilio-hypogastric and ilio-inguinal nerves are in series with the subcostal nerve and closely resemble it in their course and distribution.

The **ilio-hypogastric nerve** is the highest branch of the first lumbar nerve. It receives fibres also from the subcostal when that nerve communicates with the first lumbar nerve. After traversing the psoas major muscle obliquely, it appears at its lateral border, on the anterior surface of the quadratus lumborum and behind the kidney. It courses through the loin, lying between the transversus and obliquus abdominis internus muscles, above the iliac crest. About an inch in front of the anterior superior spine it pierces the obliquus internus (Fig. 940), and continues its course in the groin deep to the aponeurosis of the obliquus externus. It finally becomes cutaneous in the anterior abdominal wall by piercing the aponeurosis of the obliquus externus about an inch and a half above the superficial inguinal ring (Fig. 918, p. 1059).

Its **branches** are—(1) *muscular* to the muscles of the abdominal wall; and (2) *cutaneous branches*, two in number. The **lateral cutaneous branch** corresponds to the lateral cutaneous branch of an intercostal nerve. It pierces the obliquus internus and obliquus externus, becomes cutaneous just above the iliac crest, below and behind the lateral cutaneous branch of the subcostal nerve. It is small, and may be absent. It is distributed to the skin and fascia over the upper part of the lateral side of the gluteal region, in contiguity with the cutaneous branch of the posterior primary ramus of the first lumbar nerve. The **anterior cutaneous branch** is the terminal branch of the nerve. It supplies the skin and fascia of the anterior abdominal wall below the level of the subcostal nerve and above the os pubis.

The **ilio-inguinal nerve** is the second branch given off from the first lumbar nerve. It also may receive fibres from the subcostal nerve. Not infrequently the ilio-hypogastric and ilio-inguinal nerves are represented for a longer or shorter part of their course by a single trunk. When separate the nerve takes a course similar to that of the ilio-hypogastric nerve, but at a lower level, as far as the anterior abdominal wall. It appears at the lateral border of the psoas major, after traversing the muscle obliquely, and passes behind the kidney in front of the quadratus lumborum. It extends forwards between the transversus and obliquus internus, and pierces the latter muscle (Fig. 940) farther forward and

lower down than the ilio-hypogastric; it continues forwards deep to the aponeurosis of the obliquus externus, just above the inguinal ligament, and thus comes to lie in the inguinal canal; it becomes superficial after passing through the superficial inguinal ring and external spermatic fascia (Fig. 918). Whilst lying between the transversus and obliquus internus it usually communicates with the ilio-hypogastric nerve.

Its branches are *muscular* to the muscles of the abdominal wall among which it passes, and *cutaneous branches* which innervate the skin and fascia (1) of the anterior abdominal wall over the pubic symphysis, (2) of the thigh over the proximal and medial part of the femoral triangle, and (3) of the superior part of the scrotum, and root and dorsum of the penis in the male (*scrotal branches*), and of the mons pubis and labium majus in the female (*labial branches*). The last-named branches are contiguous to branches of the pudendal nerve. No lateral cutaneous branch arises from the ilio-inguinal nerve. It thus corresponds, like the anterior cutaneous part of the ilio-hypogastric nerve, to the anterior continuation of a typical thoracic nerve.

The **genito-femoral nerve** usually arises from the front of the first and second lumbar nerves by two independent roots which unite in the substance of the psoas major. It appears on the posterior abdominal wall, lying on the front of the psoas major, medial to the psoas minor. It pierces the psoas fascia, and extends behind the ureter and along the lateral side of the common and external iliac arteries downwards, to the inguinal ligament (Fig. 938). At a variable point above that ligament it divides into two branches. 1. The **genital branch** is a small nerve which passes in front of the lower part of the external iliac artery, and enters the inguinal canal through the deep inguinal ring. It ends by supplying small branches to the skin and fascia of the scrotum and adjacent part of the thigh. In the female it accompanies the round ligament to the labium majus. In its course it gives off the following small branches: (1) to the external iliac artery; (2) to the cremaster muscle; (3) to communicate with the testicular plexus of the autonomic system and the ilio-inguinal nerve. 2. The **femoral branch** continues the course of the parent nerve and passes into the thigh behind the inguinal ligament and then lies on the lateral side of the femoral artery. It becomes cutaneous by passing through the saphenous opening or through the fascia lata, and supplies an area of skin and fascia over the femoral triangle, lateral to that supplied by the ilio-inguinal nerve (Fig. 941). It communicates in the thigh with the intermediate cutaneous branch of the femoral nerve. Before piercing the deep fascia it gives a minute branch to the femoral artery.

The **lateral cutaneous nerve of the thigh** is distributed only to skin and fascia. It arises from the back of the lumbar plexus, and usually from the second and third lumbar nerves (Fig. 938). Emerging from the lateral border of the psoas major muscle, the nerve crosses the iliacus muscle, behind the fascia iliaca, to reach the anterior superior iliac spine. It enters the thigh behind the lateral end of the inguinal ligament, and either superficial or deep to the sartorius muscle, or through its upper part (Fig. 940). It extends downwards in the front of the thigh for a few inches, lying at first deep to the fascia lata, and afterwards in a tubular investment of the fascia. It gives off small branches in this part of its course, and finally, piercing the fascia about four inches distal to the anterior superior iliac spine, it separates into anterior and posterior terminal branches. The **anterior branch** is the larger, and is distributed on the lateral part of the front of the thigh as far as the knee, where it may communicate with the patellar plexus. The smaller **posterior branch** supplies the skin and fascia of the lateral side of the buttock, distal to the greater trochanter, and the skin and fascia of the proximal two-thirds of the lateral side of the thigh (Fig. 941).

Obturator Nerve

The **obturator nerve** supplies the muscles on the medial side of the thigh, gives articular branches to the hip and knee joints, and sometimes has also a cutaneous branch. It arises in the substance of the psoas major muscle by three

roots placed in front of those of the femoral nerve, and derived from the second, third, and fourth lumbar nerves (Fig. 938). Sometimes the root from the second nerve is absent. Passing vertically downwards, the nerve emerges from the psoas major at its medial border, behind the common iliac vessels, and on the lateral side of the ureter and internal iliac vessels. It passes forwards below the pelvic brim in contact with the upper part of the obturator internus muscle and in company with the obturator artery to the obturator groove of the obturator

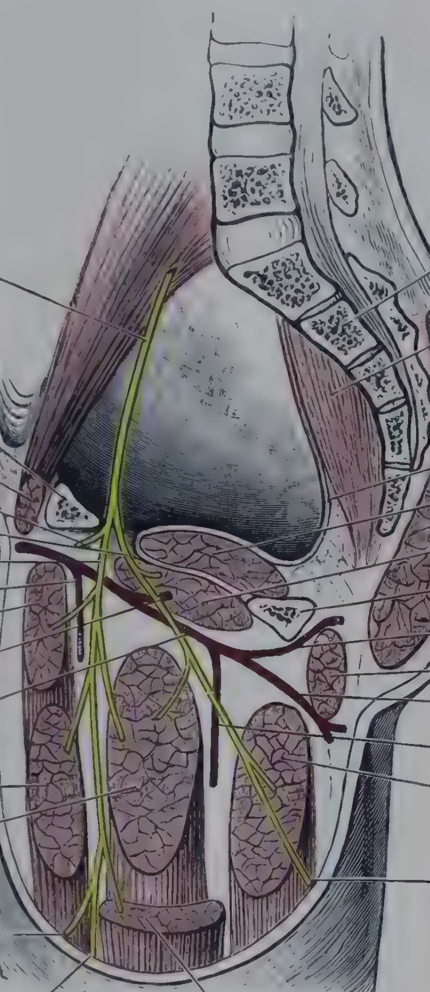

FIG. 939.—SCHEME OF COURSE AND DISTRIBUTION OF OBTURATOR NERVE.

foramen, through which it reaches the thigh. While in the obturator groove, where it lies above the obturator vessels, it separates into its two main branches, named anterior and posterior (Fig. 939).

In the thigh the **anterior branch** lies in front of the obturator externus and adductor brevis muscles, and behind the pectineus and adductor longus (Fig. 940). In the middle third of the thigh it is found coursing along the medial border of the adductor longus; and it finally divides into two slender terminal filaments.

The branches of the **anterior part** of the nerve are:—

1. An **articular branch** to the hip joint which arises from the nerve as soon as it enters the thigh, and supplies the joint through the acetabular notch.

2. **Muscular branches** to the adductor longus, gracilis, adductor brevis (usually), and the pectineus (occasionally).

3. Two *terminal branches*: (*a*) A **cutaneous branch**, of very variable size and often absent, becomes superficial between the gracilis and adductor longus (Fig. 939), in the middle third of the thigh, and may supply the skin and fascia of the distal two-thirds of the thigh on its medial side. It is generally of small size, and is connected with branches of the medial cutaneous nerve of the thigh and the saphenous nerve behind the sartorius muscle to form a plexus. The branch from the saphenous nerve to the plexus passes medially behind the sartorius

after piercing the fascial covering of the subsartorial canal. The branch from the medial cutaneous nerve is generally superficial at the point of formation of the plexus. (*b*) **A branch to the femoral artery** which enters the subsartorial canal along the medial border of the adductor longus, and ramifies over the distal part of the artery.

5. A fine **communicating branch** sometimes joins the femoral nerve in front of the hip joint.

The posterior branch of the obturator nerve reaches the thigh by piercing the obturator externus muscle. It descends between the adductor brevis and adductor magnus muscles. After passing obliquely through the adductor magnus, it enters the popliteal fossa on the popliteal artery, to which it furnishes twigs, and terminates by piercing the oblique posterior ligament of the knee joint.

Its branches are: (1) **muscular branches** to the obturator externus, adductor magnus, and the adductor brevis. The branch to the obturator externus arises in the obturator groove before the nerve enters the muscle. The nerve to the adductor magnus is given off as the obturator nerve passes through the substance of the muscle. (2) The **articular terminal branch** to the posterior part of the knee joint.

Femoral Nerve

The **femoral nerve** is the large nerve of supply for the muscles of the front of the thigh; it gives articular branches to the hip and knee joints; and it has an extensive cutaneous distribution down the medial side of the limb to the foot. It arises in the substance of the psoas major muscle, from the back of the second, third, and fourth lumbar nerves, posterior to the obturator nerve. Passing obliquely through the psoas major muscle, it emerges from its lateral border a little below the iliac crest (Fig. 938), and runs downwards in the groove between the psoas and iliacus to enter the thigh behind the inguinal ligament lateral to the femoral sheath and femoral vessels. In the femoral triangle it soon breaks up into a large number of branches (Fig. 940), among which the lateral circumflex artery passes in a lateral direction.

The **branches** of the femoral nerve, which are (1) muscular, (2) articular, (3) cutaneous, and (4) vascular, arise in the following way:—

In the abdomen a muscular branch arises from the lateral side of the nerve and enters the iliacus muscle, and a vascular branch descends to supply the femoral artery, which vessel also receives branches lower down in the thigh.

In the femoral triangle the terminal muscular, articular and cutaneous branches arise in the form of a large bundle of nerves.

1. The **muscular branches** supply the pectineus, sartorius, and quadriceps. The nerve to the *pectineus* arises close to the inguinal ligament and courses obliquely downwards and medially behind the femoral vessels to enter the muscle near its lateral border. It is not infrequently double. It sometimes gives off a fine communicating branch to the anterior part of the obturator nerve. The nerves to the *sartorius* are in two sets: a lateral set of short branches, associated with the lateral part of the intermediate cutaneous nerve, which supply the proximal part of the muscle; and a medial set of longer branches, which are associated with the medial part of the intermediate cutaneous nerve, and enter the middle of the muscle. The parts of the *quadriceps* are supplied by several branches. The vastus lateralis and rectus femoris are supplied on their deep surface by separate branches which are accompanied by branches of the lateral circumflex artery. The vastus intermedius muscle is supplied superficially by a branch which passes through the muscle, and supplies also the muscle of the knee joint (articularis genu). This muscle receives fibres also from one of the nerves to the vastus medialis. The vastus medialis muscle is supplied by two nerves: a proximal trunk, which supplies the proximal part of the muscle, and sends fibres to the vastus intermedius as well: and a distal trunk, which descends on the lateral side of the femoral artery along with the saphenous nerve; it passes deep to the sartorius, deep or superficial to the aponeurotic covering of the subsartorial canal, and enters the

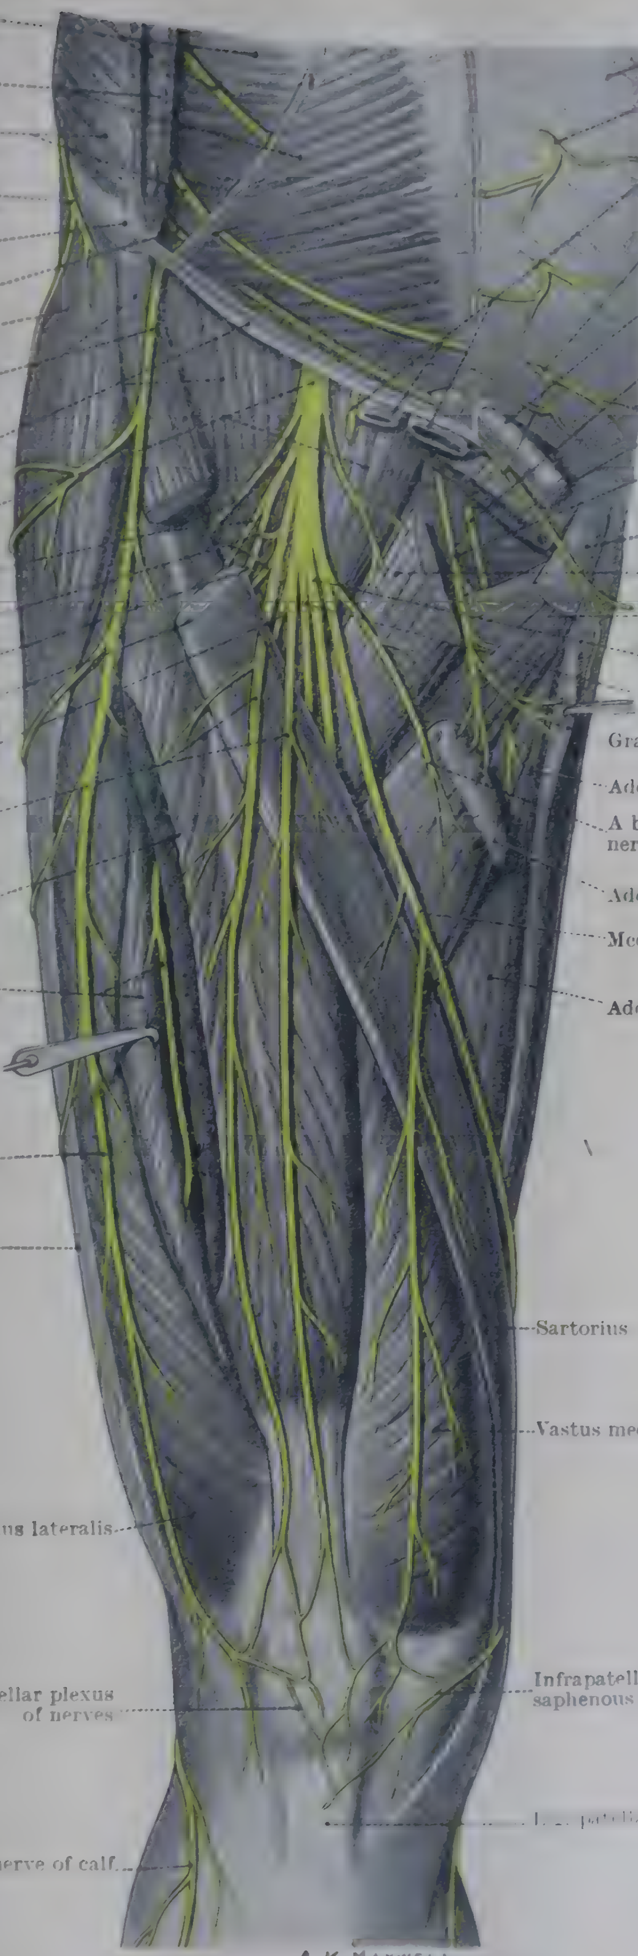

FIG. 940.—NERVES OF FRONT OF THIGH.

medial side of the muscle. That nerve gives off a small branch which enters the nutrient canal of the femur.

2. The **articular branches** supply the hip and knee joints. The articular branch to the hip joint arises from the nerve to the rectus femoris, and is accompanied by branches from the lateral circumflex artery. The articular branches to the knee joint are four in number. Three of them arise from the nerves to the

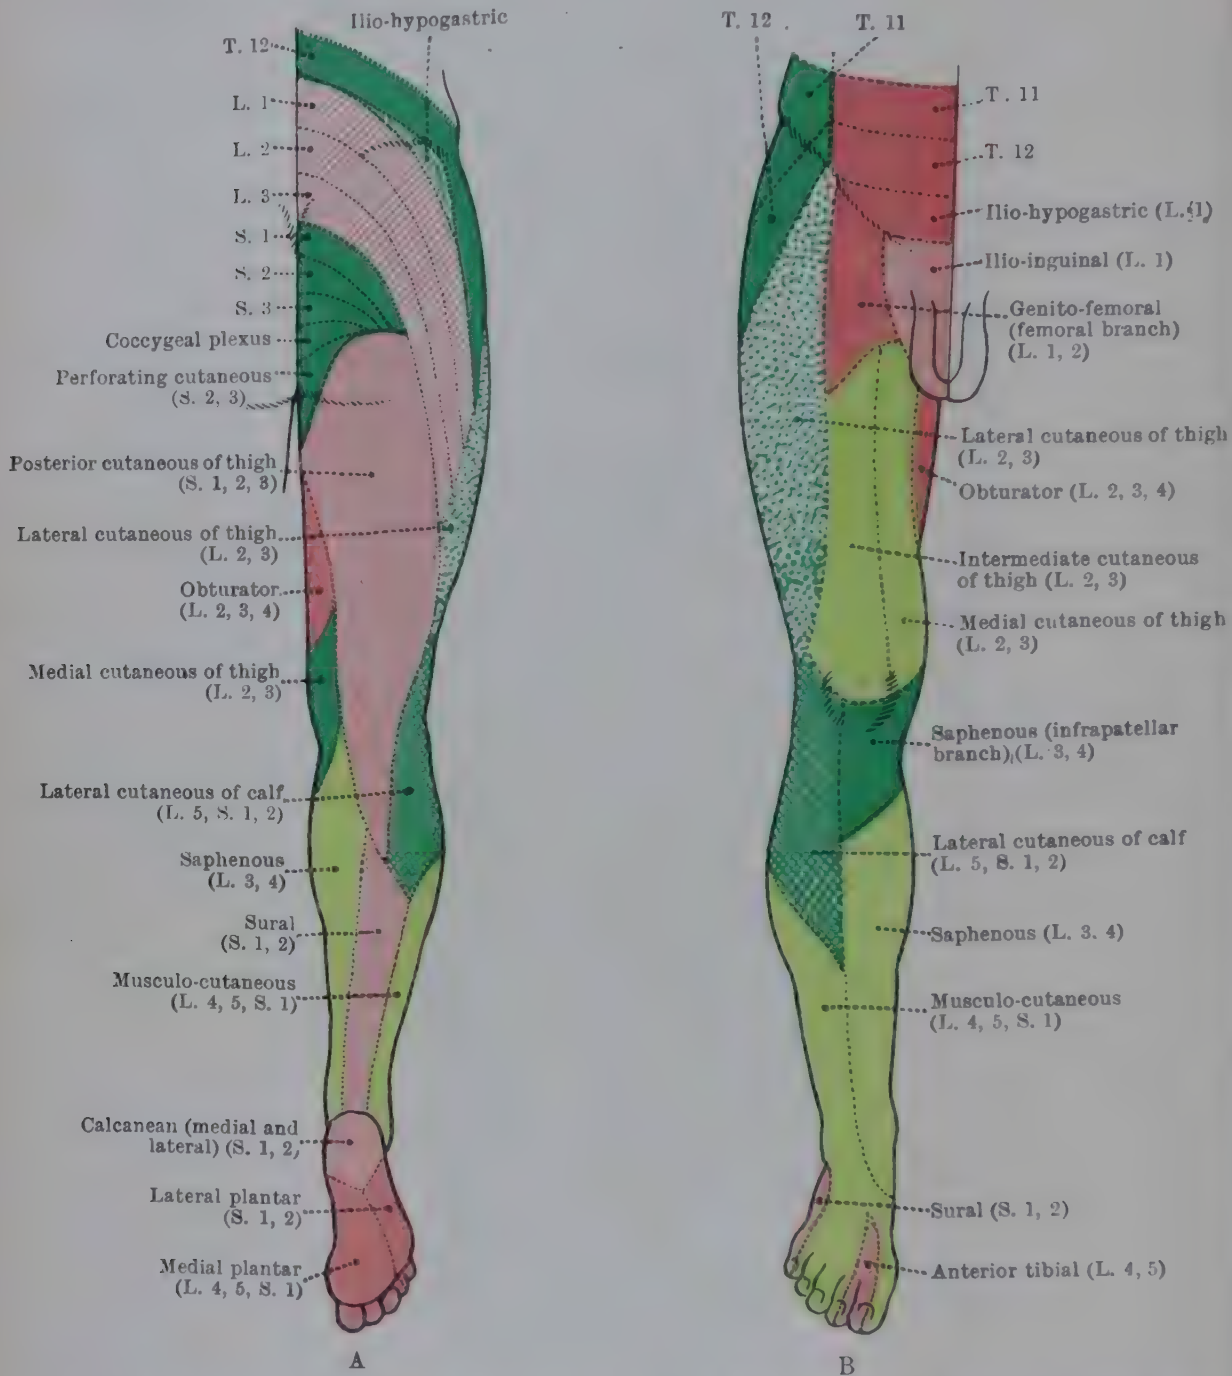

FIG. 941.—DISTRIBUTION OF CUTANEOUS NERVES: A, ON THE BACK: B, ON THE FRONT OF LOWER LIMB. The dorsal surfaces of the terminal phalanges are supplied by the plantar nerves (Fig. 949). The overlapping of nerve-areas, and of dermatomes in Fig. 942, is not shown (see p. 1053). The segmental distribution of individual spinal nerves in the lower part of the trunk and upper part of the thigh is represented, according to more recent clinical data, in the dermatome diagrams in Fig. 942.

vastus lateralis, vastus intermedius, and vastus medialis, which, after the muscular branches are given off, are continued downwards to the knee joint along the front of the femur. A fourth articular branch arises (sometimes) from the saphenous nerve.

3. The **cutaneous branches** are the intermediate and medial cutaneous nerves, and the saphenous nerve (Figs. 940, 941).

The **intermediate cutaneous nerve of the thigh** arises in two parts, a *lateral* and a *medial branch*, in the proximal part of the femoral triangle. The two branches

descend vertically and become cutaneous by piercing the fascia lata over the proximal third of the sartorius muscle. They carry muscular branches to the sartorius, and the lateral branch in many cases pierces the muscle. The two nerves supply the skin and fascia of the distal three-fourths of the front of the thigh, between the lateral cutaneous nerve of the thigh laterally and the medial cutaneous on the medial

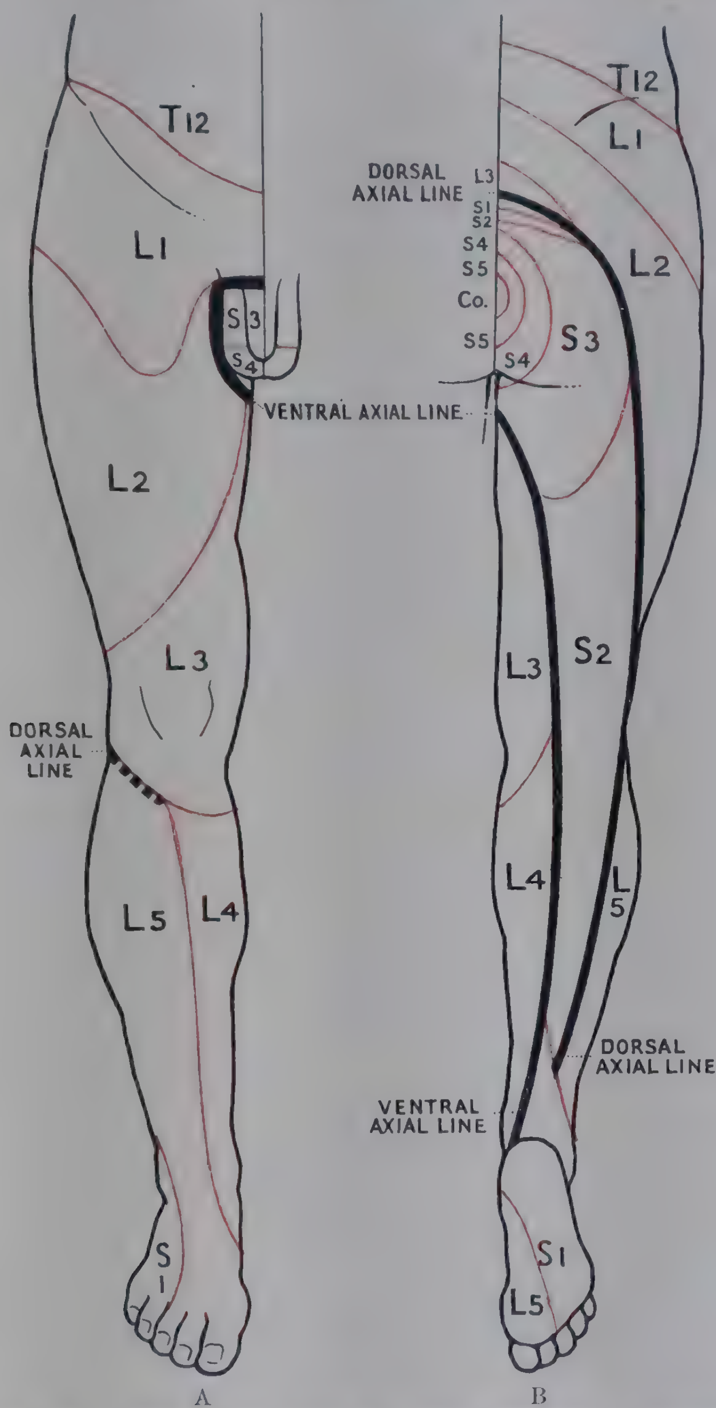

FIG. 942.—DERMATOMES OF LOWER LIMB, SHOWING THE SEGMENTAL CUTANEOUS DISTRIBUTION OF SPINAL NERVES (T 12, L 1-5, S 1-5, Co.) ON A, THE FRONT, AND B, THE BACK OF THE LIMB AND LOWER PART OF TRUNK (AFTER HEAD, 1893 AND FOERSTER, 1933). See p. 1053 for definition of "dermatome" and p. 1114 for more particular reference to the segmental innervation of the lower limb.

side. They reach to the front of the patella, and there assist in the formation of the patellar plexus. The lateral branch communicates, in the proximal third of the thigh, with twigs from the femoral branch of the genito-femoral nerve.

The **medial cutaneous nerve of the thigh** lies at first in the femoral triangle on the lateral side of the femoral vessels. At the apex of the triangle it crosses over the femoral vessels, and is directed downwards superficial to or through the sartorius muscle, and deep to the fascia lata, to the distal third of the thigh. It is distributed to the skin and fascia of the distal two-thirds of the thigh on the medial side by means of three branches—proximal, middle, and distal.

The *proximal branch* may be represented by two or more twigs. It arises from the main nerve near its origin, and pierces the fascia lata near the apex of the femoral triangle. It is distributed to the skin and fascia of the proximal part of the thigh along the line of the long saphenous vein. The *middle* or *anterior branch* is a larger nerve. It separates from the distal branch at the apex of the femoral triangle, and, passing superficial to the sartorius muscle, becomes cutaneous in the middle third of the thigh on the medial side. It supplies the skin and fascia of the distal half of the medial side of the thigh, extending as far as the knee, where it joins in the formation of the patellar plexus.

The *distal branch* represents the termination of the nerve. It passes along the medial side of the thigh superficial to the sartorius muscle, and communicates in the middle third of the thigh with the saphenous and obturator nerves to form a plexus. Piercing the fascia lata on the medial side of the thigh in the distal third, it ramifies over the medial side of the knee, and assists in the formation of the patellar plexus.

The size of the medial cutaneous nerve of the thigh varies with the size of the cutaneous part of the obturator, and of the saphenous nerve.

The **saphenous nerve** may be regarded as the terminal branch of the femoral nerve. It is destined for the skin and fascia of the leg and foot. From its origin in the femoral triangle it descends alongside the femoral vessels to the subsartorial canal. In the canal it crosses obliquely in front of the femoral artery from lateral to medial side. At the distal end of the canal, accompanied by the saphenous branch of the descending genicular artery, it passes anterior to the tendon of the adductor magnus, and becomes cutaneous opposite the medial side of the knee joint by passing between the sartorius and gracilis muscles (Fig. 940). The nerve then extends downwards in the leg with the long saphenous vein, passes over the front of the medial malleolus and terminates at the middle of the medial border of the foot.

Branches.—1. A **communicating branch** arises in the subsartorial canal and, passing medially behind the sartorius, joins with branches of the obturator nerve in forming a plexus.

2. The **infrapatellar branch** arises at the distal end of the subsartorial canal, and, piercing the sartorius muscle, is directed downwards and forwards below the patella and over the medial condyle of the tibia to the front of the knee and proximal part of the leg. It enters into the formation of the patellar plexus.

3. An **articular branch** sometimes arises from the nerve at the medial side of the knee.

4. The **terminal branches** of the saphenous nerve are distributed to the skin and fascia of the front and medial side of the leg and the posterior half of the dorsum and medial side of the foot.

The **patellar plexus** consists of fine communications, beneath the skin in front of the knee, between the branches of the cutaneous nerves supplying that region. The nerves which enter into its formation are the infrapatellar branch of the saphenous, medial and intermediate cutaneous, and sometimes the lateral cutaneous nerve of the thigh.

The **accessory obturator nerve** is only occasionally present (29 per cent, Eisler, 1891). It arises from the third, or third and fourth lumbar nerves, between the roots of the obturator and femoral nerves. It is associated with the obturator nerve, from which, however, it is quite separable. It appears in the abdomen at the medial side of the psoas muscle and passes over the pelvic brim behind the external iliac vessels, leaves the obturator nerve, and enters the thigh in front of the os pubis.

In the thigh, behind the femoral vessels, it usually ends in three branches: a nerve which replaces the branch from the femoral nerve to the pectineus, a nerve to the hip joint, and a nerve which communicates with the anterior part of the obturator nerve. In some cases it supplies only the nerve to the pectineus; more rarely it is of considerable size, and reinforces the obturator nerve in the innervation of the adductor muscles.

It is more closely associated with the femoral than with the obturator. Its origin is behind the roots of the obturator: it is separated, like the femoral, from the obturator by the pubic bone; and its chief branch—the branch to the pectineus muscle—replaces the normal branch from the femoral nerve. On the other hand, for a part of its course it accompanies the obturator, and in rare cases it may replace branches of that nerve.

SACRAL PLEXUS

The sacral plexus is usually formed by the anterior primary rami of the following nerves—a part of the fourth lumbar nerve (n. furcalis), the fifth lumbar, the upper three sacral nerves and part of the fourth.

Position and Constitution.—The plexus is placed on the dorsal wall of the pelvis between the piriformis muscle and its fascia. In front of it there are the internal iliac vessels and the ureter, and, in addition, the pelvic colon on the left side, coils of the ileum on the right side.

The nerves which form the plexus converge towards the inferior part of the greater sciatic foramen, and unite to form a broad triangular band, the apex of which is continued through the greater sciatic foramen below the piriformis muscle into the gluteal region as the **sciatic nerve**. From the anterior and posterior surfaces of the triangular band numerous small branches arise and are distributed to the parts in the neighbourhood of the origin of the nerve.

The sciatic nerve ends in the thigh by dividing into two large nerves—the *medial popliteal* and *lateral popliteal*. In many cases these two nerves are distinct at their origin, and are separated sometimes by fibres of the piriformis muscle. In all cases, on removal of the sheath investing the sciatic nerve, the two divisions can be traced up to the plexus, from which they invariably take origin by distinct and separate roots.

Formation.—The descending branch of the fourth lumbar nerve after emerging from the border of the psoas major muscle, medial to the obturator nerve, divides behind the iliac vessels into anterior and posterior (ventral and dorsal) parts, each of which joins a corresponding part of the fifth lumbar nerve. The anterior primary ramus of the fifth lumbar nerve descends over the ala of the sacrum and in front of the sacro-iliac joint, and divides into anterior and posterior parts, which are joined by the corresponding parts of the fourth lumbar nerve. The two resulting trunks lie close together and are called the **lumbo-sacral trunk**. The first and second sacral nerves pass laterally from the anterior sacral foramina, and divide in front of the piriformis into similar anterior and posterior parts. The third sacral nerve runs laterally to join the second. The fourth divides into two parts, of which the upper joins the sacral plexus and the lower joins the coccygeal plexus. Of those nerves the fifth lumbar and first sacral are the largest; the others diminish in size as they are traced downwards.

The principal nerve that arises from the sacral plexus is the sciatic, and its two components (lateral and medial popliteal) are formed in the following way. Lying in apposition, and converging on the lower part of the greater sciatic foramen, the *posterior* (dorsal) *trunks* of the fourth and fifth lumbar nerves, and of the first and second sacral nerves, combine to form the **lateral popliteal nerve**. The *anterior* (ventral) *trunks* of the fourth and fifth lumbar nerves, and of the first and second sacral nerves, together with part of the third sacral nerve, unite to form the **medial popliteal nerve** (Fig. 937).

Branches.—Besides the sciatic nerve, the sacral plexus gives rise to numerous smaller nerves, some of which arise from the front of it and some from the back.

Anterior Branches.

- Nerve to quadratus femoris and inferior gemellus (L. 4, 5, S. 1)
- Nerve to obturator internus and superior gemellus (L. 5, S. 1, 2)
- Pelvic splanchnic nerves (S. 2, 3, 4)
- Pudendal nerve (S. 2, 3, 4)

Posterior Branches.

- Muscular twigs to piriformis (S. 1, 2) and to coccygeus and levator ani (S. 3, 4)
- Superior gluteal nerve (L. 4, 5, S. 1)
- Inferior gluteal nerve (L. 5, S. 1, 2)
- Posterior cutaneous nerve of thigh (S. 1, 2, 3)
- Perforating cutaneous nerve (S. 2, 3)
- Perineal branch of S. 4.

We shall deal with these *collateral* branches before we trace the course and distribution of the large, *terminal* branch (the sciatic) and its subdivisions.

Collateral Branches of Sacral Plexus

The **nerve to the quadratus femoris** (and **inferior gemellus**) arises from the front of the fourth and fifth lumbar and first sacral nerves. It leaves the pelvis through the lower part of the greater sciatic foramen, passes downwards over the back of the ischium near the capsule of the hip joint (to which it sends a fine branch) deep to the sciatic nerve, gemelli, and obturator internus muscles. It supplies a nerve to the inferior gemellus, and terminates in the deep surface of the

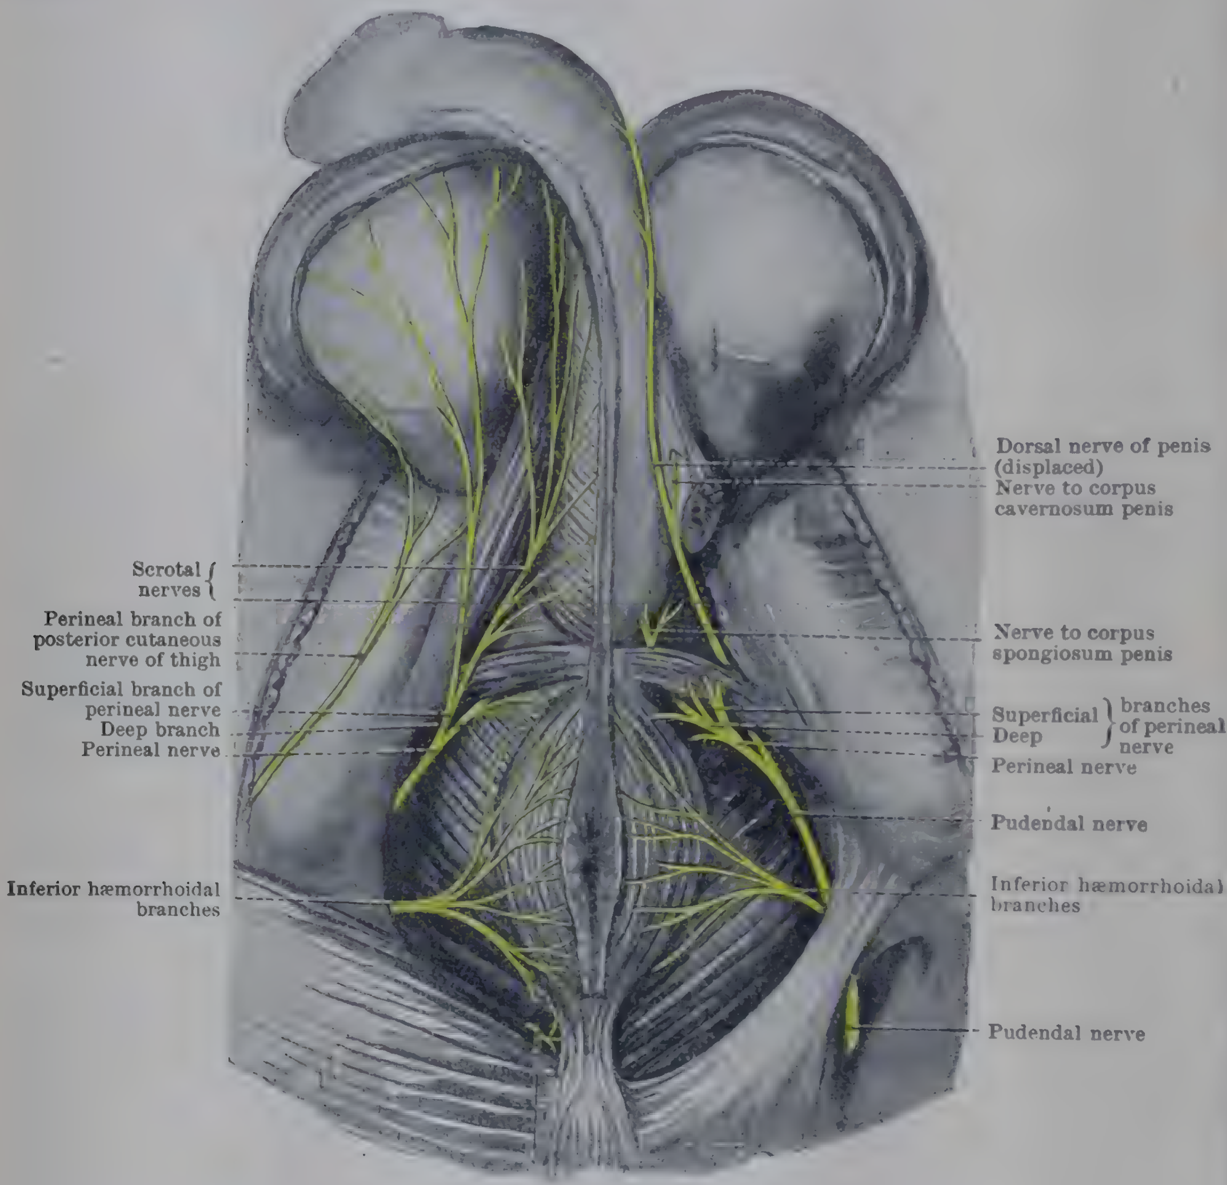

Fig. 943.—Distribution of the Pudendal Nerve.

quadratus femoris. The branch to the hip joint may arise from the medial popliteal part of the sciatic.

The **nerve to the obturator internus** (and **superior gemellus**) arises from the front of the fifth lumbar and first two sacral nerves. In the gluteal region it lies medial to the sciatic nerve on the lateral side of the internal pudendal vessels: crossing the ischial spine, it enters the ischio-rectal fossa through the lesser sciatic foramen. The nerve supplies, in the gluteal region, a branch to the superior gemellus, and it terminates by entering the perineal surface of the obturator internus.

The **pelvic splanchnic nerves**, as mentioned already, are composed of parasympathetic fibres. They are two slender filaments that spring from the second and third or third and fourth sacral nerves, and pass forwards to join the sympathetic plexuses, by which they are distributed to viscera—urogenital organs and the lower part of the large intestine.

The **pudendal nerve** is the principal nerve for the supply of the perineum. It arises in the pelvis usually by three roots from the second, third, and fourth sacral nerves (Fig. 937). The nerve passes to the gluteal region through the greater sciatic foramen, medial to the sciatic nerve, and lies on the sacro-spinous ligament medial to the internal pudendal artery. With that artery, it passes through the lesser sciatic foramen into the perineum and enters the pudendal canal of the obturator fascia, which is deeply placed on the lateral wall of the ischio-rectal fossa. As the nerve enters the canal it gives off the inferior hæmorrhoidal nerve, and shortly afterwards it divides into its terminal branches—the perineal nerve and the dorsal nerve of the penis or clitoris—which run forwards in the pudendal canal towards the posterior border of the perineal membrane.

The branches of the pudendal nerve are essentially the same in the two sexes. As a rule, it gives off no branches until it enters the perineum, but sometimes the inferior hæmorrhoidal nerve has a separate origin from the plexus and merely

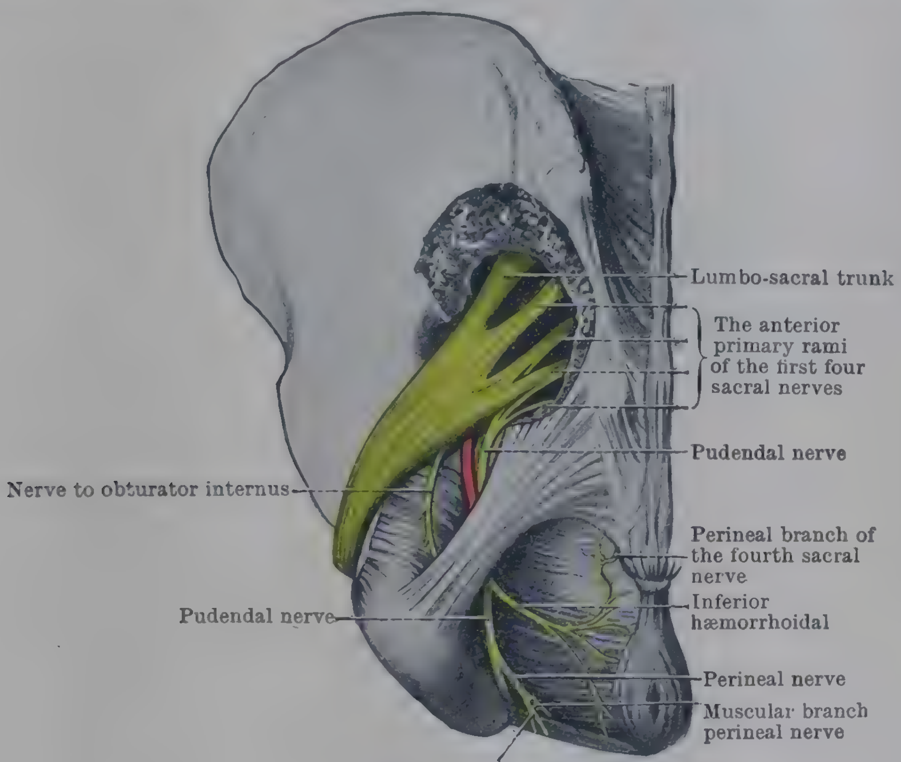

FIG. 944.—ORIGIN AND COURSE OF THE PUDENDAL NERVE.

accompanies the pudendal nerve in the first part of its course; and in exceptional cases the perforating cutaneous nerve is a branch of the pudendal nerve.

The **inferior hæmorrhoidal nerve** arises from the pudendal nerve under cover of the gluteus maximus, at the posterior part of the ischio-rectal fossa. When it has an independent origin from the plexus, it arises from the third and fourth sacral nerves. It crosses the ischio-rectal fossa in company with the inferior rectal vessels, and separates into numerous branches—muscular, cutaneous, and communicating.

The **muscular branches** end in the sphincter ani externus muscle. The **cutaneous branches** supply the skin and fascia around the anus. The **communicating branches** connect the inferior hæmorrhoidal nerve with the perineal branches derived from the posterior cutaneous nerve of the thigh and from the pudendal and fourth sacral nerves.

The **perineal nerve** runs forwards in the pudendal canal towards the posterior border of the perineal membrane, near which it gives off the scrotal or labial branches, and then divides into terminal branches.

The *scrotal* or *labial branches* become superficial and are distributed to the skin and fascia of the perineum and the scrotum or the labium majus. They communicate with the perineal branch of the posterior cutaneous nerve of the thigh and with the inferior hæmorrhoidal nerve.

The *terminal branches* supply the muscles in the deep and superficial perineal pouches, and one of these enters the bulb of the penis and supplies the erectile tissue of the bulb and the corpus spongiosum penis, as well as the mucous membrane of the urethra, as far as the glans penis.

The **dorsal nerve of the penis** or **clitoris** accompanies the internal pudendal artery through the pudendal canal into the deep perineal pouch. There it passes forwards close to the side of the pubic arch, lying under cover of the crus and ischio-cavernosus and perineal membrane, and below the sphincter urethræ muscle. It sends a slender branch through the perineal membrane to supply the erectile tissue of the crus and corpus cavernosum of penis or clitoris: and then, piercing the perineal membrane near its anterior border at the lateral side of the dorsal artery it passes on to the dorsum of the penis or clitoris, to which it is distributed in its distal two-thirds, sending branches round the sides of the organ to reach its under surface. In the female the nerve is much smaller than in the male.

The **nerve to the piriformis muscle** may be double. It arises from the back of the second, or first and second sacral nerves, and at once enters the pelvic surface of the muscle.

The **nerves to coccygeus and levator ani** arise from a loop between the third and fourth sacral nerves and descend to these muscles. The **perineal branch of the fourth sacral nerve** arises from the lower part of the same loop; it descends through the coccygeus, appears in the posterior angle of the ischio-rectal fossa, and runs forwards to end in the posterior part of the external sphincter ani. It gives branches also to the overlying fascia and skin.

The **perforating cutaneous nerve** arises from the second and third sacral nerves (Fig. 937). At its origin it is associated with the lower roots of the posterior cutaneous nerve of the thigh. Passing downwards it pierces the sacro-tuberous ligament, and, after winding round the lower border of the gluteus maximus muscle or piercing its lower fibres, it becomes cutaneous a little distance from the coccyx, and supplies the skin and fascia of the lower part of the buttock and the medial part of the fold of the buttock.

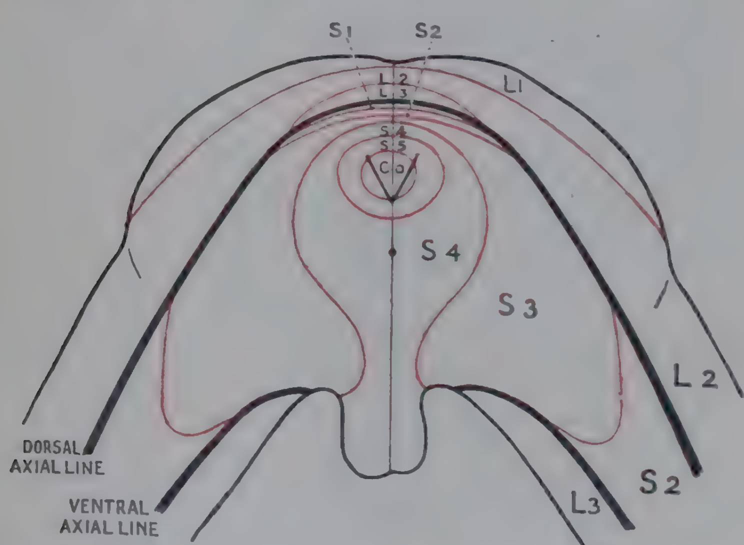

FIG. 945.—PERINEAL DERMATOMES, SHOWING SEGMENTAL CUTANEOUS DISTRIBUTION OF SPINAL NERVES (L 1-3, S 2-5, Co.) TO PERINEUM AND ADJACENT PARTS OF TRUNK AND LOWER LIMB. (After Head & Foerster.)

The perforating cutaneous nerve is not always present. In a minority of cases it is associated at its origin with the pudendal nerve. When absent as a separate nerve, its place is taken by (1) gluteal branches of the posterior cutaneous nerve of the thigh, or (2) a branch from the pudendal nerve, or (3) a small nerve (n. perforans coccygeus major, Eisler, 1891) which arises separately from the third and fourth sacral nerves.

The **superior gluteal nerve** arises from the posterior surface of the fourth and fifth lumbar and first sacral nerves, and is directed backwards and laterally into the gluteal region above the piriformis muscle, along with the superior gluteal artery. Under cover of the gluteus maximus and gluteus medius it passes over the gluteus minimus, along with the inferior branch of the deep division of the superior gluteal artery, to the deep surface of the tensor fasciæ latæ, in which it ends. On its way it supplies branches to the gluteus medius and gluteus minimus muscles.

The **inferior gluteal nerve** arises from the posterior surface of the fifth lumbar and upper two sacral nerves. It appears in the gluteal region at the lower border of

the piriformis muscle, superficial to the sciatic nerve, and at once breaks up into a number of branches for the supply of the gluteus maximus. Till it enters the buttock it is closely associated with the posterior cutaneous nerve of the thigh.

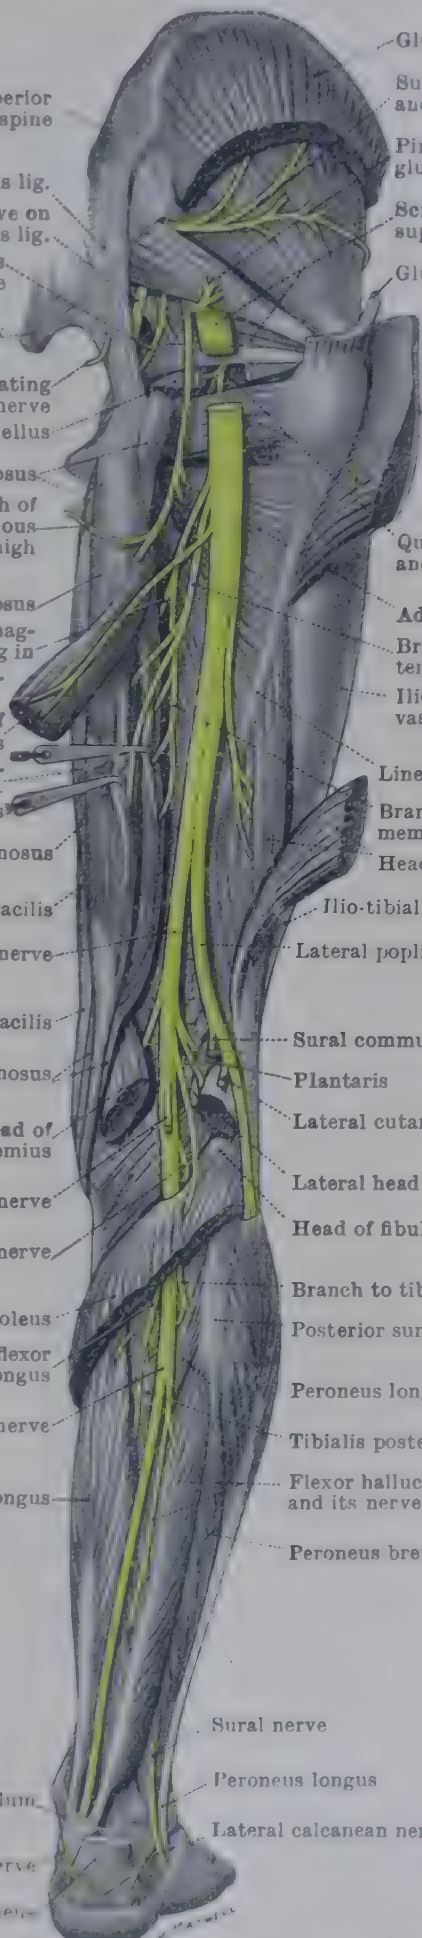

Fig. 946.—Nerves of Back of Lower Limb.

The **posterior cutaneous nerve of the thigh** (Fig. 937) is derived from the upper three sacral nerves or from the second and third. It is distributed to the lower limb and perineum, and is associated with other nerves belonging to both regions. Its higher roots from the first and second sacral nerves are intimately associated with the origin of the inferior gluteal nerve; its lowest root from the third sacral nerve is associated with the origins of the perforating cutaneous or of the pudendal nerve. It enters the gluteal region through the greater sciatic notch, below the piriformis, along with the inferior gluteal artery and nerve. Proceeding downwards with the sciatic nerve, it enters the thigh at the lower border of the gluteus maximus muscle, where it gives off considerable branches. Becoming gradually smaller as it descends over the hamstring muscles to the popliteal fossa, it finally pierces the deep fascia as one or more cutaneous branches which supply the skin and fascia over the calf of the leg for a variable distance (Fig. 941).

Branches.—The nerve is distributed solely to skin and fascia. It supplies branches to the perineum, buttock, thigh, and leg.

The *perineal branch* arises at the lower border of the gluteus maximus muscle (Fig. 947). It sweeps in a medial direction across the hamstring muscles

below the ischial tuberosity towards the perineum; and, becoming subcutaneous after passing over the pubic arch, its terminal branches supply the skin and fascia of the scrotum and root of the penis, or, in the female, the labium majus and clitoris, communicating with branches of the ilio-inguinal nerve. Some of them pass backwards towards the anus and the perineal body and communicate with the inferior hæmorrhoidal and perineal branches of the pudendal nerve. In its course to the perineum the nerve gives off *collateral branches* to the upper medial part of the thigh (Fig. 943).

The *gluteal branches*, large and numerous, arise from the nerve deep to the gluteus maximus and become subcutaneous by piercing the fascia lata at different points along its lower border. They supply the skin and fascia of the lower half of the buttock. The most lateral branches, reaching to the back of the greater trochanter, overlap the terminal filaments of the gluteal branches of the lateral cutaneous nerve of the thigh and the posterior primary rami of the upper three lumbar nerves. The most medial branches, which may pierce the sacro-tuberous ligament, reach nearly to the coccyx, and are co-extensive in their distribution with the branches of the perforating cutaneous nerve, which they reinforce and may replace.

The *branches to the thigh* pierce the fascia lata at intervals, and supply the skin and fascia of the back of the thigh.

The *branches to the calf* are two or more slender nerves which pierce the fascia over the popliteal fossa and are distributed to the fascia and skin for a variable extent over the back of the leg. They may stop short over the popliteal fossa, or may reach as far as the ankle. Usually they extend as far as the middle of the calf and communicate with the sural nerve.

When the sciatic nerve is naturally divided at its origin into medial and lateral popliteal nerves (*e.g.*, by the piriformis muscle), the posterior cutaneous nerve also is separated into two parts: a **posterior part**, associated with the lateral popliteal nerve and arising in common with the lower roots of the inferior gluteal nerve (usually from the first and second sacral nerves), and comprising the branches to the gluteal region and lateral part of the back of the thigh and leg; and an **anterior part**, associated with the medial popliteal nerve and arising usually from the second and third sacral nerves, along with the perforating cutaneous and pudendal nerves, and comprising the branches to the perineum and medial part of the limb.

Sciatic Nerve

The **sciatic nerve** is the thickest nerve in the body. It consists of two nerves —the medial and lateral popliteal—bound together by an investing sheath, which contains, in addition to these nerves, a branch from each, viz., the nerve to the hamstring muscles from the medial popliteal nerve, and the nerve to the short head of the biceps femoris from the lateral popliteal nerve. From the account given of the origin of the fibres of the medial and lateral popliteal nerves, it follows that the fibres of the sciatic nerve are derived from the fourth and fifth lumbar and first, second, and third sacral nerves. A thick band about half an inch in breadth is formed, consisting, from the medial to the lateral side, of (1) the nerve to the hamstring muscles, (2) the medial popliteal nerve, (3) the lateral popliteal nerve, (4) the nerve to the short head of the biceps femoris.

The sciatic nerve leaves the pelvis and enters the gluteal region through the greater sciatic foramen between the piriformis and the superior gemellus (Fig. 947). It runs laterally and then downwards through the gluteal region, in the hollow between the greater trochanter of the femur and the ischial tuberosity, accompanied by the inferior gluteal artery and its own companion artery. It is covered posteriorly by the gluteus maximus, and is in relation anteriorly with the following structures, from above downwards: (1) the posterior surface of the ischium and the nerve to the quadratus femoris, (2) the superior gemellus, (3) the obturator internus, (4) the inferior gemellus, (5) the quadratus femoris.

The nerve enters the thigh at the lower border of the quadratus femoris and lies at first in the angle between the lower border of the gluteus maximus above and laterally, and the hamstring muscles medially. It then runs down the back

of the thigh, on the posterior surface of the adductor magnus, and is covered by the long head of the biceps femoris, which crosses behind the nerve from the medial to the lateral side.

It usually terminates at the proximal angle of the popliteal fossa by

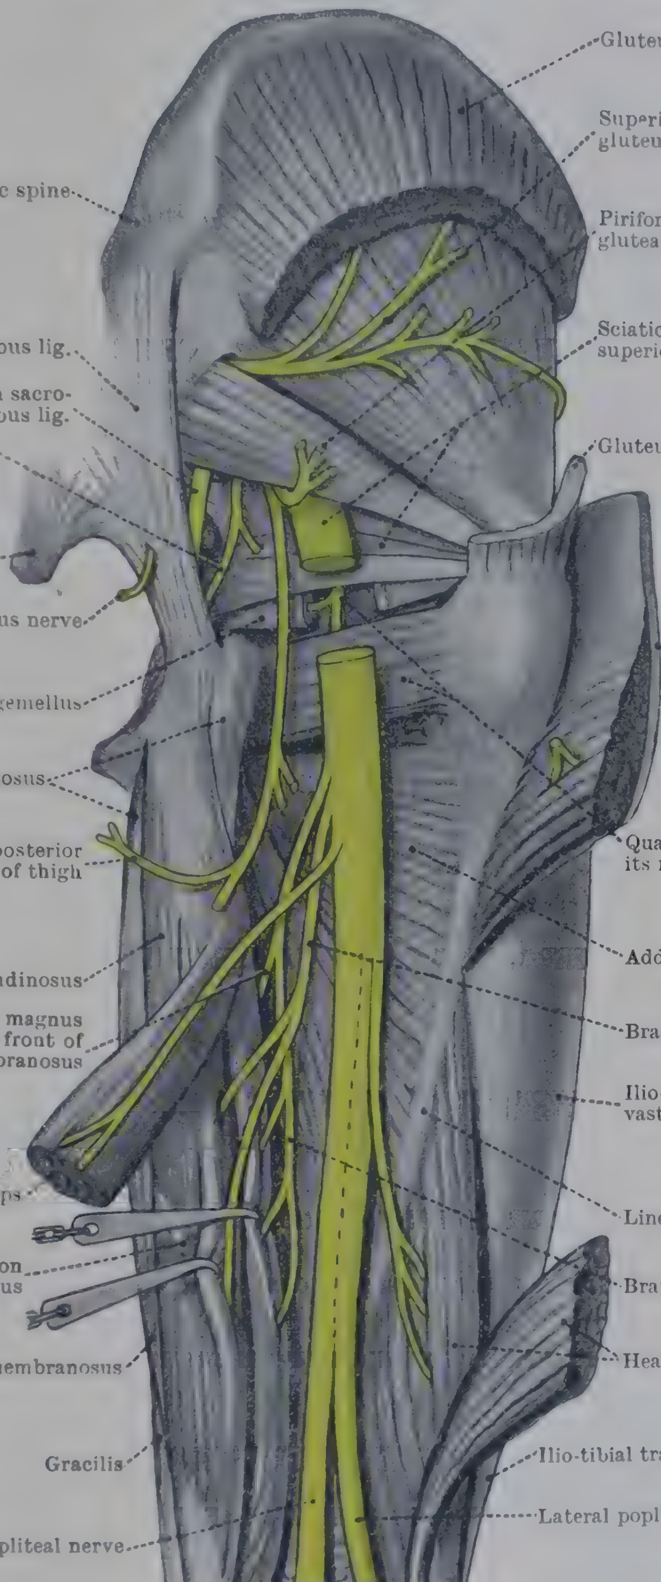

FIG. 947.—NERVES OF GLUTEAL REGION AND BACK OF THIGH.

dividing into the medial and lateral popliteal nerves (Figs. 946, 947); but the separation may occur at any higher level, and, as already noted, these two nerves may even be distinct at their origin, in which case the lateral popliteal usually pierces the piriformis.

The **nerve to the hamstring muscles** forms the most medial part of the sciatic trunk in the lower part of the buttock. It arises from all the roots of the medial popliteal nerve on their anterior aspect, viz., from the fourth and fifth

lumbar and the first three sacral nerves. The fibres from the different roots unite to form a cord which is at first closely associated with the medial popliteal part of the sciatic nerve, but leaves it just below the quadratus femoris to be distributed to the hamstring muscles (except the short head of the biceps) by a series of branches which, however, may be given off separately by the sciatic nerve (Fig. 947). The nerve to the semitendinosus is double, and the branch to the part above the tendinous intersection may be associated with the nerve to the long head of the biceps. The nerve to the ischial portion of the adductor magnus arises in common with the nerve to the semimembranosus, which runs downwards in front of the lateral margin of its muscle, giving several branches to it.

The **nerve to the short head of the biceps** springs from the lateral side of the lateral popliteal trunk in the proximal part of the thigh. When traced to its origin, it is found to arise (sometimes in combination with the inferior gluteal nerve) from the fifth lumbar and first two sacral nerves. In its course it is closely applied to the lateral popliteal nerve, from which it separates in the middle third of the thigh, usually in combination with the articular branches of that nerve for the knee joint. In some cases it has an independent course in the thigh, and it may be associated in the buttock with the inferior gluteal nerve.

An **articular branch** for the lateral and anterior parts of the knee joint generally arises from the lateral popliteal nerve in common with the nerve to the short head of the biceps. When traced up to the plexus, it is found to arise from the posterior surface of the fourth and fifth lumbar and first sacral nerves. It passes through the proximal part of the popliteal fossa concealed by the biceps muscle, and separates into proximal and distal branches, which accompany the superior and inferior lateral articular arteries to the knee joint.

Terminal Branches of Sciatic Nerve.—The **lateral popliteal** and **medial popliteal nerves** are the two main trunks resulting from the combination of the posterior and anterior cords respectively of the sacral plexus. The lateral popliteal nerve is homologous with the radial nerve of the upper limb; the medial popliteal nerve represents a median-ulnar trunk.

Lateral Popliteal Nerve

The **lateral popliteal nerve** arises from the posterior part of the sacral plexus from the fourth and fifth lumbar and first two sacral nerves. Incorporated in the sciatic nerve in the gluteal region and proximal part of the thigh, it descends from the bifurcation of that nerve through the popliteal fossa to its termination at a point about an inch distal to the head of the fibula. It is concealed at first by the biceps muscle. Following the tendon of that muscle, it passes obliquely through the proximal and lateral part of the popliteal fossa and over the lateral head of the gastrocnemius muscle to the back of the head of the fibula. In the distal part of its course it is quite superficial except at its termination, where it is covered by the peroneus longus muscle and lies between that muscle and the neck of the fibula, round which it winds (Figs. 947, 948, 950).

Collateral Branches.—They are divided into two sets: (*a*) *Nerves arising while it is in combination with the medial popliteal nerve in the sciatic trunk.* They have been already described as a **muscular branch** to the short head of the biceps and an **articular branch** to the knee joint. (*b*) *Nerves arising in the popliteal fossa.* Those are **cutaneous branches**, viz., the lateral cutaneous nerve of the calf and the sural communicating branch.

The **lateral cutaneous nerve of the calf of the leg** is inconstant in size and distribution, and may be represented by two or more branches. It arises from the lateral popliteal nerve in the popliteal fossa, often in common with the succeeding nerve, pierces the deep fascia over the lateral head of the gastrocnemius, and is distributed to the skin and fascia on the lateral part of the back of the leg in the proximal two-thirds (Fig. 941). The extent of its distribution varies with that of the posterior cutaneous nerve of the thigh and the sural nerve.

The **sural communicating branch** begins in the popliteal fossa, passes over the lateral head of the gastrocnemius, deep to the deep fascia, to the middle third of the

leg, where it joins the sural nerve. The two branches do not always unite. The sural communicating branch then may be limited in its distribution to the skin and fascia of the lateral side of the leg, or it may be distributed to the area usually supplied by the sural nerve.

A small *recurrent branch* arises immediately above the division of the lateral popliteal nerve into its two terminal branches. Passing forwards under cover of the origin of the peroneus longus muscle and through the extensor digitorum longus, the recurrent branch divides, just below the lateral condyle of the tibia, into branches which supply the proximal fibres of the tibialis anterior muscle, the superior tibio-fibular joint, and the knee joint (Fig. 948).

Terminal Branches.—The terminal branches of the lateral popliteal nerve are two in number: anterior tibial and musculo-cutaneous. They begin immediately below the head of the fibula, and are directed forwards, diverging in their course, under cover of the peroneus longus muscle.

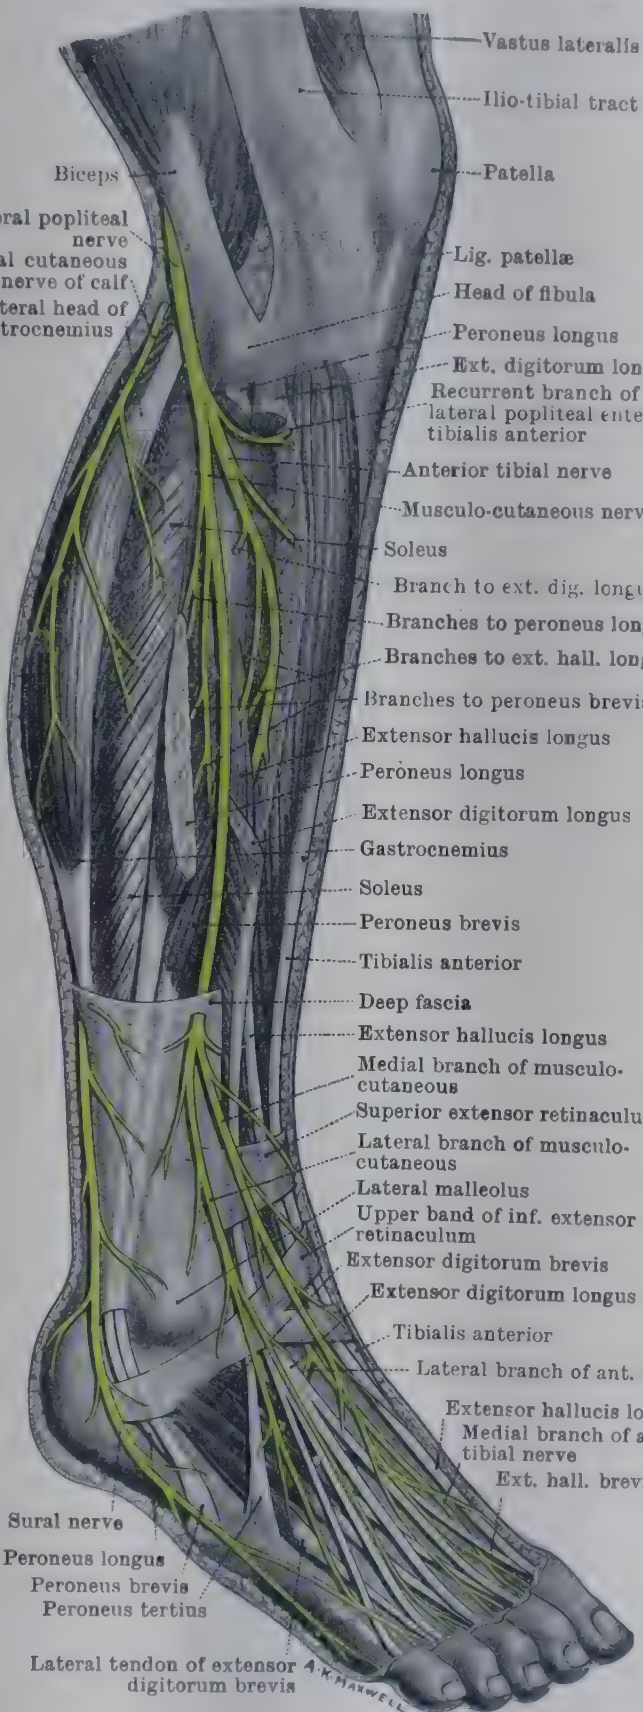

FIG. 948.—NERVES OF FRONT AND LATERAL SIDE OF LEG AND DORSUM OF FOOT.

ANTERIOR TIBIAL NERVE

The **anterior tibial nerve** passes obliquely downwards, under cover of the peroneus longus, extensor digitorum longus, and extensor hallucis longus muscles, to the front of the leg. In its course it is deeply placed on the interosseous membrane and the distal part of the tibia, in company with the anterior tibial artery, lying first lateral to the vessel, then anterior, and then lateral to it again. At the ankle it lies under cover of the superior extensor retinaculum and the tendon of the extensor hallucis longus, and, after crossing the ankle joint, it divides on the dorsum of the foot into its terminal branches.

1. **Collateral Branches** (in the leg).—These are given off to the muscles between which the nerve passes, namely: tibialis anterior, extensor hallucis longus, extensor digitorum longus, and peroneus tertius. A fine articular branch supplies the ankle joint.

2. **Terminal Branches** (on the foot).—The terminal branches are medial and lateral. The **medial (digital) branch** passes over the dorsum of the foot, along the lateral side of the dorsalis pedis artery, to the first interosseous space, where it divides into two *dorsal digital branches* for the supply of the skin and fascia of the lateral side of the big toe and the medial side of the second toe. Each of these branches communicates with branches of the musculo-cutaneous nerve. It gives off one or two branches which supply the medial tarso-metatarsal and metatarso-phalangeal joints, and enter the first dorsal interosseous muscle.

The **lateral branch** passes obliquely over the tarsus under cover of the extensor digitorum brevis, and ends in a gangliform enlargement (similar to the gangliform enlargement on the interosseous nerve of the forearm at the back of the wrist). From the enlargement, muscular branches arise for the supply of the extensor digitorum brevis, along with branches for the tarsal, tarso-metatarsal, and metatarso-phalangeal joints. Its *articular branches* may be as many as four in number. Of those the lateral two, extremely small, may only reach the tarso-metatarsal joints. The medial two are fine branches, which, besides supplying the joints, may give branches (probably afferent) to the second and third dorsal interosseous muscles.

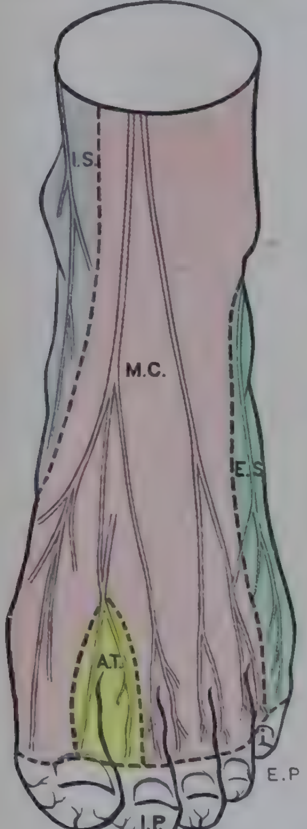

FIG. 949.—DISTRIBUTION OF CUTANEOUS NERVES ON DORSUM OF THE FOOT.

S., Saphenous nerve; M.C., Musculo-cutaneous nerve; A.T., Anterior tibial nerve; E.S., Sural nerve. The extremities of the toes are supplied by the medial and lateral plantar nerves (I.P., E.P.).

MUSCULO-CUTANEOUS NERVE

The **musculo-cutaneous nerve** passes downwards in front of the fibula, in a sheath in the intermuscular septum between the peronei and the extensor digitorum longus, to the distal third of the leg, where its two terminal branches pierce the deep fascia.

Its branches are: (1) *collateral* muscular branches distributed to the peroneus longus and peroneus brevis, as the nerve lies in relation to these muscles; (2) *terminal* cutaneous branches, medial and lateral.

The **medial branch** courses downwards over the extensor retinacula, and after supplying offsets to the distal third of the leg and to the dorsum of the foot divides into three branches. (1) The most medial branch supplies the skin and fascia of the dorsum of the foot and the medial side of the big toe, and communicates with the saphenous nerve. (2) The intermediate branch passes to the interval between the big toe and the second, and divides into two branches which communicate with the medial branch of the anterior tibial nerve. (3) The lateral branch passes to the interval between the second and third toes, and divides into *dorsal digital branches* to supply the adjacent sides of these toes.

The **lateral branch** of the musculo-cutaneous nerve also passes over the extensor retinacula, and after supplying branches to the distal part of the leg and to the dorsum of the foot divides into two parts, which, passing to the intervals between the third and fourth, and fourth and fifth toes, divide into *dorsal digital branches* for the adjacent sides of these toes. The latter branches communicate with offsets of the sural nerve.

The arrangement of the cutaneous branches of the musculo-cutaneous nerve is liable to considerable variation. The lateral division of the nerve may be increased in size, and may supply the nerve to the adjacent sides of the second and third toes; or it may be reduced in size, in which case the sural nerve takes its place on the dorsum of the foot, often supplying as many as two and a half toes (Kosinski, 1926).

The cutaneous nerves on the dorsum of the toes are much smaller than the corresponding plantar digital nerves. They are reinforced on the dorsum of the terminal phalanges by twigs from the plantar nerves, which supply the tips of the toes and the nails.

Medial Popliteal Nerve

The **medial popliteal nerve** arises from the anterior surface of the sacral plexus, usually from the fourth and fifth lumbar and first three sacral nerves (Fig. 937, p. 1088). It is incorporated in the sciatic trunk in the gluteal region and proximal part of the thigh. At the bifurcation of the sciatic nerve it passes onwards through the popliteal fossa and becomes the *posterior tibial nerve* at the lower border of the popliteus muscle. The course of the nerve through the gluteal region and thigh has already been described (p. 1104). In the popliteal fossa it is concealed at first by the semimembranosus and the other hamstring muscles. It passes behind the popliteal vessels from the lateral to the medial side, and is thereafter found behind the popliteus muscle, under cover of the gastrocnemius and plantaris (Fig. 950).

The **collateral branches** are divided into two sets:—(*a*) *Nerves arising while it is incorporated in the Sciatic Nerve.*—They have been already described as *the nerve to the hamstring muscles*, and an occasional *articular branch* to the hip joint. (*b*) *Nerves arising in the Popliteal Fossa.*—These are in three sets—articular, muscular, cutaneous. Vascular branches to the popliteal artery also are described.

1. The **articular branches** are slender nerves, variable in number. There are usually two, one of which pierces the oblique ligament of the knee joint, while the other, a long fine nerve, crosses the popliteal vessels, and descends to accompany the inferior medial articular artery to the knee joint. In its course it sometimes gives off a fine branch which accompanies the superior medial articular artery.

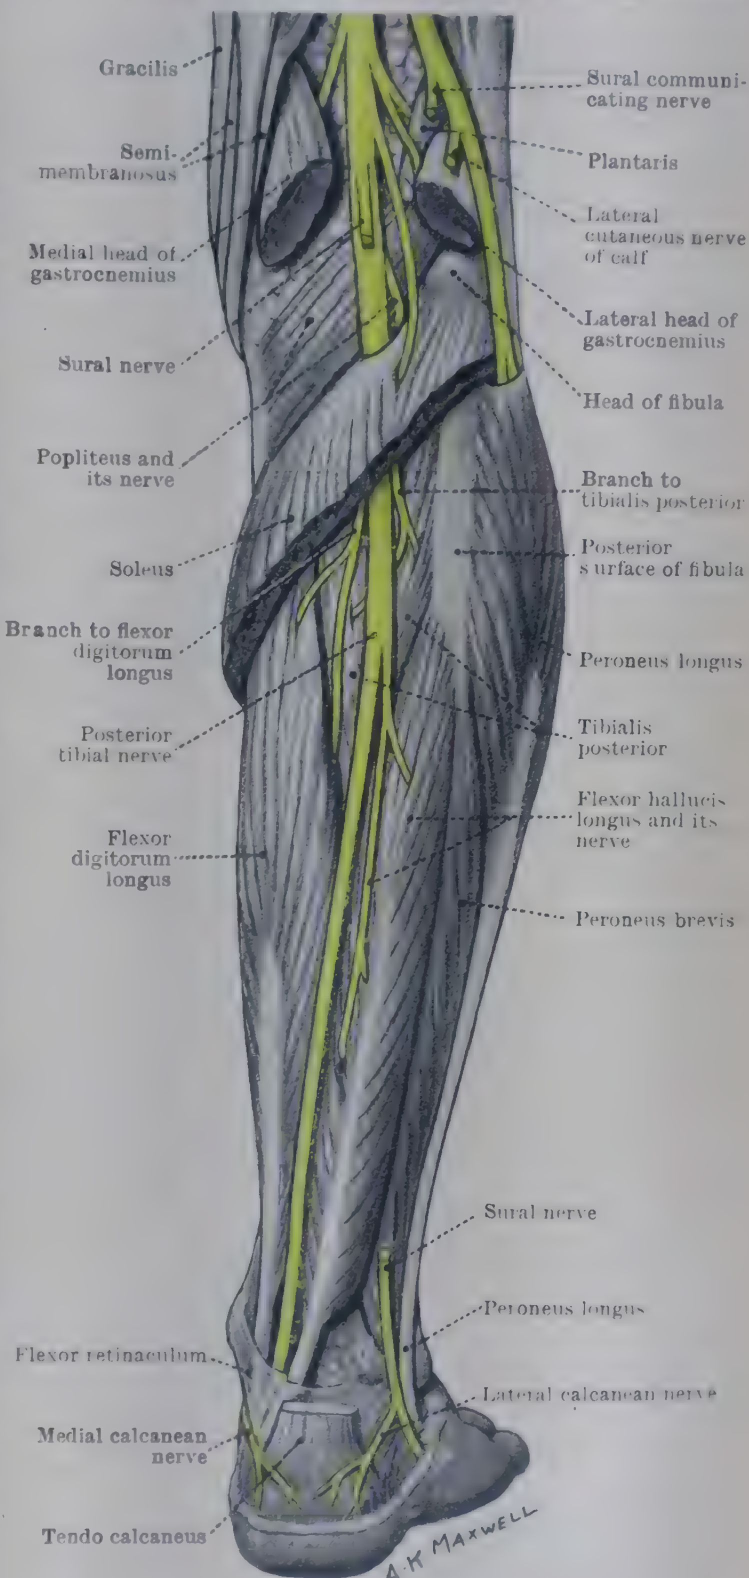

Fig. 950.—Nerves of Popliteal Fossa and Back of Leg.

2. The **muscular branches** are five in number. Nerves for the two heads of the *gastrocnemius*, and for the *plantaris* enter those muscles at the borders of the popliteal fossa. A nerve for the *soleus* enters the superficial surface of the muscle. A nerve to the *popliteus* muscle passes behind that muscle, and, after winding round its distal border, supplies it on its anterior surface; as this nerve curves round the lower border of the popliteus it supplies branches to the *tibialis posterior*, a branch for the interosseous membrane, which can be traced as far as the inferior tibio-fibular joint, an *articular*

branch for the superior tibio-fibular joint, and a *medullary* branch for the shaft of the tibia.

3. The **cutaneous branch** is the **sural nerve.** That nerve passes from the popliteal fossa in the groove between the two heads of the gastrocnemius muscle, and afterwards lies on the tendo calcaneus. It pierces the deep fascia in the middle third of the back of the leg, and is joined immediately afterwards by the sural communicating branch from the lateral popliteal nerve. The sural nerve reaches the foot by winding round the back of the lateral malleolus along with the short saphenous vein. It supplies cutaneous branches to the lateral side and back of the distal third of the leg, the ankle and heel (*lateral calcanean branches*) and the lateral border of the foot, as well as articular branches to the ankle joint and the tarsal joints.

The sural nerve communicates on the foot with the musculo-cutaneous nerve (Fig. 949), and its size varies with the size of that nerve. It may extend on to the dorsum of the foot for a considerable distance, and may either reinforce or replace the branches of the musculo-cutaneous nerve to the intervals between the fourth and fifth and the third and fourth toes. Frequently the sural communicating branch does not join the sural nerve, and in such cases the sural communicating branch may sometimes be distributed to the area usually supplied by the sural nerve.

Posterior Tibial Nerve

The **posterior tibial nerve** is a direct continuation of the medial popliteal, and begins at the distal border of the popliteus muscle. As the nerve passes downwards from this point it lies on the tibialis posterior muscle and the tibia, and, along with the posterior tibial vessels, occupies a sheath in the intermuscular septum separating the superficial and deep muscles of the back of the leg (Fig. 950). In the proximal part of the leg the nerve is medial to the posterior tibial vessels, but, crossing behind them, it lies on their lateral side in the distal portion of its course. It terminates under cover of the flexor retinaculum by dividing into the lateral and medial plantar nerves.

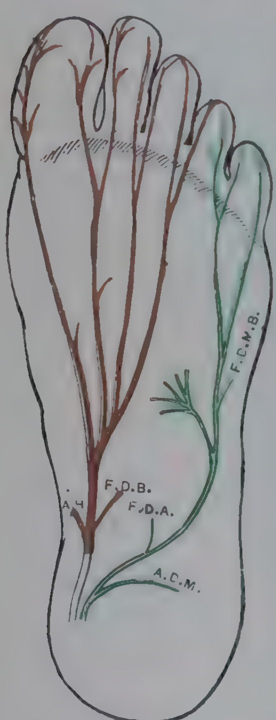

FIG. 951.—SCHEME OF DISTRIBUTION OF THE PLANTAR NERVES.

In brown, medial plantar nerve, and its cutaneous and muscular branches; F.D.B., Flex. dig. brev.; A.H., Abd. hall.; Flex. hall. brev. and 1st lumbrical shown but not lettered. *In green*, lateral plantar nerve, and its cutaneous and muscular branches; F.D A., Flex. dig. access.; A.D.M., Abd. dig. min.; F.D.M.B., Flex. dig. min. brev.

The branches are muscular, cutaneous and terminal.

The **muscular branches** are four in number, comprising nerves to the soleus (entering its deep surface) and tibialis posterior, often arising by a common trunk, and nerves to the flexor digitorum longus and flexor hallucis longus, the latter generally accompanying (and supplying) the peroneal artery for some distance. The nerve to the tibialis posterior supplies twigs to the posterior tibial artery.

The **cutaneous branches** are the **medial calcanean branches**, which pierce the flexor retinaculum, and are distributed to the skin and fascia of the heel and posterior part of the sole of the foot.

In addition, a *medullary nerve* to the fibula and a small *articular branch* to the ankle joint are supplied by the posterior tibial nerve.

The terminal branches of the posterior tibial nerve are the *medial* and *lateral plantar nerves*.

Medial Plantar Nerve

The **medial plantar nerve** is homologous with the median nerve in the hand and is rather larger than the lateral plantar (Figs. 951, 952). It courses forwards in the sole of the foot, under cover of the flexor retinaculum and abductor hallucis, to the interval between that muscle and the flexor digitorum brevis, in company with the medial plantar artery.

The **collateral branches** are muscular, cutaneous, articular and vascular. The *muscular* branches supply the abductor hallucis and the flexor digitorum brevis. The plantar *cutaneous* branches are small twigs which pierce the deep fascia in the interval between the above-mentioned muscles to supply the medial part of the

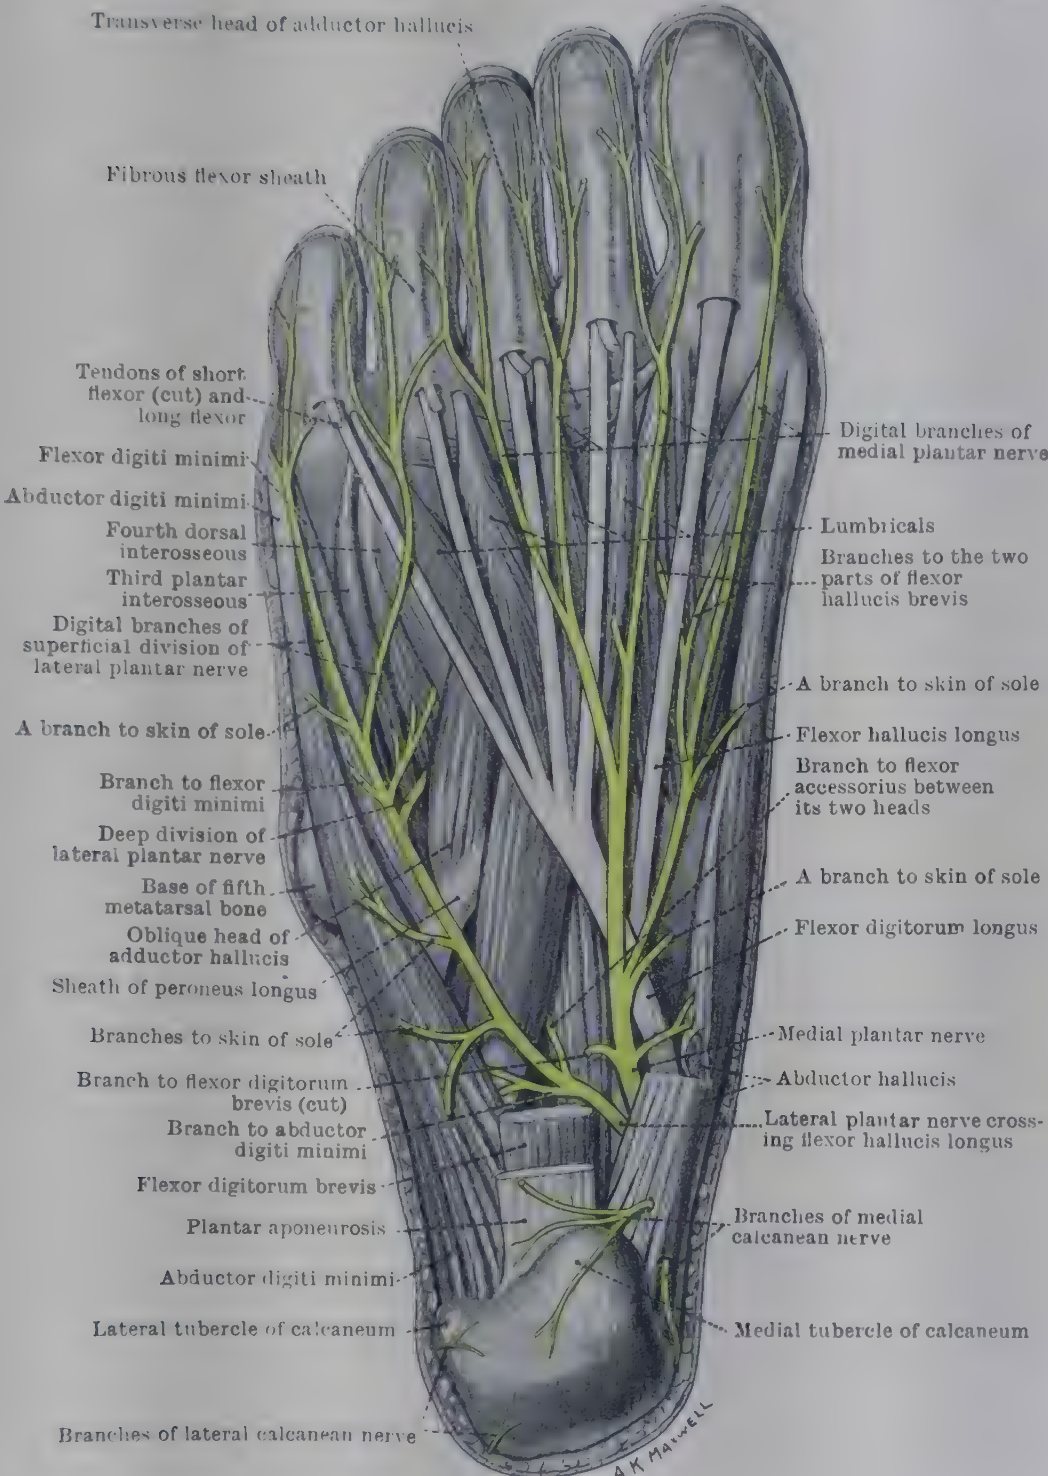

FIG. 952.—PLANTAR NERVES.

sole of the foot. The *articular* branches are minute twigs which supply the tarsal and tarso-metatarsal joints. *Vascular branches* are given to the neighbouring arteries by the main nerve and its branches.

The **terminal branches** are four in number—the *plantar digital nerves*—and may be designated first, second, third, and fourth, from medial to lateral side.

The **first** (most medial) branch separates from the nerve before the others, and pierces the deep fascia behind the ball of the big toe. It supplies a muscular branch to the flexor hallucis brevis and cutaneous branches to the medial side of the foot and ball of the big toe. It terminates as the plantar digital nerve for the medial side of the big toe.

The **second branch** arises along with the third and fourth; after supplying a

branch to the first lumbrical muscle, it becomes superficial in the interval between the first and second toes, and terminates by dividing into two digital nerves for the supply of the adjacent sides of these toes.

The **third** and **fourth branches** are distributed to skin and fascia and certain joints of the toes. They become superficial in the intervals between the second and third and the third and fourth toes, respectively, and there divide into branches for the supply of the adjacent sides of these toes.

Lateral Plantar Nerve

The **lateral plantar nerve** is homologous with the ulnar nerve in the hand. From its origin, under cover of the flexor retinaculum, it extends forwards and laterally in the sole, along the medial side of the lateral plantar artery, between the flexor digitorum brevis and the flexor digitorum accessorius towards the base of the fifth metatarsal bone. There it ends by dividing into superficial and deep terminal branches (Fig. 952).

Collateral Branches.—*Muscular branches* are given off from the undivided nerve to the flexor digitorum accessorius and abductor digiti minimi muscles. *Cutaneous branches* pierce the plantar fascia at intervals along the line of the intermuscular septum between the flexor digitorum brevis and abductor digiti minimi. *Vascular filaments* are given to neighbouring arteries by the lateral plantar nerve and its branches.

Terminal Branches.—The **superficial branch** is mainly cutaneous. Passing forwards between the flexor digitorum brevis and abductor digiti minimi, it divides into lateral and medial parts.

The lateral part, after supplying the flexor digiti minimi brevis muscle, and sometimes one or both interossei of the fourth space, becomes superficial behind the ball of the little toe, and supplies cutaneous twigs to the sole of the foot and ball of the toe. It ends as the *plantar digital nerve* for the lateral side of the little toe.

The medial part passes forwards to the interval between the fourth and fifth toes, where it becomes cutaneous and divides into two branches (*plantar digital nerves*) for the supply of the adjacent sides of those toes. It communicates with the fourth terminal branch of the medial plantar nerve. Both branches provide filaments to the joints of the toes to which they are distributed.

The **deep branch** of the lateral plantar nerve runs medially along with the lateral plantar artery towards the big toe, under cover of (*i.e.*, dorsal to) the flexor digitorum accessorius and oblique head of the adductor hallucis. It gives off *articular branches* to the tarsal and tarso-metatarsal joints and *muscular branches* to the interossei of each space (except in some cases the muscles of the fourth space), to the adductor hallucis, and the lateral three lumbrical muscles. The muscular branches enter the deep surfaces of the muscles, that to the second lumbrical reaching its muscle after passing forwards dorsal to the transverse head of the adductor hallucis.

Plantar digital nerves.—These nerves arise from both medial and lateral plantar nerves. They supply the whole length of the toes on the plantar surface, and, in relation to the distal phalanges, furnish minute dorsal offsets for the supply of the nails and tips of the toes on their dorsal surfaces. Filaments from the digital nerves supply the metatarso-phalangeal and interphalangeal joints.

Coccygeal Plexus

By the union of part of the anterior primary ramus of the fourth with those of the fifth sacral and coccygeal nerves, the **coccygeal plexus** is formed. A fine branch of the fourth sacral nerve descends to join the fifth sacral nerve, which then descends alongside the coccyx and is joined by the coccygeal nerve, so that a plexiform cord results, homologous with the inferior caudal trunk of tailed animals. Fine twigs arise from it, some of which enter the coccygeus and adjoining part of the levator ani, while others pierce the coccygeus and the overlying ligaments to supply the skin and fascia in the neighbourhood of the coccyx and behind the anus, medial to the branches of the perforating cutaneous nerve.

Communications with Autonomic System.—Like the other spinal nerves, the fourth and fifth sacral and coccygeal nerves are provided with fine *grey rami communicantes* from the sacral sympathetic trunk which join them after a short course on the front of the sacrum.

Morphology of Nerves of Perineum

The structures which occupy the perineum are placed in the ventral axis of the body, and comprise, from before backwards, the penis and scrotum, or mons pubis and vulva, the perineal body, the anus and ischio-rectal fossa, and the coccyx. They are placed on the medial side of the attachment of the lower limbs—the penis or mons pubis in relation to the preaxial border of the limb, the coccyx in relation to the postaxial border.

The nerves of the perineum, thus reaching the ventral axis of the trunk, are homologous with the anterior (ventral) terminations of other nerves. They are separable into two series. The perineum is supplied mainly by the lower four sacral nerves and the coccygeal nerve, but it is also innervated to a minor extent by the first lumbar nerve through the ilio-inguinal nerve, which reaches the root of the penis and the scrotum. The region is thus supplied by two series of widely separated nerves which have their meeting-place on the dorsum and side of the penis and scrotum. This junction of the ilio-inguinal and pudendal nerves constitutes the beginning of the **ventral axial line** (Fig. 953), which extends peripherally along the medial side of the lower limb. Apart from this break in their distribution, a definite numerical order may be followed in the arrangement of the perineal nerves. The higher parts of the perineum are innervated by the higher spinal nerves; the lower parts, by the lower nerves. This is best exemplified in the distribution of the cutaneous nerves. The base of the penis and scrotum (or mons pubis) is supplied by the first lumbar nerve (ilio-inguinal). The dorsal nerve of the penis (or clitoris), when traced back, is found to come from the second sacral nerve, and to a less extent from the third; the scrotal or labial nerves (perineal branches of the pudendal and posterior cutaneous nerve of the thigh) similarly arise from the third sacral nerve, and to a less extent from the second; the skin of the ischio-rectal fossa and anus is innervated by the inferior hæmorrhoidal (third and fourth sacral nerves), and the perineal branch of the fourth sacral nerve. The coccygeal plexus, lastly, supplies the skin and fascia round the coccyx (fourth and fifth sacral and coccygeal nerves).

Judged from its nerve-supply the perineum is to be regarded as occupying, for the most part, a position behind or more caudal than that of the lower limb in relation to the trunk, and there is a remarkable gap in the numerical sequence of the nerves that supply the ventral axis of the body. All the nerves between the first lumbar and the second sacral fail to reach the mid-ventral line of the trunk and are wholly concerned in the innervation of the lower limb.

At the preaxial border of the limb (groin) the first lumbar nerve—the highest nerve supplying the perineum—is concerned also in innervating the skin and fascia of the limb. At the postaxial border of the limb (fold of the buttock and back of the thigh), the second and third sacral nerves are also implicated in innervating that border of the limb. The fourth sacral nerve is concerned only to a very slight extent in the innervation of the limb by means of the perineal branch, which reaches the beginning of its postaxial border; the last two spinal nerves are wholly unrepresented in the limb proper and end entirely in the trunk behind the limb.

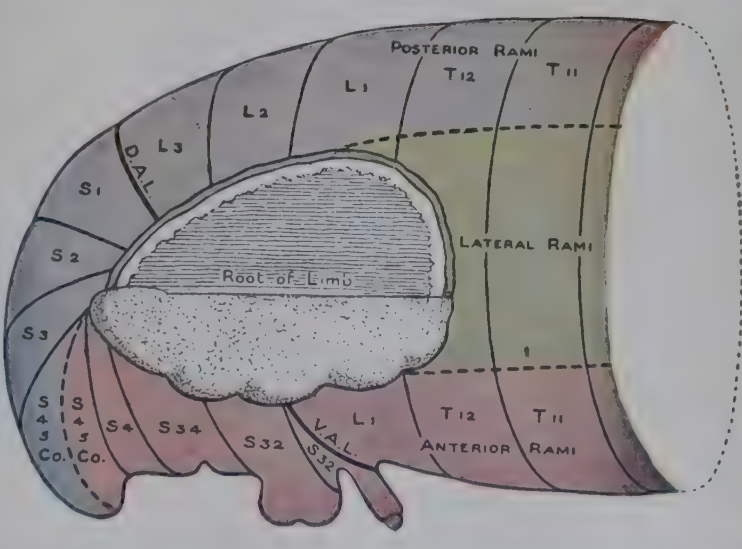

Fig. 953.—Scheme of Innervation of Hinder Portion of Trunk and of Perineum. The scheme shows the interruption of the segmental arrangement of the nerves due to the formation of the limb. See also Figs. 942 and 945.

Distribution of Spinal Nerves to Muscles and Skin of the Limbs

By dissection, experiment, and clinical observation, it is conclusively proved that, as a rule, each nerve of distribution in the limb, whether to muscle or skin, is made up of fibres derived from more than one spinal nerve; and, further, that in cutaneous distribution a considerable overlapping occurs in the course of the several peripheral nerves. Moreover, the arrangement of the distribution of the nerves to skin and to muscles is not identical. In the case of the skin of the limbs, by the covering of the limb being drawn on to it from adjacent parts in the process of growth, cutaneous nerves are engaged which are derived from sources not represented in the muscular innervation of the limbs. Again, among the

muscles, some have undergone fusion, others have become vestigial, and others again have altered their position in the limb.

Innervation of Skin of the Limbs

While the scheme of cutaneous innervation of the limbs is fundamentally segmental, yet the arrangement is confused and complicated by various causes. The growth of the limb from the trunk has caused the skin to be drawn out over it like a stretched sheet of india-rubber (Herringham, 1886), and at the same time the extent of either the dorsal or the ventral area of the limb is increased at the expense of the other. The central nerves of the plexus remain buried deeply in the substance of the limb, coming to the surface only towards the periphery. The proximal parts of both surfaces of the limb thus become innervated by cutaneous nerves otherwise not necessarily concerned in the innervation of the limbs. Herringham has shown that: *(a) of two spots on the skin, that nearer the preaxial border tends to be supplied by the higher nerve: (b) of two spots in the preaxial area, the lower tends to be supplied by the lower nerve; and of two spots in the postaxial area, the lower tends to be supplied by the higher nerve.* In other words, from the root of the limb along the preaxial border to its distal extremity, and along the postaxial border to the root of the limb again, there is a definite numerical sequence of spinal nerves supplying skin-areas through nerves of the limb-plexuses, as is illustrated, for example, in Fig. 941, p. 1096. A similar numerical sequence in the arrangement of the nerves is also found extending over the dorsal and ventral surfaces of the limbs from preaxial to postaxial border, except in certain situations.

On the dorsal and ventral surfaces of both upper and lower limbs there is a hiatus, for a certain distance, in the numerical sequence of the spinal nerves in their cutaneous distribution, explicable on the ground that the central nerves of the plexus, which fail to reach the surface in those situations, are replaced by cutaneous branches from neighbouring nerves. This hiatus has been named the *axial line.*

In the upper limb the *dorsal axial line* extends from the median line of the back, opposite the vertebra prominens, downwards on the back of the arm towards the elbow. The *ventral axial line* extends anteriorly from the median plane of the trunk, at the manubrio-sternal joint, across the chest, and downwards along the front of the upper arm and forearm.

In the lower limb the *dorsal axial line* may be traced from the median plane of the back over the posterior superior iliac spine, across the gluteal region and thigh, to the head of the fibula and the lateral side of the leg. A *ventral axial line* can also be traced from the root of the penis along the medial side of the thigh and knee, and along the back of the leg to the heel.

Those lines represent the meeting-place and overlapping of nerves which are not in numerical sequence; and it is only at the peripheral parts of the limbs, on the dorsal and ventral surfaces, that the nerves appear in numerical sequence from the preaxial to the postaxial border. In the case of the upper limb the hiatus is caused, in both surfaces of the limb, by the absence of cutaneous branches of the seventh cervical nerve; in the case of the lower limb the hiatus is due to the absence of branches from the fifth lumbar nerve on both surfaces of the limb, and the absence of branches from the fourth lumbar nerve, in addition, on the dorsal surface.

These points in the innervation of the skin of the limbs are illustrated by Figs. 928, (p. 1074), 929, and Figs. 941 (p. 1096), 942.

Innervation of Muscles of the Limbs

The following laws appear to be applicable to the upper and lower limbs alike:—

1. *No limb-muscle receives its nerve-supply from posterior primary rami.*

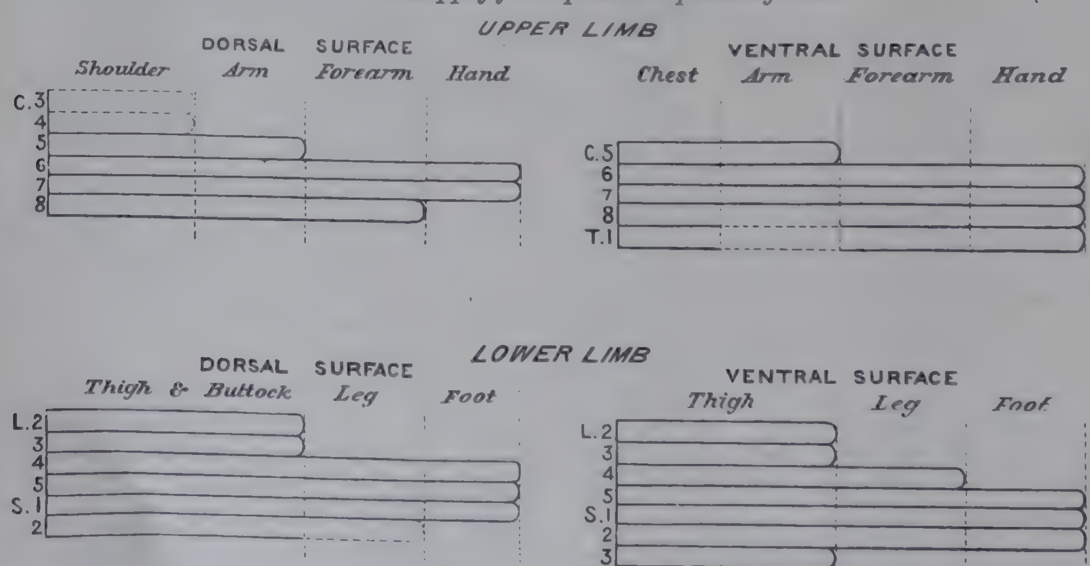

Fig. 954.—Diagram of Segmental Distribution of the Muscular Nerves of Upper and Lower Limbs.

2. *The dorsal and ventral strata of muscles are always supplied by the corresponding dorsal and ventral branches of the nerves concerned. The ventral muscular stratum is more extensive than the*

dorsal; the ventral nerves are the more numerous, and the additional nerves are postaxially placed. The spinal nerves supplying muscles of the upper limb are C. 5, 6, 7, 8 (dorsal), and C. 5, 6, 7, 8, T. 1 (ventral); the nerves for the muscles of the lower limb are L. 2, 3, 4, 5, S. 1, 2 (dorsal), and L. 2, 3, 4, 5, S. 1, 2, 3 (ventral).

3. *The dorsal and ventral trunks of the nerves are distributed in the limb in a continuous, segmental manner*; so that, "of two muscles, that nearer the head end of the body tends to be supplied by the higher nerve, and that nearer the tail end by the lower nerve" (Herringham, 1886).

4. *The nerves placed most centrally in the plexus extend farthest into the limb, and the more preaxial nerves terminate sooner in the limb than the more postaxial nerves.*

The only exception to this rule is on the ventral (anterior) surface of the upper arm, where a suppression of the muscle-elements leads to an absence of the regular series of segmental nerves (C. 8, T. 1) on its postaxial border. These nerves reappear in the forearm, and the occasional "axillary arches" may be regarded as the muscular elements usually suppressed, and, when present, supplied by these nerves. (See also the Tables of the segmental innervation of the limb-muscles in the Surface and Surgical Section.)

Muscles with Double Nerve-Supply.—The existence of more than one nerve to a muscle indicates usually that the muscle is composite and is the representative of originally separate elements belonging to more than one segment or to both surfaces of the limb. In the case of the pectoralis major, subscapularis and flexor digitorum profundus, adductor magnus, and soleus, parts of the same (ventral or dorsal) stratum have fused, to form muscles innervated from the corresponding ventral or dorsal nerves. The other muscles having a double nerve-supply—biceps femoris, and (sometimes) pectineus—are examples of fusion at the preaxial or postaxial border of muscular elements derived from the dorsal and ventral surfaces of the limb, which are correspondingly innervated by branches from both dorsal and ventral series: *e.g.*, the biceps femoris by the lateral popliteal (short head) and medial popliteal nerves (long head); and the pectineus, by the femoral and (sometimes) obturator nerves. The brachialis commonly receives branches from both the musculo-cutaneous and the radial nerves, but electrical tests have shown that the fibres from the radial are afferent ones.

Composition of Limb-Plexuses

In all mammals the same definite plan underlies the constitution of the limb-plexuses (Paterson, 1887). The nerves concerned are the anterior primary rami of certain segmental spinal nerves, which (with certain exceptions at the preaxial and postaxial borders) are destined wholly and solely for the innervation of the limb. Each of the anterior rami engaged divides into a pair of **secondary trunks,** named **dorsal** or posterior, **ventral** or anterior. The dorsal and ventral trunks again subdivide into **tertiary trunks** which combine with the corresponding subdivisions of neighbouring dorsal and ventral trunks to form the **nerves of distribution**. The combinations of *dorsal trunks* provide a series of nerves for the supply of that part of the limb which is derived from the *dorsal surface* of the embryonic limb-bud; the combinations of *ventral trunks* give rise to nerves of distribution to the regions corresponding to its *ventral surface.* Cutaneous nerves are less strictly dorsal and ventral than motor nerves. In the upper limb (Fig. 928, p. 1074) ventral offsets of the plexus tend to overlap the dorsal surface; whilst in the lower limb (Fig. 941, p. 1096) the dorsal offsets tend to overlap the ventral (*i.e.*, flexor) surface.

Intraneural Plexuses

With certain exceptions, such as the anterior and posterior spinal nerve-roots and the motor and sensory roots of the fifth nerve, the majority of peripheral nerves show progressive changes in the arrangement of their constituent fibres and bundles of fibres as they are traced peripherally. Within the peripheral nerves the fibres are disposed in fasciculi separated by perineurium. The fascicular pattern is continually modified along the entire course of the nerve by the repeated division, anastomosis and migration of bundles and there is no predictable plan of fasciculation. The confluence of the various nerve-fibres which will form a particular branch of a nerve occurs proximal to the point at which the branch leaves the parent nerve, but the distance run by such a branch within the parent nerve is, though at times considerable, quite variable. The pattern of fasciculation cannot therefore be explained wholly on the necessity for a regrouping of fibres relative to their ultimate peripheral distribution. (O'Connell, 1936; Sunderland, 1945 *d.*)

Blood-Supply of Peripheral Nerves

All nerves are supplied with blood-vessels which are essential to their normal functioning. Deprivation of blood-supply, by spasm, thrombosis or embolism, may induce sensory or motor loss and the nerve affected may even show degenerative changes.

The arteries supplying a nerve are derived from adjacent vessels and most often they are of small size and only of moderate regularity of position. On reaching a nerve the nutrient artery breaks up into ascending and descending branches which anastomose in the epineurium with similar branches from other nutrient arteries. From such epineural vessels branches penetrate into the perineurium where further anastomoses occur and finally smaller vessels penetrate into the fasciculi and form there a rich longitudinally disposed capillary network which runs

up and down the nerve in unbroken continuity. **This intrafascicular network is reinforced along its length by the contributions from the various nutrient vessels which reach the epineurium, but** *no part of the intrafascicular plexus may be regarded as being dominated by any one nutrient artery* (Durward, 1948). Some nerves, *e.g.*, the sciatic and median, may have associated arteries of considerable size; such vessels are to be regarded as embryological persistences and do not imply any preferential supply. Sympathetic nerve-fibres, presumably vasomotor in function, accompany the arteries which supply nerves. (Adams, 1942, 1943; Sunderland, 1945 *a*, *b* and *c*.)

Veins leave the capillary plexus of the nerve but do not generally unite to form a common channel; most often they drain into adjacent muscular veins rather than to superficial veins—an arrangement which has been claimed to assist in the circulation within the nerve.

DEVELOPMENT OF SPINAL NERVES AND GANGLIA

I. Origin of Spinal Nerve-Roots.—Whilst both the posterior and anterior roots are developed from cells of the neural plate, they differ as regards their exact site of origin.

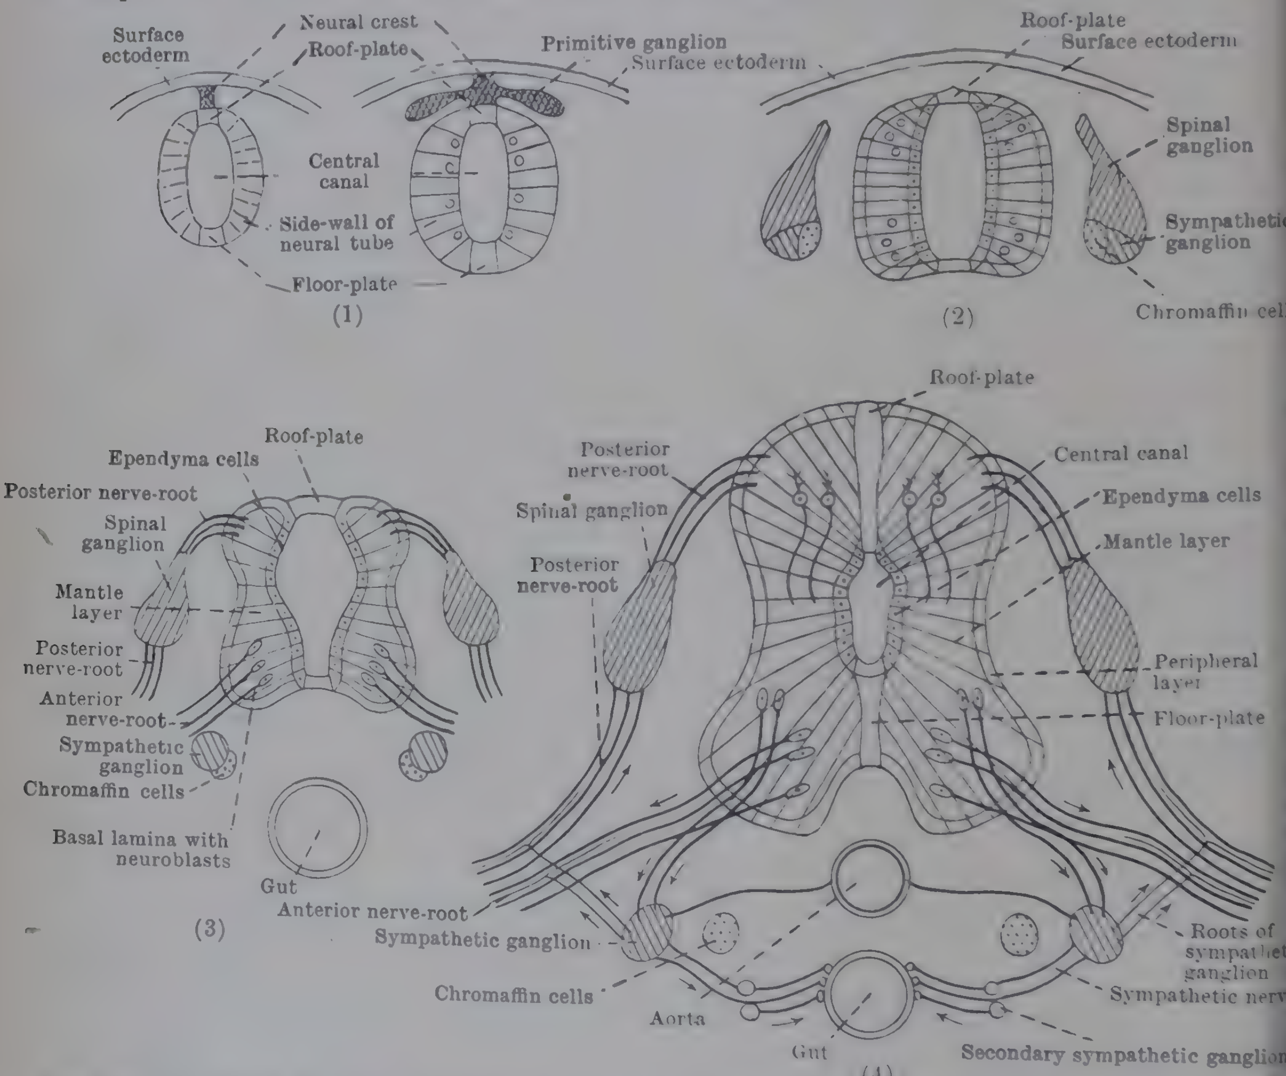

FIG. 955.—DIAGRAMS illustrating:—(1) The formation of the rudiments of the primitive ganglia from the neural crest. (2) The differentiation of different parts of the primitive ganglion into permanent root ganglion, sympathetic ganglion, and masses of chromaffin cells. (3) The formation of the anterior and posterior nerve-roots. (4) The differentiation of the walls of the neural tube into ependymal and peripheral layers.

The cells of the primitive ganglion which form the neurolemmal sheaths of the nerves are not shown.

The **posterior roots** are derived entirely **from the neural crest, the origin of which from the** cells of the lateral margin of the neural plate is described in the Section on Human Embryology (p. 60). At the time when they first appear, **the neural crest is a flattened cellular band which** extends from the auditory vesicle along the **dorsal border of the neural tube to its caudal** extremity. In the spinal region the crest shows segmental ganglionic enlargements along its **ventral border, whilst its dorsal border** shows a continuous cellular bridge throughout its length.

The cells comprising the crest are, from the viewpoint of their ultimate fate, of several types and, amongst them, the following groups of cells are of interest in relation to the development of the peripheral nervous system. (1) The majority of the cells are *neuroblasts* and develop into receptor neurons. Each such cell sends a central process dorsally, which grows into the

alar lamina of the neural tube. The central processes enter the cord in bundles and gradually the continuous bridge of crest material disappears and each ganglion is connected with the cord by only the nerve-strands composed of the central processes of the neuroblasts. Further, from each cell a peripheral process grows ventrally and joins up with the outward-growing processes of the cells in the basal lamina of the neural tube, *i.e.*, the ventral nerve-root, to form a spinal nerve. Such peripheral processes will ultimately reach some sensory area and so link it with the cord. The neuroblasts are therefore in the first place bipolar cells, but in development the central and peripheral processes, close to the cell, become approximated to produce a typical pseudo-unipolar cell of the spinal ganglion (Fig. 734, p. 847). Other cells of the crest produce (2) *sympathoblasts*, which, though developing into nervous elements, differ from the neuroblasts

described above in migrating away from the region of the spinal ganglia to form ganglion-cells in the sympathetic trunk and plexuses (Fig. 955). They are further discussed on p. 1146. (3) Certain cells which ultimately form the chromaffin tissue of the body are located in the neural crest; they are known as *phæochromoblasts* and they, like the sympathoblasts, migrate to other regions to form isolated clumps of chromaffin tissue; such tissue may be found associated with sympathetic ganglia but it is best exemplified by the medullary tissue of the suprarenal glands. (4) Certain cells with no nervous potentialities form the neurolemmal sheath-cells (Schwann cells) of the nerve-fibres in peripheral nerves and the capsular cells in spinal and sympathetic ganglia. These are known as spongioblasts or *lemnoblasts*. They too of course must migrate since they form the neurolemmal sheaths of outward-growing nerve-processes in both posterior and anterior nerve-roots and their continuations—the peripheral nerves (Harrison, 1924). See pp. 1146-1147 for further discussion of neural crest derivatives.

The **anterior roots**, on the contrary, are developed from the neural tube, which is a derivative of the neural plate. Processes from the neuroblasts situated in the mantle zone of the basal lamina grow out in small bundles which pierce the external limiting membrane and emerge in a continuous longitudinal series of rootlets from the ventro-lateral wall of the tube. Outside the tube the rootlets are grouped into segmental bundles—the anterior roots—which join the posterior roots just peripheral to the spinal ganglia.

II. **Formation of Spinal Nerve.**—The fibres of the spinal ganglion and the anterior root grow by extension from the cells with which they are respectively connected, and meet in the space between the myotome and the side of the neural tube to form the **spinal nerve.** In the adult there is a fundamental primary division of the spinal nerve into posterior and anterior rami. In the process of development the separation is even more obvious. As the fibres of the posterior and anterior roots approximate, they separate at the same time, each into two unequal portions: the smaller parts of the two roots unite together to form the **posterior primary ramus** of the spinal nerve, and the larger parts unite to form the **anterior primary ramus.**

The **posterior primary ramus,** curving laterally and backwards, passes through the myotome and is connected with it. In the substance of the myotome it separates into branches as it proceeds towards the dorsal wall of the embryo. At a later stage, the branches are definitely arranged into a lateral and a medial series.

The **anterior primary ramus** grows gradually in a ventral direction under cover of the growing myotome towards the somato-splanchnic angle of the cœlom (Fig. 956). It spreads out at its distal end and eventually separates into two portions: a smaller, splanchnic or visceral; and a larger, somatic or parietal portion. (1) The **splanchnic** or **visceral portion** grows inwards to be connected through the sympathetic trunk with the innervation of organs in the splanchnic area. That branch of the spinal nerve becomes the **white ramus communicans** of the sympathetic. It is not present in the case of all the spinal nerves, but only in relation to the thoracic and upper lumbar and the third and second or fourth sacral nerves. It will be referred to again in connection with the sympathetic system. (2) The **somatic** or **parietal portion** becomes the main part of the anterior primary ramus of the nerve. It continues the original ventral course of the nerve, and, reaching the body-wall, divides into two terminal branches—a *lateral branch,* which grows laterally and downwards and reaches the side of the trunk after piercing the myotome; and a ventral or *anterior branch,* which grows onwards in the body-wall to reach the ventral axis. That arrangement is met with in the trunk between the limbs and in the neck.

III. **Formation of Limb-Plexuses.**—The method of growth of the spinal nerves, just described, is modified in the regions where the limbs are developed. In relation to the limbs, which exist in the form of buds of undifferentiated cellular mesoderm before the spinal nerves have any connexion with them, the development of the anterior primary ramus of the nerve proceeds exactly in the way described, up to the point of formation of somatic and splanchnic branches. The **somatic branches** then stream out into the limb-bud, passing into it below the ends of the myotomes and spreading out into a bundle of fibres at the basal attachment of the limb. Later, the nerves separate, each into a pair of definite trunks, named posterior or **dorsal** and anterior or **ventral,** which proceed into the limb-bud on the dorsal and ventral surfaces respectively of the central core of mesoderm. While that process is going on, a *secondary union* takes place between parts of adjacent dorsal and ventral trunks. Dorsal trunks unite with dorsal trunks, ventral trunks unite with ventral trunks, to form the nerves distributed ultimately to the surfaces and periphery of the limb. These **dorsal and ventral trunks** are homologous with the **lateral** and **ventral branches** of the somatic nerves in other regions.

AUTONOMIC NERVOUS SYSTEM

The **autonomic nervous system,** like the rest of the peripheral nervous system, is a dependency of the central nervous system and linked with it by both afferent and efferent systems of fibres. It is indeed impossible to define any precise boundary between the autonomic and the cerebro-spinal nervous systems, for the two mechanisms are closely interconnected, particularly within the brain and spinal cord. In the periphery, however, the autonomic system acquires a greater or less degree of individuality in different parts of the body. The details of those parts of the autonomic system that lie within the cerebro-spinal axis have been dealt with elsewhere.

The autonomic nervous system is peculiar in that it is concerned in the main with the automatic or non-voluntary control of visceral structures, *e.g.,* glands, blood-vessels, and gut, and not with peripheral mechanisms, such as skeletal muscles, which are under more apparent voluntary control. For this reason the autonomic system has been called the "involuntary" nervous system—just as plain or visceral muscle is commonly known as "involuntary" muscle—but the use of this expression is not advisable since the autonomic system is frequently interlinked functionally in mechanisms which are in large measure voluntary, *e.g.,* micturition. It has been described as that part of the nervous system primarily concerned with the regulation of the internal environment of the body and the maintenance of its stability. (See the standard works of Delmas & Laux (1933); White & Smithwick (1942); and Kuntz, 1946.)

As originally described by Langley (1921), the autonomic system was regarded as an efferent system and no account was taken of the afferent neurons which pass centrally from the various visceral structures under autonomic control. Much less is known of these afferent fibres—the splanchnic or visceral afferents—but it seems expedient to regard them as the afferent counterpart of the classic efferent autonomic system of Langley. If we include the splanchnic afferent fibres, the autonomic system differs from the rest of the nervous system, as in the case of efferent fibres, in that the incoming impulses subserve different kinds of sensation from those carried by ordinary somatic peripheral nerves; they do not generally arouse any, or any highly coloured, conscious state. Moreover, they

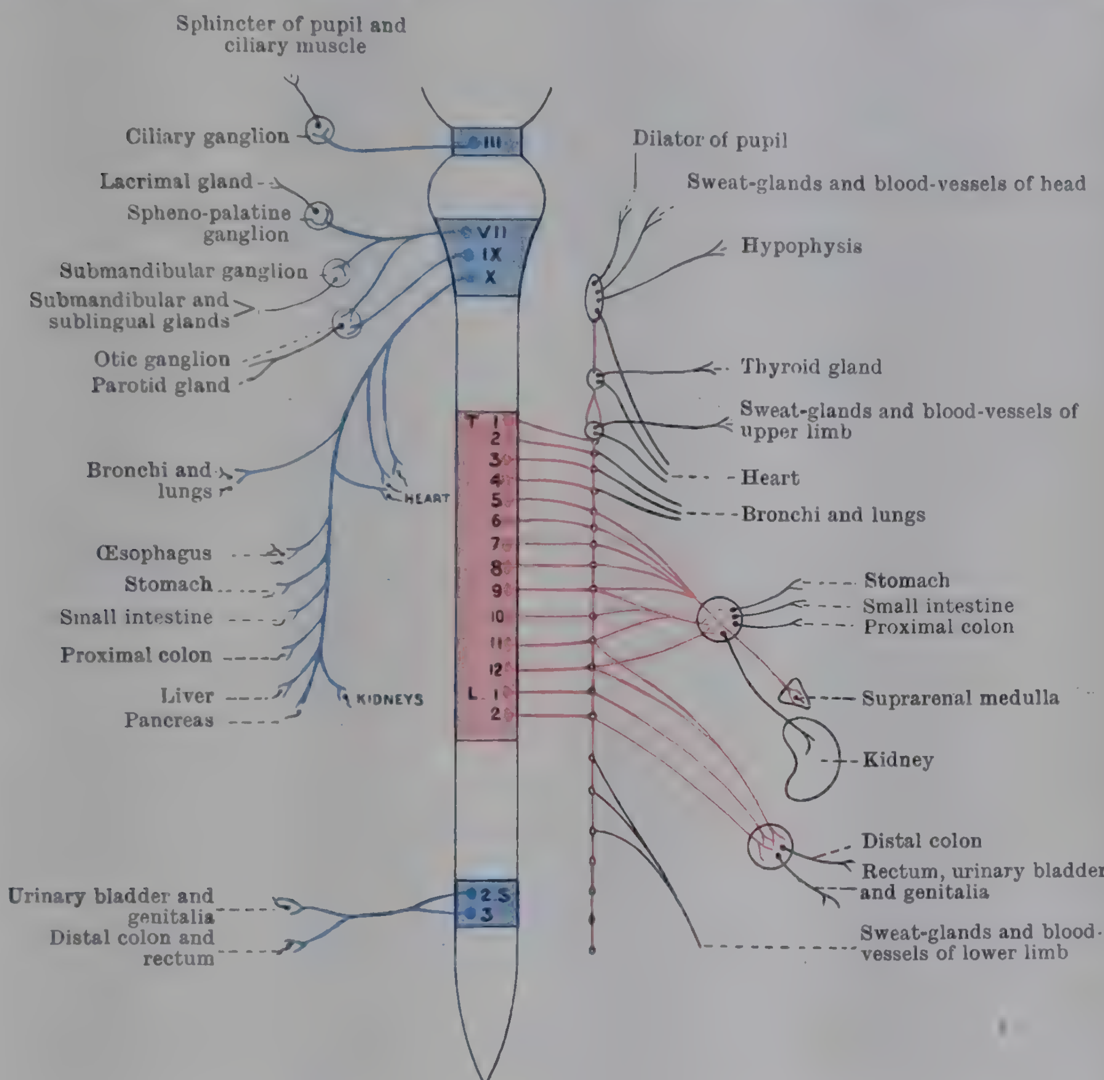

FIG. 957.—SCHEME OF GENERAL ARRANGEMENT OF AUTONOMIC NERVOUS SYSTEM.
Preganglionic fibres of the parasympathetic system in *blue* and of the sympathetic system in *red*. Postganglionic fibres of both systems in *black*. Afferent fibres are not included.

come from regions within the body, *e.g.*, lungs, gut, vessels, which are not normally exposed to the same range of stimuli as somatic peripheral nerves. They may, however, under normal conditions arouse conscious states, *e.g.*, the feeling of fullness in the stomach or bladder or perhaps even a feeling of well-being under appropriate stimulation; and under abnormal conditions otherwise unnoticed impulses from the viscera may arouse conscious appreciation. It may then be said that the efferent side of the autonomic nervous system is generally divorced from any apparent voluntary control and that the afferent side is most often concerned with impulses which, though of great significance in visceral reflex mechanisms, do not as a rule enter consciousness. The autonomic nervous system is widely distributed throughout the body, and it consists of neurons arranged as ganglia and strands of fibres which often produce plexuses by interlacement. The main aggregations of autonomic elements are found in the thorax and abdomen close by the viscera to be supplied, but all parts of the

body are served by autonomic fibres, which in their course often associate themselves with the blood-vessels and peripheral nerves of the regions concerned.

We have seen how in the somatic nerves the final motor neuron had its origin in a cell within the central nervous system and its axon passed out in some peripheral nerve to the effector agent, *e.g.*, skeletal muscle. In the autonomic system there is a very characteristic difference in that two neurons are interposed between the brain or cord on the one hand and the peripheral effector on the other. The first of these has its cell-body within the brain-stem or the cord, from which its axon passes out to reach a ganglion or gangliated plexus of the autonomic system where it terminates in a synapse with the second or excitor neuron. This second or excitor neuron then influences some effector agent, *e.g.*, plain muscle or gland. There is therefore a peripheral synapse separating a **preganglionic neuron** from a **postganglionic neuron.** This arrangement is fundamental and constitutes the most striking anatomical difference between splanchnic and somatic efferent nerves. Further, in the ganglia and plexuses there are many more postganglionic neurons than there are preganglionic fibres leaving the central nervous system; this arrangement is admirably suited to the wide diffusion of autonomic effects.

Splanchnic afferent fibres proceed towards the brain or cord, and, like other afferent neurons, have their cell-bodies in the spinal ganglia or in the ganglia associated with certain cranial nerves. In their course centrally they may accompany somatic nerves or run through autonomic plexuses and ganglia, where, of course, they do not have any synaptic interruption. Our knowledge of the distribution and of the central connexions of such splanchnic afferent fibres is much less complete than for the efferent part of the autonomic system.

Mainly on the basis of functional differences the autonomic system has been divided into two components—sympathetic and parasympathetic (Figs. 957, 962).

The **Sympathetic System** is connected with the cord in the thoraco-lumbar region by fibres which constitute the *thoraco-lumbar outflow.*

The **Parasympathetic System** is connected with the central nervous system through certain cranial and sacral nerves by fibres which constitute the *cranio-sacral outflow.*

These two components of the autonomic system are distinguished not so much by their place of origin as by the fundamentally different effects of their activity and by different reactions to certain drugs. Both are very widely distributed, and commonly their fibres run side by side to the same organ, where they are capable of producing antagonistic effects. For example, both systems supply the heart, whose rate is increased by the sympathetic system and decreased by the parasympathetic; or, again, the sympathetic supply to the eyeball dilates the pupil while the parasympathetic regulates its degree of constriction. In the alimentary tract the parasympathetic system is the main motor agency for the control of the onward movement of the contents, whereas the sympathetic effects a cessation of peristalsis and closure of the sphincters. In the integuments the sympathetic produces sudomotor and pilomotor effects, and on blood-vessels generally the sympathetic causes constriction with a consequent rise in blood-pressure. It has therefore been suggested that the sympathetic system, which tends to produce widespread effects in the body, prepares the individual for a struggle or puts the internal environment in tune with some external crisis, whereas the parasympathetic is concerned rather with conservation and the building-up of energy. This generalization is useful, and many other examples might be quoted to support it; but it must be clearly understood that the two systems are not acting antagonistically in respect of the individual's well-being, but rather by their harmonious interaction they strike a balance and allow of multiple gradations between the extremes that each system if acting alone might produce. It should be noted, too, that not all organs are innervated by both systems.

The theory of the humoral transmission of nervous impulses (Elliott, 1905; Loewi, 1935; Dale, 1934, 1938) has been worked out in large measure on the autonomic system and there would appear to be pronounced differences in the nature of the chemical substances liberated at the termination of the excitor neurons. Sympathetic excitor (*i.e.*, postgang-

lionic) neurons liberate an adrenalin-like substance which is claimed to act as a sort of deputy between the neuron and the effector agent, *e.g.*, plain muscle. They have therefore been called *adrenergic* fibres in contrast to parasympathetic postganglionic neurons which liberate at their termination acetyl-choline or similar substance and are therefore known as *cholinergic* fibres. This classification, which gains considerable physiological acceptance to-day, is not, however, to be regarded merely as a basis for an alternative nomenclature for parasympathetic and sympathetic, because the two conceptions overlap in several instances, *e.g.*, the sympathetic system undoubtedly activates the sweat-glands, but the chemical mediator is acetyl-choline and not an adrenalin-like substance. A physiological monograph should be consulted for detailed discussion of these and related matters.

PARASYMPATHETIC SYSTEM

Much of the topographical anatomy of this system has been covered already in the description of some of the cranial and sacral nerves. It remains to review

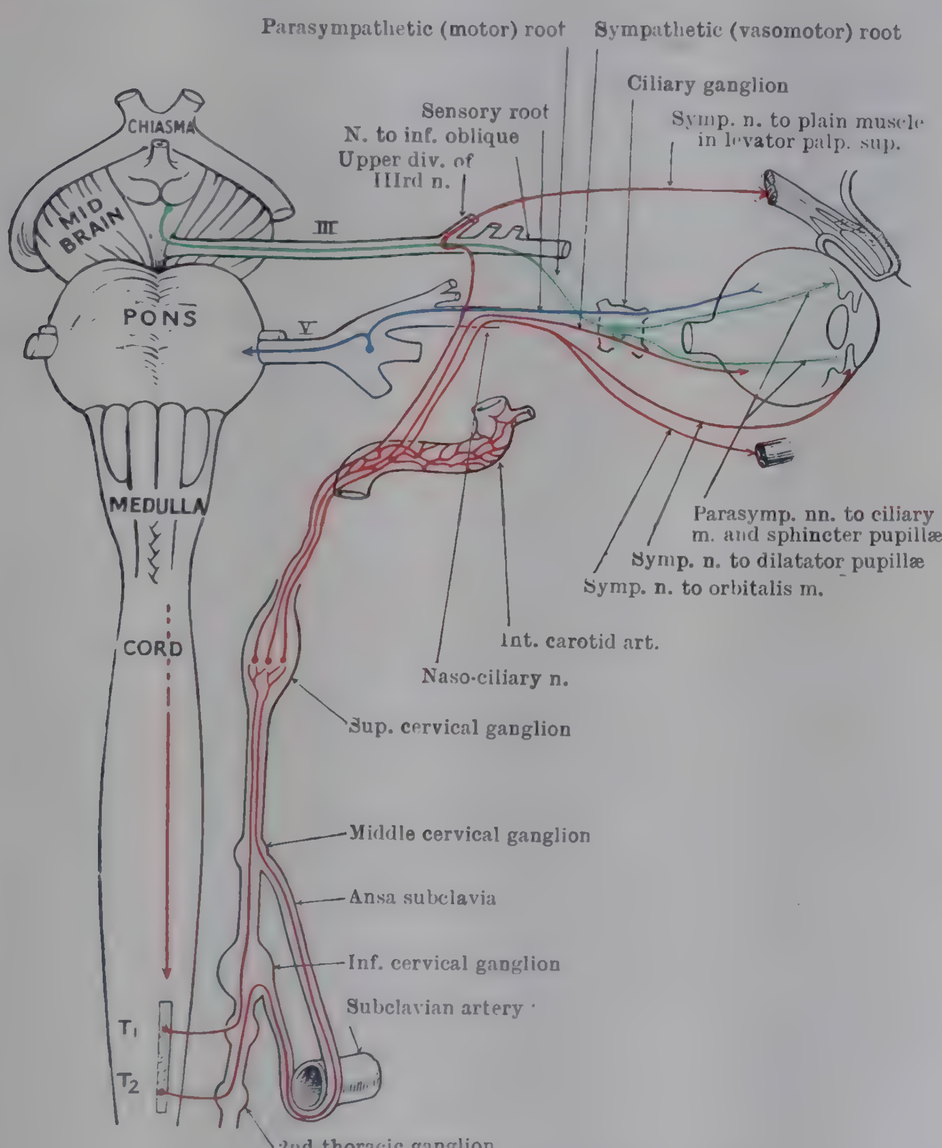

Fig. 958.—Diagram of Ciliary Ganglion and Connexions of Autonomic Nervous System with the Eye.

all the components and to discuss the parasympathetic in more detail as a system. It is customary to subdivide it into two main parts (Fig. 957):—

1. The **Cranial Parasympathetic** or cranial outflow. This is linked with the brain-stem by the following nerves: the oculomotor, the facial, the glosso-pharyngeal, and the vagus.
2. The **Sacral Parasympathetic** or sacral outflow linked with the spinal cord by the second and third (or third and fourth) sacral anterior primary rami.

Neither of these parts has any direct association with the sympathetic trunk, although not uncommonly parasympathetic and sympathetic fibres ultimately reach a viscus in a common bundle and are indistinguishable from each other. As in the sympathetic, so here we have the same fundamental arrangement of pre- and post-ganglionic neurons. The former are located within the central nervous system and their axons leave it to meet the postganglionic neurons in peripheral ganglia. A distinctive feature is that generally the parasympathetic ganglia are situated close to the viscus concerned and not infrequently in the wall of the viscus; the post-ganglionic neuron therefore is commonly a short one. Further, the various peripheral parts of the parasympathetic system tend to remain discrete and the effects are therefore much more localized than in the case of the sympathetic, where a preganglionic neuron may influence many postgang-

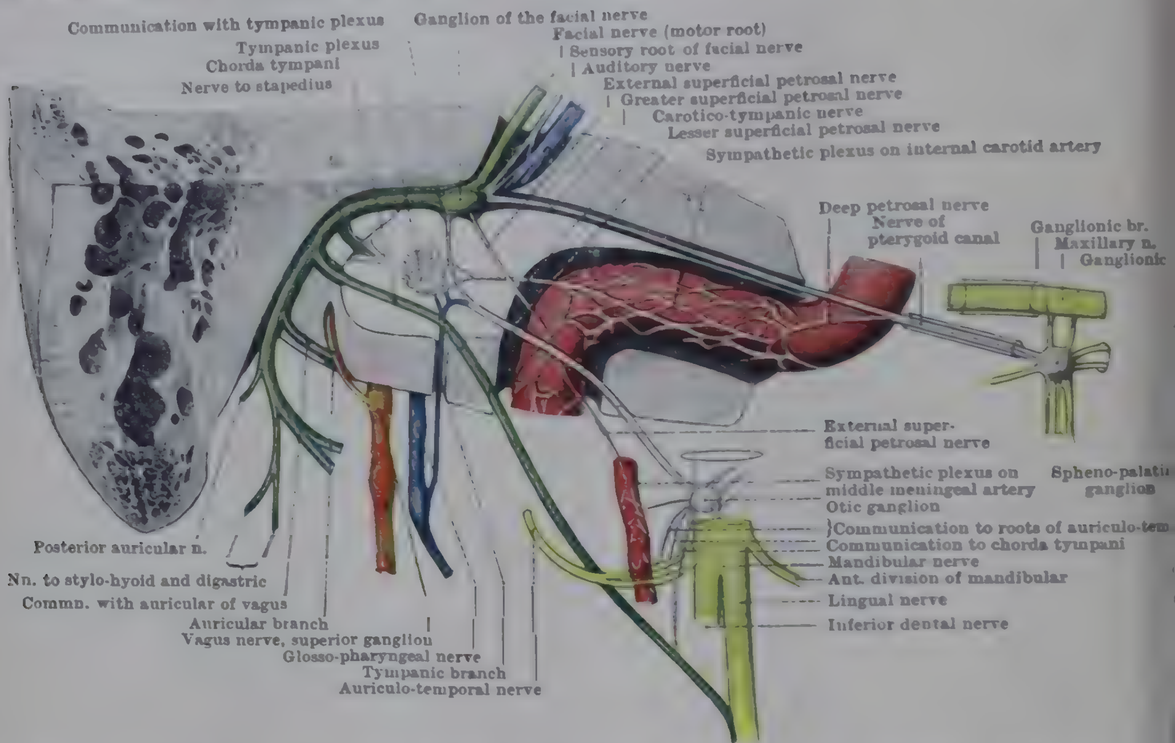

Fig. 959.—Branches of Facial and Glosso-Pharyngeal Nerves in the Temporal Bone, and Connexions of Spheno-Palatine and Otic Ganglia.

lionic neurons at different levels and so produce a much more widespread and diffuse effect.

The wide separation of the two parasympathetic outflows—cranial and sacral—necessitates the very extensive distribution of certain of its components. The fibres associated with the third, seventh, and ninth nerves have a rather localized field in the head region and are linked with certain ocular and ingestive mechanisms there. The tenth nerve, however, has a very wide distribution in the head, neck, thorax, and abdomen, and extends downwards indeed until it meets the sacral outflow. The sacral outflow is concerned in the main with the terminal parts of the alimentary and urogenital systems and plays an important rôle in emptying them.

CRANIAL PARASYMPATHETIC

Oculomotor Nerve.—The parasympathetic or splanchnic efferent fibres that run with this nerve arise probably from the Edinger-Westphal component of the oculomotor nuclear complex in the mid-brain (see p. 935). They accompany the oculomotor nerve into the orbit and then (from the branch to the inferior oblique muscle) they proceed as a delicate twig to the *ciliary ganglion*, constituting its parasympathetic or motor root (Fig. 958). Here, the preganglionic fibres end in synapses with the nerve-cells of the ganglion. A few ganglion cells may be found above the eyeball (Nathan & Turner, 1942) and are to be regarded as detached portions of the ciliary ganglion. The new, postganglionic fibres proceed

in short ciliary nerves to the eyeball, where, after piercing the sclera, they proceed forwards between it and the choroid to supply the ciliary muscle and the circular muscle of the iris (sphincter pupillæ). They can thus influence the convexity of the lens, and, by varying the tonus of the circular muscle of the iris, they are responsible for the control of pupillary size. It is of interest to note the association together in the third nerve of the fibres responsible, during accommodation, for convergence (somatic fibres to medial rectus muscle) and the fibres (parasympathetic) which

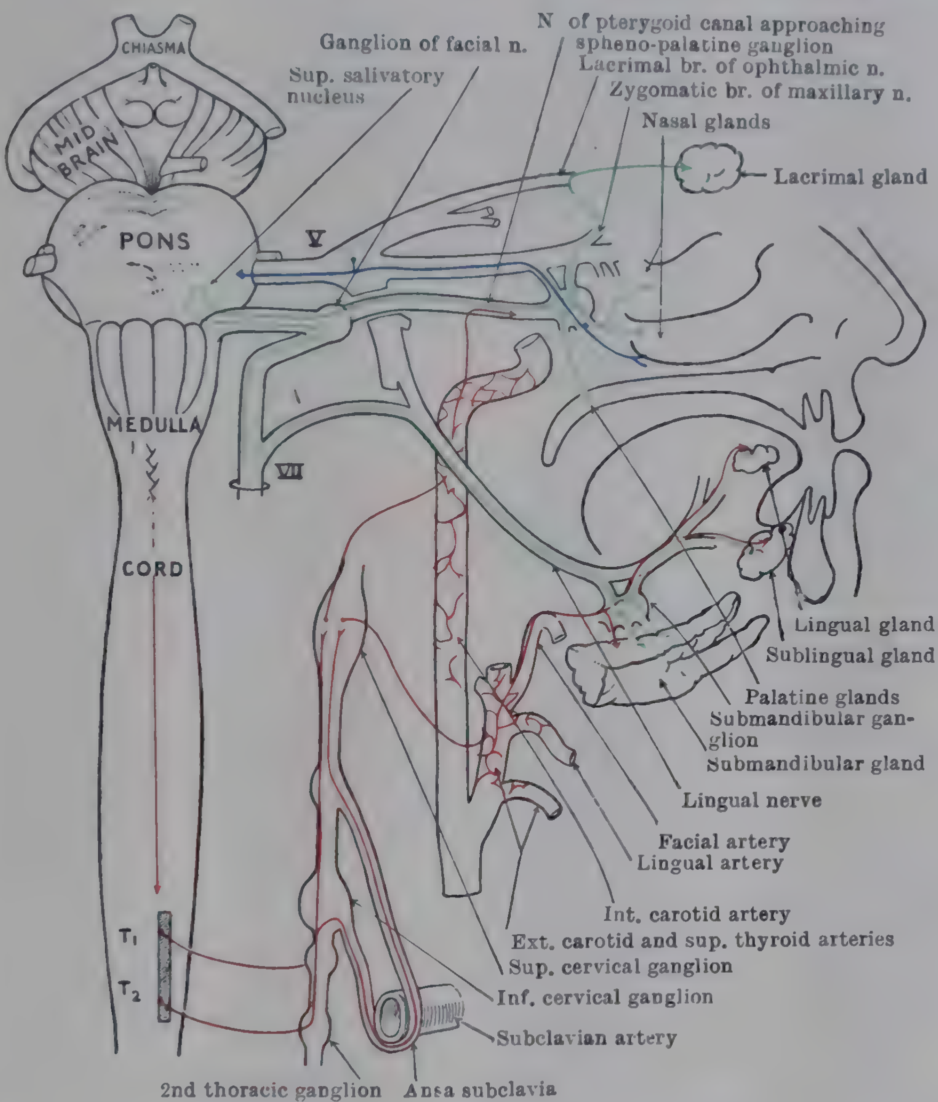

FIG. 960.—DIAGRAM OF CONNEXIONS OF SPHENO-PALATINE AND SUBMANDIBULAR GANGLIA WITH DISTRIBUTION OF PARASYMPATHETIC COMPONENTS OF SEVENTH CRANIAL NERVE.

produce changes in the lens and pupil. For the disposition of pupillo-constrictor fibres in the third nerve, see p. 1016.

Facial Nerve.—The splanchnic efferent fibres associated with the seventh nerve arise from a group of nerve-cells, alongside its motor nucleus in the pons, known as the *superior salivatory nucleus.* The preganglionic fibres leave the brain in the sensory root and in the temporal bone they leave that root in two of its branches—greater superficial petrosal and chorda tympani (Fig. 959).

1. The **greater superficial petrosal nerve**. After a course in the middle cranial fossa, foramen lacerum and pterygoid canal during which it receives sympathetic additions, this nerve reaches the *spheno-palatine ganglion.* Here the parasympathetic preganglionic neurons end in synapses around nerve-cells whose postganglionic fibres proceed to the lacrimal gland as its secreto-motor supply (Fig. 960) and to the glands of the nasal cavity and the palate.
2. The **chorda tympani** arises from the descending part of the seventh nerve in the temporal bone and, after a course through the middle ear, it emerges through the petro-tympanic fissure and shortly joins the

lingual branch of the mandibular division of the trigeminal, with which it runs towards the tongue. On the hyoglossus muscle the parasympathetic preganglionic fibres leave the lingual nerve to join the *submandibular ganglion*, where they end in synapses. From the ganglion, postganglionic fibres proceed directly to the submandibular gland or run back to the lingual nerve for distribution to the sublingual gland and glands of the tongue as their secreto-motor supply (Fig. 960). Some of the preganglionic fibres may proceed beyond the ganglion to meet scattered ganglionic cells in the glands concerned. Amongst the chorda tympani fibres are some which on stimulation cause vasodilatation of blood-vessels in its field of distribution. Kuntz & Richins (1946) suggest, however, that the parasympathetic supply to salivary glands is essentially glandular and that the sympathetic supply is vasomotor.

Accompanying these groups of secreto-motor parasympathetic fibres are afferent fibres concerned with taste in the anterior parts of the tongue and perhaps with taste-impulses from the palate. Their cell-bodies are in the ganglion of the seventh nerve, from which the central processes proceed towards the brain with the sensory root. They are special splanchnic afferent fibres, and may be regarded functionally as the afferent counterpart of the essentially motor parasympathetic fibres described above. Their connexions within the brain-stem are discussed elsewhere (p. 930).

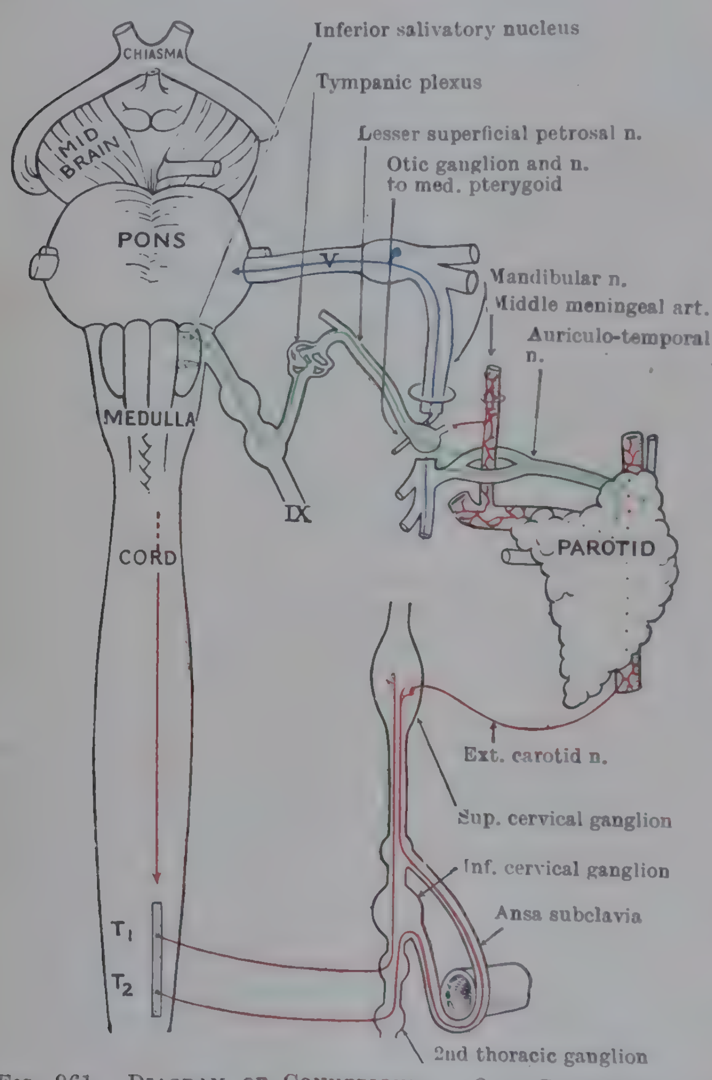

FIG. 961.—DIAGRAM OF CONNEXIONS OF OTIC GANGLION WITH DISTRIBUTION OF PARASYMPATHETIC COMPONENTS OF NINTH CRANIAL NERVE.

A communication is described between the seventh nerve and the tympanic plexus in the temporal bone by which preganglionic fibres of the seventh may be conveyed to the lesser superficial petrosal nerve and so to the otic ganglion. If this is so, then these fibres could conceivably influence the parotid gland through its supply from the otic ganglion.

Glosso-Pharyngeal Nerve.—Parasympathetic fibres which arise in the *inferior salivatory nucleus* in the medulla oblongata emerge from the brain-stem in the glossopharyngeal nerve and leave it below the skull in its tympanic branch. After a course through the temporal bone, they form the lesser superficial petrosal nerve, which ultimately joins the *otic ganglion*. Here the preganglionic fibres end in synapses around nerve-cells whose postganglionic axons proceed in the auriculo-temporal nerve to the parotid gland as its secreto-motor supply (Fig. 961).

The ninth nerve conveys to the brain many afferent fibres concerned with taste from the posterior part of the tongue and adjacent regions. These are special splanchnic afferent fibres and, as in the case of the seventh nerve, they may in

large measure be regarded as the afferent counterpart of the splanchnic efferent fibres described above. Their connexions within the brain-stem are described elsewhere (p. 929).

An important group of vaso-sensory fibres (the sino-carotid nerve) is carried centrally by the ninth nerve from the carotid sinus and the carotid body (Fig. 689, p. 808) (Sheehan, Mulholland, & Shafiroff, 1941).

Vagus Nerve.—This is the largest member of the cranial parasympathetic group and has a very wide distribution. It is composed of various types of fibres which include a large number of splanchnic efferent (parasympathetic) fibres and also many splanchnic afferents.

The parasympathetic efferent fibres differ from those in other cranial nerves in not passing to obvious dissectable ganglia, but to ganglion-cells in diffuse plexuses such as the cardiac or in the walls of viscera supplied. The chief fields of distribution are the heart, the alimentary tract, and the lungs. In general, the various branches of the vagus both in the thorax and the abdomen become intimately associated with sympathetic fibres and it is quite impossible by dissection to unravel the two sets: functionally, however, each retains its individuality and, as explained previously, their actions on a particular viscus are different.

In the alimentary system the various branches—œsophageal, gastric, and intestinal—derived from the vagus nerves provide the nervous pathway for impulses which control motility of the gut and the onward movement of its contents. Secreto-motor fibres induce secretion of the associated glands; other fibres are inhibitory to sphincters, *e.g.*, pyloric and ileo-colic. Such branches extend to the distal colon, after which the sacral parasympathetic system is the source of control.

In the respiratory system vagal fibres induce broncho-constriction, and in the heart they decrease the rate of contraction.

The many splanchnic afferent fibres incorporated in the vagus have a field of distribution equally wide—from the alimentary and respiratory tracts and from the heart. A great many of these are "silent" afferent fibres in that they generally give rise to no conscious state, but others, *e.g.*, from pharynx and larynx and to a less extent from the œsophagus, provoke obvious conscious states and also provide the afferent side of reflex mechanisms such as coughing. Other afferents from vessels provide the afferent side of important cardio-vascular reflexes —*e.g.*, from the aortic arch and its associated glomus aorticum, vaso-sensory impulses are conveyed by the vagus to the medulla. All the various afferent fibres have their cell-bodies in the vagal ganglia.

The details of the course of the vagus nerve and its various branches and the position of the plexuses are covered in the description of the vagus nerve (pp. 1037-1042) and in the section dealing with the sympathetic plexuses of thorax (p. 1138) and abdomen (p. 1140). These sections should be studied in conjunction with the above remarks.

SACRAL PARASYMPATHETIC

The sacral parasympathetic nerves arise as a number of delicate branches from the anterior primary rami of the second and third, or third and fourth sacral nerves. Sheehan (1941) found that the sacral outflow was carried most commonly by the third and fourth sacral nerves; the second and the fifth were not regularly implicated. Their cells of origin are in the sacral part of the spinal cord, and they have therefore a considerable course in the cauda equina before they appear in the pelvis. These two or three strands, known as the **pelvic splanchnic nerves**, are composed of medullated preganglionic fibres (comparable therefore with white rami communicantes) which proceed to the pelvic plexuses in association with sympathetic fibres. They meet their postganglionic neurons either in these plexuses or in the walls of the viscera which they supply, viz., distal colon and rectum, and the pelvic parts of the urogenital system. Further details of the course of the fibres concerned are given with the sympathetic system in the pelvis (p. 1144).

The sacral parasympathetic replaces the vagus probably in the region of the descending colon and is concerned with the emptying-mechanisms of the various hollow viscera—rectum, uterus, and bladder—and also with the phenomenon of erection (vaso-dilatation) of the genital organs and the neuro-muscular control of ejaculation. In comparison with the cranial outflow and with the thoraco-lumbar outflow the sacral is small and also more variable.

SYMPATHETIC SYSTEM

The foundation of the sympathetic nervous system is laid by *splanchnic efferent fibres* which emerge from a sharply limited region of the spinal cord between the first thoracic and the second lumbar segments. These efferent fibres arise from cells in the lateral grey column of the cord and pass outwards in the anterior nerve-roots to reach the anterior primary rami of the spinal nerves concerned. They leave the anterior ramus (Fig. 963) as a bundle of fibres, generally medullated, known as the **white ramus communicans**, which joins the gangliated **sympathetic trunk**. These fibres are preganglionic fibres and collectively constitute what is known as the *thoraco-lumbar outflow*. They meet the postganglionic neurons either in the ganglia of the sympathetic trunk or in the gangliated plexuses associated with the trunk. It is important to understand from the outset that each preganglionic fibre may effect synaptic contact with a number of postganglionic neurons; this accounts for the greater number of postganglionic neurons and also for the wide diffusion of sympathetic effects. Further, all sympathetic elements, wherever found in the body, derive their efferent connexion from the central nervous system through this limited region of the cord between the origins of the two great limb-plexuses from the cervical and lumbar enlargements. So, from this thoraco-lumbar source, there has to be a means of distributing fibres upwards to the neck and head, and downwards to the lumbar and pelvic regions, as well as locally in the thoraco-lumbar zone. We find that the sympathetic trunk continues upwards and downwards along the whole length of the vertebral column, composed of groups of postganglionic cells—the ganglia—linked by strands of fibres, but that no accession of preganglionic fibres reaches it beyond the limits of the thoraco-lumbar outflow; its extensions upwards and downwards are a means of distributing the preganglionic neurons to levels where no preganglionic outflow exists. Further, the continuity of the trunk from level to level permits a preganglionic neuron, by means of its collaterals, to influence numerous postganglionic neurons.

A. The **ganglia** are composed of aggregations of nerve-cells mostly of the multipolar variety, though a few may be bipolar or pseudo-unipolar. They are all excitor neurons, and their axons are the postganglionic fibres of the sympathetic. There is no adequate evidence that the cell-bodies of receptor neurons are found in sympathetic ganglia.

Each ganglion-cell is enclosed in a nucleated capsule and is provided with one axon and a number of dendrites. Some of the dendrites ramify beneath the capsule and hence are termed intracapsular; they may form a network round the cell or may be localized in the form of a glomerulus. Other dendrites are extracapsular; they pierce the capsule and run throughout the ganglion, taking part in the formation of an intercellular plexus and making contact with the capsules of other cells. This plexus is joined by the ramifications of the entering preganglionic fibres, some of which also pierce the capsules of the cells to meet the intracapsular dendrites. One preganglionic fibre can, in that way, influence many postganglionic neurons, which explains the difference between the comparatively small number of fibres that enters the ganglion and the large number that leaves it. There appears to be no evidence of commissural neurons or of sensori-motor synapses among ganglion-cells. The axon of a ganglion-cell (a postganglionic fibre) is usually non-medullated, though this need not hold throughout its length.

The ganglia are classified as follows:—

(1) The **paravertebral** or **central ganglia** are more or less segmental in position but variable in number, form, and size. They are all interconnected by narrow cords formed of ascending and descending fibres and in that way a gangliated

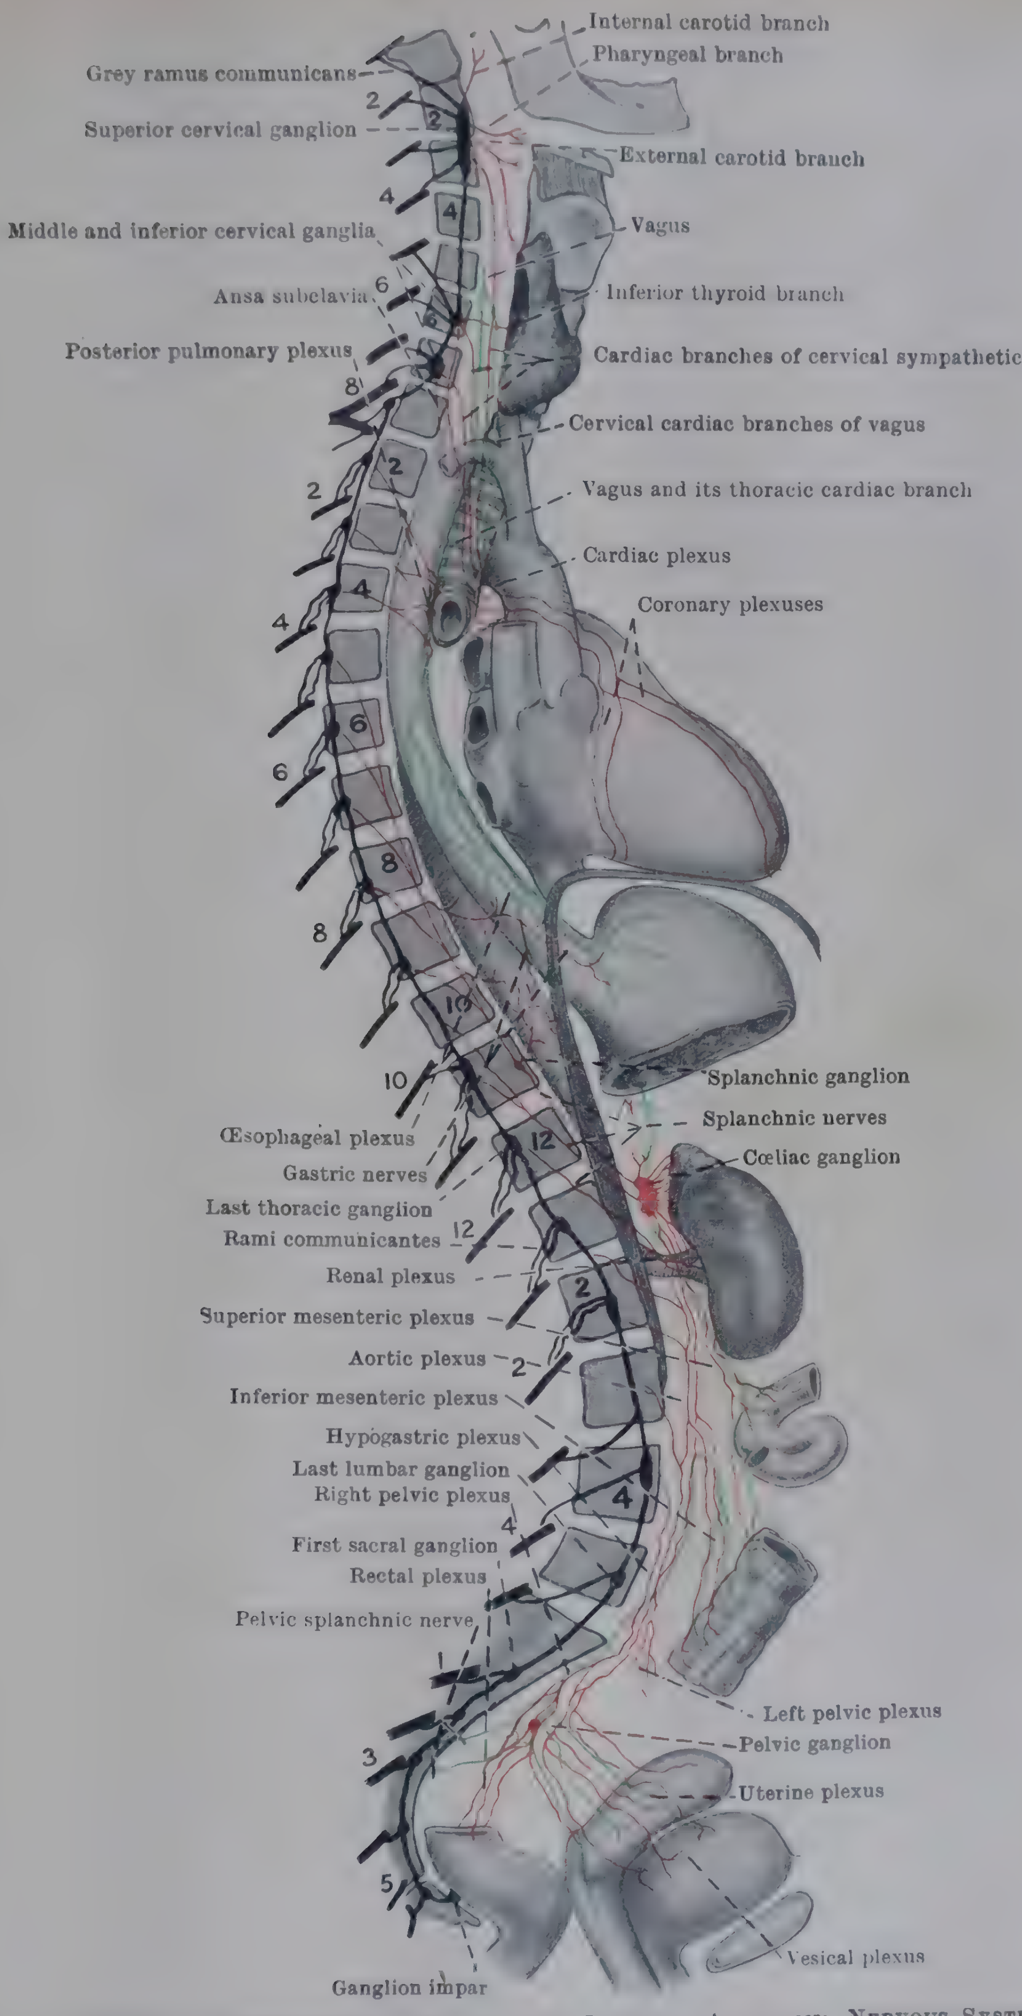

FIG. 962.—TOPOGRAPHICAL PLAN OF MAIN PARTS OF AUTONOMIC NERVOUS SYSTEM.

The spinal nerves, sympathetic trunk, and rami communicantes are shown in *black*; sympathetic branches of distribution and plexuses in *red*; parasympathetic nerves (vagus and sacral) in *green*. The vertebræ and spinal nerves are numbered.

sympathetic trunk is formed on each side, flanking the vertebral column. The connecting strand between any two ganglia may be duplicated. There are twenty-one or twenty-two ganglia in each trunk of which three are associated with cervical nerves, ten or eleven with the thoracic, four with the lumbar, and four with the sacral nerves. At their lower ends the two sympathetic trunks unite either by communicating strands or in a single, median ganglion placed on the front of the coccyx—the *ganglion impar*. At the upper end each sympathetic trunk is continued into the cranial cavity in the form of plexuses around the internal carotid artery and it thereby establishes relations with certain cranial nerves. There are no communications between the trunks of the two sides except occasionally towards their lower ends.

(2) **Collateral (prevertebral) ganglia** are found in connexion with the great prevertebral plexuses of the thorax and abdomen. They are much more diffuse than the paravertebral ganglia and must be regarded rather as gangliated plexuses. They are not arranged in a segmental manner but permit fibres to be collected for distribution to one organ or to a group of organs physiologically related to one another.

(3) **Terminal ganglia** may be found on or in the walls of viscera; but these belong mainly to the parasympathetic system.

B. The **nerve-fibres** in the sympathetic system may be medullated or non-medullated. Preganglionic fibres, which link up the central nervous system with the sympathetic trunk, are medullated but rather smaller than somatic efferent fibres. The fibres that arise from cells of the sympathetic ganglia are postganglionic and generally non-medullated or very finely medullated, or they may be medullated in part and non-medullated elsewhere along their length. Fibres of the above types (efferent) as well as medullated afferent fibres are found in the rami communicantes, in the interganglionic cords, and in the branches of distribution from the trunk. These may now be considered severally (Fig. 962).

(1) **White rami communicantes** are the only true rami communicantes since they alone provide an efferent connexion between the central nervous system and the sympathetic system. They are composed of finely medullated fibres and arise from the anterior primary rami of the spinal nerves from the first thoracic to the second lumbar inclusive. The cervical, lower lumbar, and the sacral nerves do not give off white rami to the sympathetic system—*i.e.*, they are beyond the limits of the thoraco-lumbar outflow. The fibres of the white rami pass through both posterior and anterior roots of the spinal nerves but mainly through the anterior. The *fibres from the anterior root* are of small size and are axons of nerve-cells situated in the lateral grey column of the cord. After running in the anterior roots, the anterior primary rami, and the white rami communicantes, they terminate in arborizations around cells of sympathetic ganglia: they are therefore preganglionic fibres. Three courses are open to such a fibre (Fig. 963): (*a*) it may end in the ganglion immediately adjacent to the ramus; (*b*) it may course upwards or downwards to reach neighbouring ganglia; (*c*) it may pass beyond the sympathetic trunk to end in relation with cells of some collateral ganglion. All the above are preganglionic **splanchnic efferent fibres**. The *fibres from the posterior root* of the spinal nerve which enter into the composition of the white ramus are the peripheral processes of the cells of a spinal ganglion and are **splanchnic afferent fibres** from viscera and vessels. They traverse the various branches of the sympathetic trunk and the trunk itself, but have no synaptic relationship with the cells of the sympathetic ganglia: they terminate in the grey matter of the cord. It is not certain that afferent fibres of this category are found only in nerves provided with distinct white rami; similar medullated fibres are found also in grey rami communicantes.

(2) The **interganglionic cords** of the trunk are composed of white and grey fibres arranged as one or more connecting links between the ganglia. The *white fibres* are: (i) **splanchnic efferent fibres** passing to a ganglion above or below their points of entrance to the sympathetic system; (ii) **splanchnic afferent fibres** passing along the connecting cord and over or through the ganglia on their way to the posterior nerve-root and spinal cord. The *grey fibres* are axons of sympathetic ganglion-cells and they may pass up or down the sympathetic trunk

before leaving it as one of its branches. There is no evidence of purely associative neurons uniting one ganglion of the trunk with another.

(3) **Fibres of distribution** may leave the trunk by several routes: they may join spinal nerves (grey rami communicantes) or certain cranial nerves; they may travel along blood-vessels; or they may pass as direct visceral or splanchnic

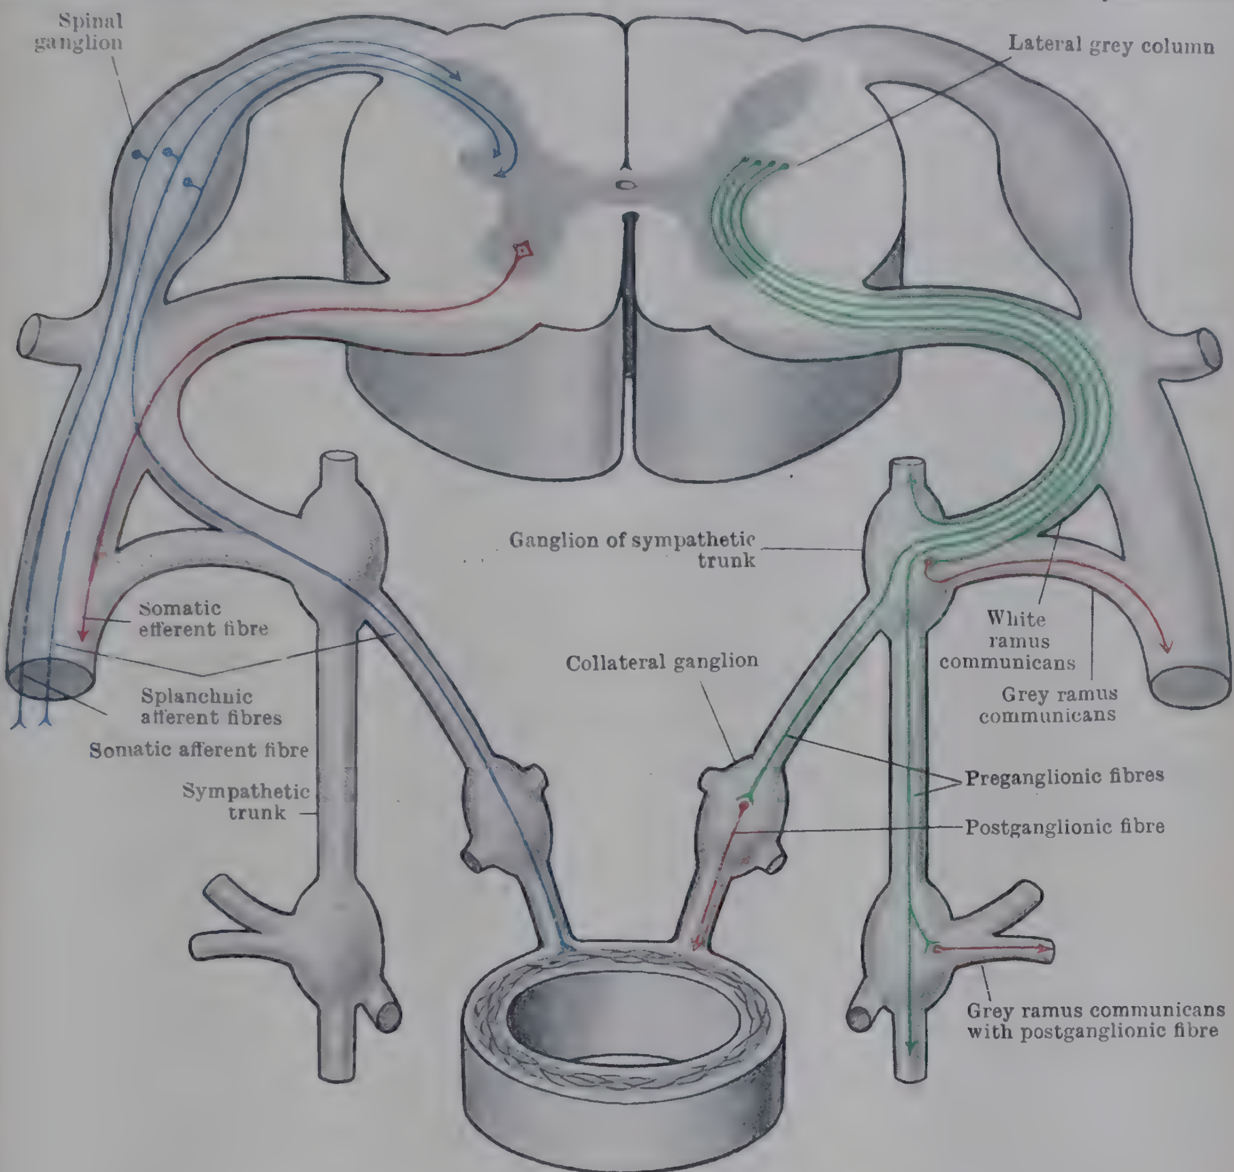

Fig. 963.—Scheme showing Relation of Sympathetic System to Spinal Nerves and Spinal Cord.

Splanchnic efferent fibres (preganglionic, *green*; postganglionic, *red*) are shown on the right side; a somatic efferent fibre (*red*) and somatic and splanchnic afferent fibres (*blue*) on the left. For the relative position of white and grey rami, see p. 1130. Compare with Fig. 730, p. 845 and Fig. 910, p. 1046.

branches to some peripheral plexus and thence to viscera. Each of these possibilities may be considered in greater detail.

(*a*) **Accompanying Nerves.**—Such fibres are all *postganglionic* branches from cells of the paravertebral ganglia. In the head-region some branches of this type join with certain cranial nerves to be distributed along with them as vasomotor, pilomotor, and sudomotor fibres. The vast majority, however, are distributed with spinal nerves and this latter group form the branches of the trunk known as the **grey rami communicantes**. The name is unfortunate for, in contrast to white rami communicantes, they are not communications with the central nervous system, but are purely branches of distribution. Further, unlike the white rami communicantes, the grey are composed predominantly of non-medullated fibres (some are finely medullated) and they link the sympathetic trunk to each and every spinal nerve. Their arrangement tends to be irregular; they arise either from ganglia or from interganglionic cords and they may be multiple—going to adjacent spinal nerves—so that a spinal nerve may receive rami from more than one ganglion. In the thoraco-lumbar region, where both white and grey rami are present, it is the white

ramus which joins the spinal nerve the more distally, the grey ramus more proximally (Pick & Sheehan, 1946). These authors have confirmed the observation of Botár (1932) that in the lower thoracic and upper lumbar regions the grey ramus is normally transverse, running between a ganglion and the nerve of the same segment, whilst the white ramus passes obliquely between a nerve and the ganglion of the next lower segment. Not uncommonly rami of the two categories show some degree of admixture.

(*b*) **Accompanying Blood-Vessels.**—Offsets from various parts of the sympathetic trunk associate themselves with blood-vessels and proceed along such vessels, their branches often forming perivascular plexuses. Such fibres are again postganglionic axons of splanchnic efferent cells in the paravertebral ganglia.

(*c*) **Direct Visceral Branches.**—From each level of the sympathetic trunk—cervical, thoracic, lumbar, and sacral—there are given off branches which proceed to viscera usually after passage through a plexus. The visceral branches from the trunk are composed in the main of preganglionic fibres, and these undergo synapse sooner or later with postganglionic neurons scattered irregularly in the visceral branches and the plexuses. At times the postganglionic cells are aggregated into dissectable groups to which names have been given, but it must be clearly understood that the visceral branches, before they reach the so-called plexuses, also contain ganglion-cells, and that the whole arrangement constitutes a diffuse gangliated plexus. Somewhere in this system the preganglionic fibre makes synaptic contact with postganglionic neurons. It follows, therefore, that grey and white fibres will be found side by side in such situations. The final passage of the postganglionic fibres to viscera is often in the form of perivascular nerves.

Accompanying all the branches of distribution mentioned above are splanchnic afferent fibres. These are medullated and pass centrally through plexuses, the trunk and rami (grey and white) to reach the posterior nerve-roots. Their unipolar cell-bodies are situated in spinal ganglia ; and the central processes end in the grey matter of the cord.

It will now be appreciated that in many sympathetic nerves medullation or non-medullation as such helps little in the identification of fibres of different functional types—*e.g.*, in a visceral branch there may be running side by side medullated preganglionic fibres, non-medullated preganglionic fibres, postganglionic, both non-medullated and finely medullated, and splanchnic afferent medullated fibres. Further, in their ultimate peripheral distribution, sympathetic fibres are quite commonly associated with parasympathetic fibres. Finally, it should be noted that a fibre may be in one part medullated and elsewhere in its course devoid of any myelin sheath.

SYMPATHETIC TRUNK

Cervical Part of Trunk.—The sympathetic trunk in the neck is to be regarded as an upward extension of the thoracic part, from which all its preganglionic fibres come ; *it has no white rami communicantes.* Developmentally, it is composed of segmentally arranged ganglia, but fusion of the ganglia has reduced their number to three—the superior, middle, and inferior cervical ganglia. Failure of the fusion may occasionally leave four ganglia, or at times the process may proceed so far as to reduce the number to two.

The cervical part of the trunk lies on the prevertebral muscles and behind the carotid vessels (Fig. 964). It consists of a slender strand of fibres, both medullated and non-medullated, connecting the three ganglia. Superiorly, it is continued into the cranium in the form of branches accompanying the internal carotid artery ; and inferiorly it is continuous with the thoracic part in front of the neck of the first rib, where there is a pronounced change in direction of the trunk as it passes backwards into the thorax.

The **superior cervical ganglion** is an elongated fusiform structure 1 inch or more in length, placed behind the neuro-vascular bundle formed by the internal carotid artery, internal jugular vein, and the last four cranial nerves, and lying on the fascia of the longus capitis muscle, to which it tends to adhere. It extends above to within 2 cm. of the entrance of the carotid canal, its upper pole lying deep to

the posterior belly of the digastric muscle, and below it reaches the level of the angle of the jaw; its lower pole varies somewhat in level according as the bifurcation of the common carotid is high or low. It is formed by fusion of the upper four cervical segmental ganglia.

The **middle cervical ganglion** is the smallest and most variable of the cervical ganglia. At times it may not be recognizable or it may be greatly reduced in size owing to complete or partial fusion with the inferior ganglion. It probably represents the fifth and sixth cervical segmental ganglia. Its most usual position is close to the inferior thyroid artery as the latter passes behind the common carotid trunk at the level of the sixth cervical transverse process; it may lie in front of the inferior thyroid artery or behind it, or even at times be wrapped around that vessel. A lower position is not unusual, in which case it generally lies on the vertebral artery (Axford, 1928).

The **inferior cervical ganglion** is a large, irregularly shaped mass formed by fusion of the lower two (or more) cervical segmental ganglia and commonly the first thoracic ganglion (or even the first and second) as well. (The term "stellate" ganglion, though often applied to the inferior cervical ganglion, properly refers to the ganglion when thoracic ganglionic elements are incorporated in it as is common in some animals, *e.g.*, the cat.) It is situated at the junction of the cervical and thoracic portions of the trunk, and, in accordance with the marked change in direction of the whole chain at this point, the ganglion lies with its long axis almost antero-posteriorly. It occupies a space bounded in front by the vertebral artery and the associated veins, below by the dome of the pleura, and behind by the neck of the first rib and transverse process of the seventh cervical vertebra. The termination of the costo-cervical trunk will normally have a relationship to the lower pole of the ganglion (Fig. 964). Quite frequently the antero-superior pole of the ganglion may be in front of the vertebral artery and be joined to the remaining and major part of the inferior cervical ganglion by nerve strands encircling the artery. This is known as the "ganglion intermediare" and represents a fusion of some part of the middle ganglion with the inferior ganglion. Irregularities at the inferior pole are likewise due to variations in degree of fusion involving the uppermost thoracic ganglia. Linking the middle and inferior ganglia is the usual interganglionic cord. An additional connexion exists which loops downwards in front of and below the subclavian artery forming the *ansa subclavia*. If the middle ganglion is in part incorporated in the inferior the ansa may then run from the superior pole to the inferior pole of the inferior ganglion.

Thoracic Part of Trunk.—The thoracic part of the sympathetic trunk (Fig. 965) descends under cover of the pleura in front of the intercostal vessels. In the upper part of the thorax it lies on the necks of the ribs, but at mid-thoracic level it is found over the costo-vertebral joints and in the lower part of the thorax it is on the sides of the vertebræ. This change of position relative to the ribs and vertebræ is to be associated with the progressive widening of the lower thoracic vertebræ. The number of ganglia on the thoracic trunk is usually ten or eleven; but the first—and sometimes others—may be so fused with neighbouring ganglia as to reduce the number still further. They are joined together by interganglionic cords of considerable thickness which are not uncommonly duplicated between adjacent ganglia.

The change in direction of the trunk at the junction of the thoracic and cervical parts has been mentioned already. At its lower end the thoracic chain passes behind the medial arcuate ligament to become continuous with the lumbar part.

The thoracic part of the trunk receives the vast majority of the preganglionic fibres which emerge from the spinal cord. Each thoracic nerve sends a white ramus to the trunk, but a great many of the fibres in these rami are not for local distribution; some ascend to provide the preganglionic supply to the cervical part of the trunk, others descend to assist the first and second lumbar nerves in supplying preganglionic fibres to the lower lumbar and sacral parts. There is suggestive evidence that preganglionic fibres concerned with particular peripheral structures emerge at constant levels from the spinal cord, and this is of some surgical import.

Preganglionic fibres for the **head and neck** leave the cord in the upper two

thoracic nerves and proceed *via* the white rami communicantes to the sympathetic trunk, in which they ascend to the superior cervical ganglion for synapse.

Fibres destined to influence the **heart** emerge through the second and third thoracic nerves (and perhaps through some lower nerves as well) and ascend to all three cervical ganglia whence branches run to the cardiac plexuses. Some small cardiac branches pass directly from the thoracic sympathetic trunk to the cardiac plexuses (p. 1136). Splanchnic afferents of cardiac origin run in the middle and inferior cervical cardiac nerves as well as in the thoracic cardiac nerves. They enter the spinal cord between the levels of the second and fifth thoracic nerves.

Abdominal structures—viscera and blood-vessels—are controlled by the preganglionic outflow from the lower half of the thoracic cord *via* the splanchnic nerves. The preganglionic supply to the pelvic viscera arises from the upper lumbar nerves.

The preganglionic fibres destined to influence the **upper limbs** emerge from the cord between the levels of the third to the seventh thoracic nerves and undergo synapse in the first thoracic and inferior cervical ganglia, and probably also in the middle cervical ganglion. For the **lower limbs** preganglionic fibres emerge from the level of the tenth thoracic to the second lumbar, and they have their synapses in the ganglia of the trunk from third lumbar to third sacral inclusive.

Lumbar Part of Trunk.—On entering the abdomen the sympathetic trunk is directed somewhat medially and in conformity with the lumbar curvature comes to lie on a plane rather anterior to that of the thoracic chain (Fig. 967). It extends downwards on the bodies of the lumbar vertebræ medial to the psoas muscle. On the right side it lies under cover of the inferior vena cava and on the left it is overlapped by aortic lymph-glands. The two trunks tend to converge as they pass downwards. Usually the trunk lies in front of the lumbar vessels; but the occasional presence of some lumbar veins in front of the trunk is noteworthy in connexion with the operation of "lumbar sympathectomy". Inferiorly the lumbar part continues into the pelvis behind the common iliac artery. The number of ganglia is typically irregular (Pick & Sheehan, 1946; Cowley & Yeager, 1949). Usually there are four, but variations leading to increase or decrease are not uncommon.

The prevertebral position of the lumbar trunk, rather than the paravertebral position which in general characterizes the thoracic part, may be associated with the massive psoas muscle arising from the sides of the lumbar column. This displacement forwards of the chain separates it by a considerable interval from the lumbar nerves and necessitates the much greater length of the lumbar rami communicantes. The upper two (or three) lumbar nerves send white rami communicantes to the sympathetic trunk. They are not infrequently intermingled with grey. Boyd & Monro (1949) have called attention to the presence of "intermediate ganglia", situated between the first three lumbar nerves and the sympathetic trunk, and concealed by the psoas muscle, as the explanation of partial retention of autonomic function after sympathectomy.

Pelvic Part of Trunk.—This part of the sympathetic trunk lies on the pelvic surface of the sacrum and coccyx (Fig. 967). It commences above under the common iliac vessels and extends downwards and a little medially. The trunk is placed medial to the sacral foramina above: at the level of the fourth foramen it overlaps the foramen and lies on the fourth sacral nerve. Below this the two trunks end, sometimes by irregular connexions across the terminal piece of the sacrum and the coccyx, sometimes in a small swelling—the *ganglion impar*—on the front of the coccyx; or they may occasionally end quite independently. On each sacral portion there are generally four ganglia which diminish in size gradually from above downwards.

BRANCHES OF DISTRIBUTION FROM SYMPATHETIC TRUNK

The branches of distribution from the sympathetic trunk having been classified (p. 1129), it now remains to take each segment—cervical, thoracic, lumbar, and pelvic—and to consider in greater detail the distribution from each (Potts, 1925).

I. Branches from Cervical Part of Trunk

(*a*) **Accompanying Nerves.**—(1) **Grey rami communicantes** are given to all cervical nerves. The superior ganglion supplies them to the first four, the middle ganglion or adjacent trunk to the fifth and sixth, and the inferior ganglion to the seventh and eighth. These are postganglionic fibres, and they accompany the nerves which they join to be distributed in their field of supply as vasomotor, pilomotor, and sudomotor fibres.

(2) Close to the skull the *superior cervical ganglion* gives branches directly to

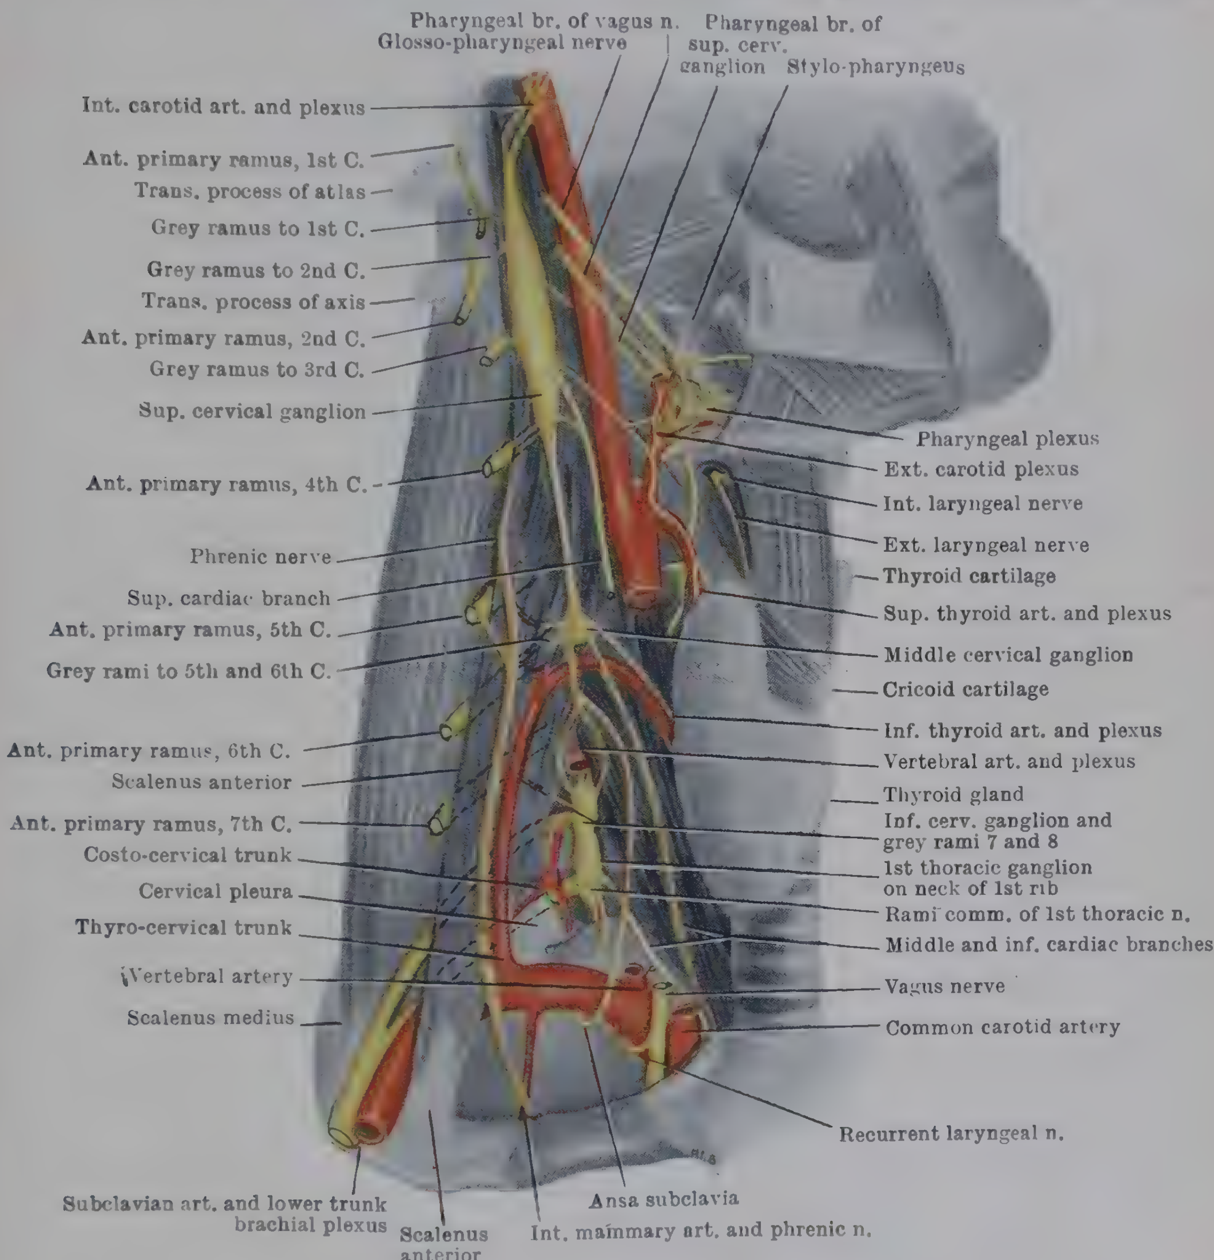

Fig. 964.—Distribution of Branches of Sympathetic Trunk and Ganglia in the Neck.

the following **cranial nerves**: to the inferior ganglion of the glosso-pharyngeal nerve, to both vagal ganglia, and to the hypoglossal nerve. The *inferior ganglion* commonly gives a branch to the recurrent laryngeal branch of the vagus.

(*b*) **Accompanying Blood-Vessels.**—(1) The *superior ganglion* gives branches to the external carotid artery, and these constitute an **external carotid plexus**, which extends along that vessel and its branches. Offshoots from it pass also to the carotid body. Other perivascular fibres, accompanying various branches of the artery, reach **glands** in the field of distribution of the artery, *e.g.*, salivary glands. Wilson (1936) found that the fibres supplying the sweat glands of the face arose from the external carotid plexus but soon joined the branches of the fifth nerve with which they were then distributed. (2) The *superior ganglion* sends upwards several branches with the internal carotid artery. They accompany the artery into the carotid canal as the **internal carotid plexus**, which sends offshoots to supply the vessel

and its branches as well as fibres to join certain cranial nerves. Occasional ganglion-cells are present in the internal carotid plexus. The distribution of the plexus, apart from the arterial branches, may be summarized as follows:—

(i) At one or other level, branches join the following **cranial nerves**: third, fourth, fifth, and sixth.

(ii) Fibres run to the vessels of the **hypophysis cerebri**.

(iii) The **deep petrosal nerve** joins the greater superficial petrosal branch of the seventh in the foramen lacerum to constitute the nerve of pterygoid canal.

(iv) **Carotico-tympanic nerves**, usually two, enter the middle ear.

(v) Some fibres constitute the **sympathetic root of the ciliary ganglion**, and pass through the ganglion to reach the eye.

It will be seen that the field of distribution of these internal carotid branches is wide and varied. They are predominantly postganglionic fibres, though some are presumably afferent; most of them are doubtless *vasomotor* in function; but some are concerned in the innervation of the *dilator muscle of the pupil* (Fig. 958) and of plain muscle in the orbit (Ingalls, 1923). Destruction or interruption of the sympathetic pathway to the eye and orbit leads to Horner's syndrome (see p. 1481).

(3) From the *middle ganglion*, or adjacent trunk, branches accompany the inferior thyroid artery to the **thyroid gland**.

(4) From the *inferior ganglion* several branches of considerable size accompany the vertebral artery and are distributed to it and its branches in the neck and within the cranium. Some fibres of the **vertebral plexus** join the fourth, fifth, and sixth cervical nerves—thus constituting an additional supply of post-ganglionic fibres to these nerves over and above those supplied by the grey rami communicantes.

(5) The *inferior ganglion*, or more commonly the *ansa subclavia*, sends branches to the **subclavian artery**. These are distributed to the vessel and its branches as vasomotor (and sensory) fibres. The fibres which accompany the subclavian artery probably do not extend farther than the axilla; thereafter, the arteries of the upper limb are innervated by sympathetic fibres which are derived from adjacent peripheral nerves.

(*c*) **Direct Visceral Branches.**—(1) A **pharyngeal branch** from the superior ganglion passes medial to the carotid sheath to join branches of the glosso-pharyngeal and vagus nerves in the formation of the **pharyngeal plexus**.

(2) **Cardiac branches**: each cervical sympathetic ganglion gives a cardiac branch which descends to the thorax. From the *superior ganglion*, the cardiac branch descends as a fine nerve behind the great vessels. The right nerve enters the thorax in front of or behind the subclavian artery and joins the deep cardiac plexus. The left nerve enters the thorax between the left common carotid and subclavian arteries, runs across the left side of the aortic arch and joins the superficial cardiac plexus. The cardiac branches of the *middle* and *inferior ganglia* are commonly associated with each other and with the cardiac branch of the superior ganglion in their course; they are distributed to the deep cardiac plexus.

Cardiac branches from the vagus, and from its laryngeal branches, are commonly intermingled with the above sympathetic branches in the thoracic part of their course.

With the possible exception of the cardiac branch of the superior ganglion, which is regarded as efferent, the above visceral branches are mixed nerves: some fibres are splanchnic afferents; others are preganglionic efferent fibres which meet their postganglionic neurons in the plexuses; and some fibres are post-ganglionic. The plexuses and their distribution will be discussed later (p. 1137).

II. Branches from Thoracic Part of Trunk

(*a*) **Accompanying Nerves.**—**Grey rami communicantes** arise from all the thoracic ganglia or from the interganglionic cords. They tend to be irregular; from any ganglion there may be several rami and these may distribute themselves to adjacent anterior primary rami of several levels so that one anterior primary ramus may receive fibres from more than one sympathetic ganglion. All anterior

primary rami receive grey rami communicantes. Not uncommonly white and grey rami associated with a particular nerve are intermingled. The postganglionic

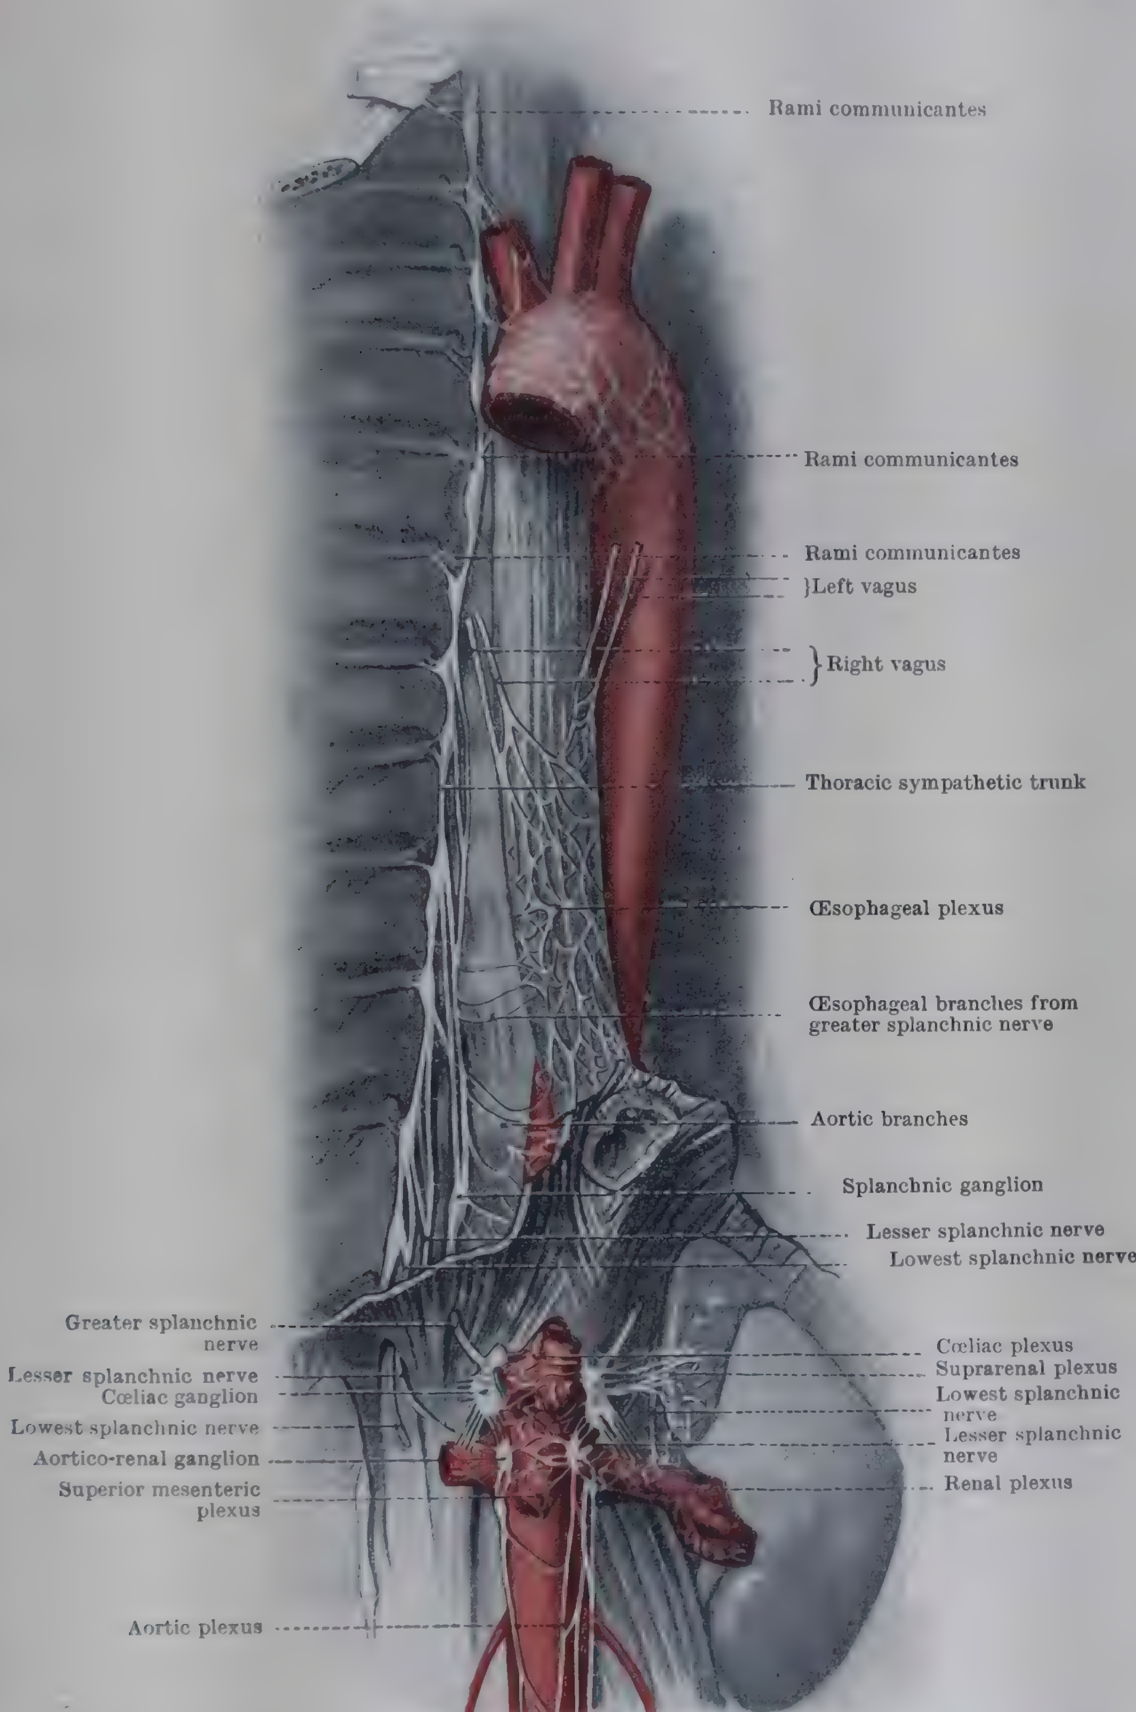

FIG. 965.—SYMPATHETIC TRUNK AND PARASYMPATHETIC FIBRES FROM THE VAGI IN THE THORAX AND UPPER ABDOMEN.

fibres are distributed with the thoracic spinal nerves as their vasomotor, pilomotor, and sudomotor components. By this means the first, and commonly also the second, thoracic ganglia contribute rami to the **brachial plexus** through the first thoracic nerve. The fibres from the second thoracic ganglion may run directly to the first thoracic nerve or they may reach that nerve by way of the communi-

cating branch between the second and first thoracic nerves (Kuntz, 1927). Such fibres are of importance in operations devised to deprive the upper limb of its sympathetic supply. Some fibres from the grey rami, or from ganglia direct, accompany the meningeal branch of the spinal nerve to the fibro-osseous coverings of the spinal cord. All the fibres mentioned above are postganglionic.

Splanchnic afferent fibres may be present in the grey rami: they pass to the spinal cord *via* the posterior nerve-roots.

(*b*) **Accompanying Blood-Vessels.**—Fine branches from the upper five thoracic ganglia are distributed to the aorta and are disposed around it as an aortic plexus (Fig. 965). They are postganglionic fibres.

(*c*) **Direct Visceral Branches.**—The thoracic visceral branches are in two main groups—those from the upper part of the thoracic trunk and those from the lower part.

(1) **Pulmonary and Cardiac Branches.**—Several branches arise in the vicinity of the second, third, and fourth thoracic ganglia and join the posterior pulmonary plexus; they communicate with the cardiac plexuses also.

(2) **Splanchnic Nerves.**—On each side three branches arise from the lower ganglia and proceed to the abdomen: they are the **greater**, the **lesser**, and the **lowest splanchnic nerves.** Each consists of nerve-fibres and scattered ganglion-cells. The fibres may be of several categories: they may be medullated *splanchnic afferent* fibres proceeding centrally towards the posterior nerve-roots and spinal cord; or *splanchnic efferent*—either non-medullated postganglionic fibres from ganglia of the sympathetic trunk or from ganglion-cells situated here and there along the course of the splanchnic nerves, or, finally, preganglionic fibres (generally medullated) which have passed without synaptic interruption through the trunk and are proceeding to meet their postganglionic neurons either in the splanchnic nerves or in the abdominal plexuses. The splanchnic nerves are therefore to be regarded as attenuated portions of a gangliated plexus which becomes, as we shall see later, much more obviously plexiform in the abdomen.

The **greater splanchnic nerve** arises from the trunk between the fifth and the ninth or tenth ganglia. By the union of several strands a nerve of considerable size is formed which descends, medial to the trunk, over the bodies of the vertebræ to pierce the crus of the diaphragm and join, in the abdomen, the upper end of the cœliac ganglion. In the thorax a dissectable enlargement (*splanchnic ganglion*) may be found on the greater splanchnic nerve about the level of the eleventh thoracic vertebra. It represents, as explained above, nothing more than an aggregation of ganglion-cells along the course of the nerve. From the thoracic part of the greater splanchnic nerve fine branches leave to be distributed to the œsophagus and thoracic aorta (Fig. 965).

The **lesser splanchnic nerve** arises in the region of the ninth and tenth ganglia and passes downwards on the vertebral bodies, medial to the trunk, to pierce the diaphragm close to the greater splanchnic nerve. It also ends in the cœliac ganglion.

The **lowest splanchnic nerve** arises from the last thoracic ganglion, or it may be from the lesser splanchnic nerve. It pierces the diaphragm to end in the renal plexus. It may not be present as a separate nerve.

The details of the plexuses in which the above splanchnic nerves end are dealt with later (p. 1140).

III. Branches from Lumbar Part of Trunk

(*a*) **Accompanying Nerves.**—**Grey rami communicantes** pass from the sympathetic trunk to the anterior primary rami of the lumbar nerves in an irregular manner. One ramus may divide to join adjacent spinal nerves; or one spinal nerve may receive several rami from different levels of the lumbar trunk. The rami have a characteristically long course in the lumbar region owing to the separation of the trunk from the spinal nerves by the psoas muscle: at times rami may pierce the muscle.

Splanchnic afferent fibres may accompany the efferent fibres of the grey rami.

(*b*) **Accompanying Blood-Vessels.**—Small vascular branches join the lumbar arteries near their origins and proceed along them to the aorta where they form a delicate plexus around the aorta; this plexus is continuous above with the thoracic aortic plexus and below with the plexus around the median sacral artery and the plexuses of the common iliac and the external and internal iliac arteries. It is reinforced by twigs from the last lumbar ganglion.

(*c*) **Direct Visceral Branches.**—Visceral branches emerge from the four lumbar ganglia (Fig. 967). Those from the upper two ganglia of each side are not uncommonly combined in a single trunk in front of the aorta about the level of origin of the inferior mesenteric artery, along which some fibres proceed, forming the **inferior mesenteric plexus**. The nerves then continue downwards to the interval between the common iliac vessels where they receive the branches from the third and fourth ganglia. The branch from the third passes between the common iliac artery and vein and that from the fourth behind both. The resulting structure formed by the confluence of all four nerves of both sides forms a loose-meshed plexus—**hypogastric plexus**—situated in front of the fifth lumbar body and between the common iliac arteries. It is continued down to the **pelvic plexuses** through which it will reach its distribution to pelvic structures (p. 1143). It will be noted that these visceral branches of the lumbar ganglia are predominantly pelvic in distribution, just as the major groups of cervical and thoracic visceral branches are directed to regions below the level of their origin from the sympathetic trunk.

The pelvic plexus is described later (p. 1143).

The fibres comprising these visceral branches are varied—*splanchnic afferent* (medullated) and both preganglionic and postganglionic *splanchnic efferent*. Ganglion-cells are found diffusely distributed along their course as in the case of the thoracic splanchnic nerves.

IV. Branches of Pelvic Part of Trunk

(*a*) **Accompanying Nerves.**—Irregularly arranged branches arise from the ganglia and are distributed to all sacral anterior primary rami and the coccygeal nerve. These are the **grey rami communicantes**, whose distribution is comparable with that of grey rami of other regions. Some fibres pass in a recurrent course towards the sacral canal, where they are distributed to the fibro-osseous structures.

(*b*) **Accompanying Blood-Vessels.**—Some fine branches are distributed to the median sacral artery and its branches.

(*c*) **Direct Visceral Branches.**—The visceral branches of the sacral ganglia are fine and not numerous. Usually two or three in number, they arise from the second and third ganglia and proceed to the pelvic plexus, in which their identity, so far as gross dissection is concerned, is lost.

Other direct visceral branches from sacral ganglia to the rectum and the ureter have been described; they would appear to be inconstant.

SYMPATHETIC PLEXUSES

Frequent reference has already been made to various plexuses in which sympathetic nerves end; it remains now to classify these and deal in greater detail with certain of them.

Some of them have been seen to be associated with the cervical sympathetic branches to certain vessels, *e.g.*, the internal carotid plexus, external carotid plexus, inferior thyroid plexus, vertebral and subclavian plexuses, and also the pharyngeal plexus. These **perivascular plexuses** are to be regarded merely as the mode of distribution of the nerves concerned for they are not rich in ganglion-cells and must be regarded as composed predominantly of *postganglionic efferent* fibres with an admixture of *splanchnic afferent*. They are doubtless vasomotor to the vessels concerned and their branches; but to a large extent they merely use the vessel as a path along which they may run to their field of distribution as sudomotor or pilomotor or vasomotor fibres.

Such perivascular plexuses are found also in connexion with the aorta in the

thorax and abdomen and extending along the proximal parts of many of its branches. Vessels in the limbs and peripheral vessels generally, however, receive their vasomotor supply from the postganglionic fibres which pass to the periphery in the spinal nerves, *i.e.*, from fibres which we have seen as components of grey rami communicantes. Perivascular plexuses are therefore associated with most blood-vessels and individual descriptions are not required.

The plexuses which remain to be discussed are known commonly as the **prevertebral** (or collateral) **plexuses**; they are concerned chiefly in the supply of thoracic, abdominal, and pelvic viscera and the associated blood-vessels. All are diffuse structures composed of fibres — pre- and post-ganglionic — and ganglionic cells. At times the fibres predominate; again cells may be so aggregated as to form dissectable ganglia which have been given precise names, but it is of fundamental importance to recognize that these prevertebral plexuses, together with their incoming and outgoing branches, are all gangliated plexuses and that ganglion-cells are scattered with varying degrees of density along the course of branches as well as in the plexus. Further, it will be noted in the description of each plexus that *both sympathetic and parasympathetic fibres are present;* in this way the plexuses form a common meeting-ground for the two different sets of fibres concerned with the supply of a particular organ or group of organs.

Thoracic Plexuses

Pulmonary Plexuses.—These are very largely parasympathetic plexuses—deriving most of their fibres from the vagus nerves—and they have been described already in connexion with that nerve (p. 1041). They are arranged behind and in front of the root of the lung; and the plexuses of the two sides communicate with one another as well as with the cardiac plexuses. The sympathetic contribution comes from the trunk at the level of the second, third, and fourth ganglia and is distributed primarily to the posterior pulmonary plexus. From the pulmonary plexuses branches are distributed to the lung, its blood-vessels, and the pulmonary pleura (Larsell, 1922).

Œsophageal Plexus.—Like the foregoing, this is, in the main, a parasympathetic plexus, and as such has been described on p. 1042. It is only necessary to state here that it receives small sympathetic contributions in the lower part of the thorax from the greater splanchnic nerve (Fig. 965).

Thoracic Aortic Plexus.—The thoracic aorta receives branches directly from the upper five thoracic ganglia of the sympathetic trunk and indirectly from the lower ganglia through the greater splanchnic nerve (p. 1141). These branches, with parasympathetic afferent fibres from the vagus nerves (pp. 1042, 1125), form a continuous fine plexus around the aorta.

Cardiac Plexus.—As the various sympathetic and vagal cardiac branches approach the heart they meet to produce a large, gangliated cardiac plexus, from which branches are distributed to the heart and also to the pulmonary plexuses. The cardiac plexus is large and diffuse and lies around the great vessels at the base of the heart. It is customary to divide the whole cardiac plexus into a superficial plexus and a deep plexus on the basis of topographical relationships.

The **superficial cardiac plexus** lies in the concavity of the aortic arch above the pericardium and in front of the ligamentum arteriosum. It commonly presents a dissectable ganglion—the *cardiac ganglion* (Wrisberg). Two nerves join this plexus: the superior cervical cardiac branch of the sympathetic and the inferior cervical cardiac branch of the vagus (parasympathetic), both of the left side. This plexus, besides communicating with the deep cardiac plexus, sends branches to the left anterior pulmonary plexus and branches of distribution to the heart, which course along the pulmonary trunk to join the right coronary plexus.

The **deep cardiac plexus** is larger and is placed between the aortic arch and the front of the trachea near its bifurcation (Fig. 966). It has communications with the superficial plexus and the pulmonary plexuses. It receives numerous branches: all the cervical cardiac branches of the sympathetic except the superior cardiac nerve of the left side, and all the cardiac vagal branches except the left

inferior cervical cardiac branch. From this plexus branches pass as noted above to the pulmonary plexuses; and the cardiac branches of distribution reach the heart by coursing along the great vessels, some along the aorta and pulmonary trunk and others along the great veins to the posterior surface of the atria.

Developmentally, the heart receives nerves at each end: an arterial supply

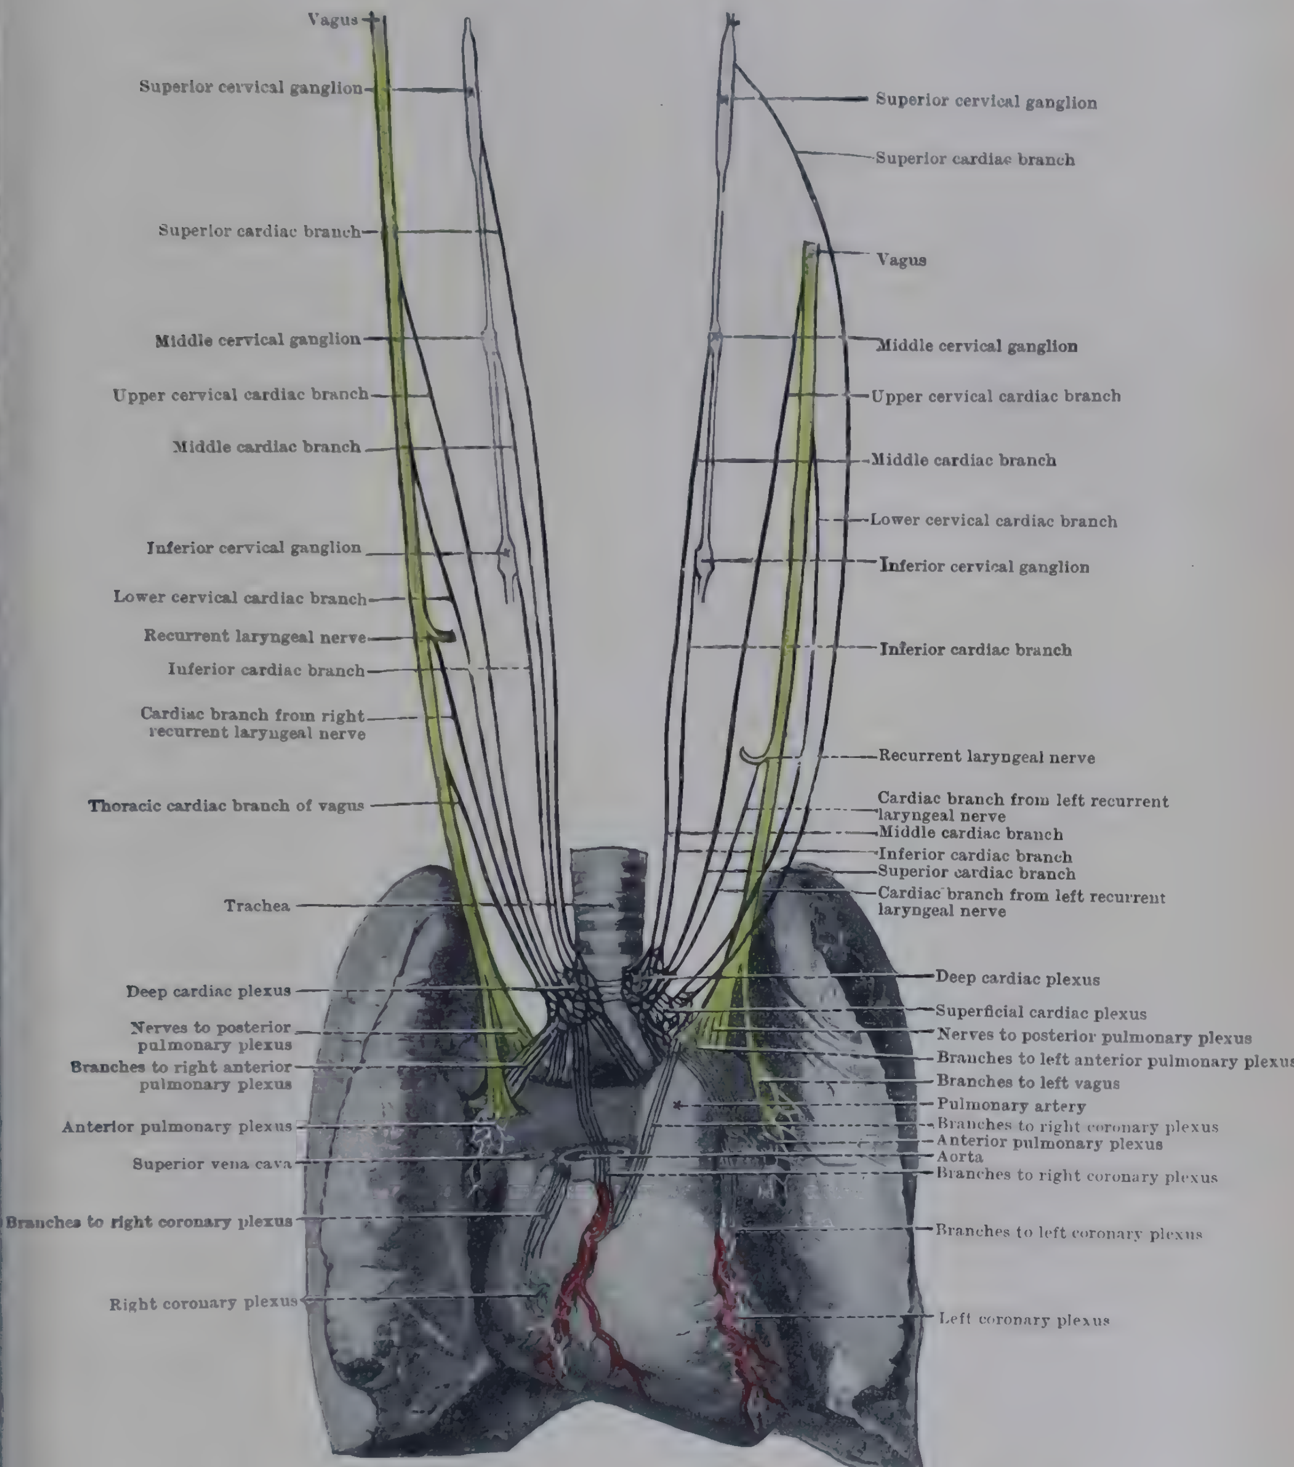

FIG. 966.—CARDIAC BRANCHES OF AUTONOMIC SYSTEM AND THE PULMONARY PLEXUSES.

which reaches it through the arterial mesocardium and is composed of the upper cardiac nerves, both vagal and sympathetic; and a venous supply which reaches it through the venous mesocardium and is composed of the lower cardiac branches of vagus and sympathetic. With approximation of the arterial and venous ends of the heart-tube in development, the two sets of nerves become more closely associated and communications are established between them. Separate arterial and venous cardiac plexuses cannot be isolated as such in the fully developed heart: *i.e.*, the superficial and deep plexuses of descriptive anatomy are not developmentally distinct; but it is possible, and certainly desirable, to consider them from the point of view of their embryonic origin (His, 1891; Perman,

1924). The superficial plexus and in large part the deep plexus are related to the arterial end of the heart, whilst the remaining elements of the deep plexus as well as the gangliated plexus on the back of the right atrium constitute the venous part.
